Sequences of *rbc*L were easily aligned by sight. Among land plants, the coding region contains little size variation through base position 1428 (numbered from the first nucleotide of methionine in the start codon, AUG). Positions 1426, 1427, and 1428 are the most common stop-codon among land plants; longer reading frames, up to 1452 in some monocots and 1458 in the Asteraceae (Kim et al., 1992), appear to be due to insertions, often of a short repeating sequence. Most laboratories have sequenced past this codon, but for phylogenetic analysis we have terminated all sequences at position 1428 to be confident that we have analyzed homologous regions (the portion of the gene included in this analysis for each species is also included in the Appendix). All sequences were entered into a text file in NEXUS format (used by PAUP 3.0; Swofford, 1991) as complete sequences and then analyzed directly in nucleotide form. Matrices used in both searches are available from the first author upon receipt of request and a diskette for each matrix.

## TREE-SEARCH STRATEGY

Parsimony-based methods permit direct examination of hypothesized character-state changes on the reconstructed tree, and this information can be used in studies of molecular evolution. (These are, however, likely to be underestimates of sequence change and could be misleading for this reason.) Numerous empirical studies have shown that not all classes of substitutions are equally likely, and this kind of information may be incorporated into weightng schemes for nucleotide data (Swofford & Olsen, 1990; Albert & Mishler, 1992; among others). Various models of molecular evolution exist, and appropriately circumspect use of these may assist in the separation of historical signal from homoplasy. The character-state weighting model of Albert et al. (1993, this issue) uses probability formulae to calculate weights for different classes of molecular change. We have used their method in the 475-taxon analysis presented here. Although the assumptions of the Albert et al. model are admittedly simplistic, we nonetheless support the investigation of weighting approaches to nucleotide data and view the model used here as a justifiable first approximation. It must be recognized that giving all categories of molecular change equal transformational weight is also an assumption, but one that the investigation of Albert et al. (1993) found to be adequate if sampling effects were not a factor. Actual weights applied in this study fall within such a narrow and minimally asymmetrical range that deviation of results from those using the "equal weighting" criterion of Fitch (1971) is likely to be slight (see Albert et al., 1993).

Recently, concern has focused on the probability that "islands" of equally parsimonious trees exist, particularly in large data sets (Maddison, 1991). Because of their enormous size, our analyses do not use methods of multiple random taxon-addition, which have been suggested to uncover such disjunct, equally optimal islands. This topic is addressed in most empirical papers in this number.

The search for parsimonious trees consisted of several separate but linked heuristic searches using either PAUP 3.0r (**Search I**; 475 taxa) or 3.0s (**Search II**; 499 taxa). All searches included the full data matrix (all codon positions). Search I was performed on a SPARC II (Sun, Inc.) workstation (PAUP 3.0 for non-Macintosh computers is available only by special arrangement with D. Swofford). For Search II, a Macintosh Quadra 800 with 20 MB RAM was used. (Although slower than a Sun computer, the more interactive nature of a search on a PC is preferred by many workers.)

In **Search I**, an initial heuristic search with character-state changes given equal weight (i.e., "unordered" status), SIMPLE data addition sequence, STEEPEST DESCENT, and NNI (nearest-neighbor interchange) branch swapping algorithm was used to find a single tree (MULPARS option deactivated). The second phase used this single tree obtained from phase one as a starting tree for another heuristic search, this time using the SPR (subtree pruning-regrafting) branch swapping algorithm with MULPARS deactivated again. The third phase paralleled the first and second; the single SPR tree from phase two was used as the starting topology for a heuristic search using the TBR (tree bisection-reconnection) branch swapping algorithm, again with MULPARS deactivated.

The fourth phase used the single TBR tree as the starting point for a heuristic search employing a character-state weighting criterion (with a different step matrix for each codon position; cf. Swofford, 1991; Albert & Mishler, 1992; Albert et al., 1993). This time MULPARS was activated.

Transversion substitutions were weighted over transitions differentially by codon position (Albert et al., 1993). The specific weights used were the following: for transitions, 5520 (first positions), 6368 (second positions), 4039 (third positions); for transversions, 6620 (first positions), 7470 (second positions), 5127 (third positions). These weights were calculated from empirically derived parameters (see Albert et al., 1993, for a complete description and justification). Because use of step matrices is CPU-intensive, this search was executed with the simplest branch-swapping algorithm, NNI. Additionally, because of dynamic RAM limitations (a tree of 475 terminals occupies a great deal of memory), we restricted our search to a maximum of 500 trees. Although the initial TBR tree was by default a member of a single island, we hoped to provide a bridge to shorter trees through use of the STEEPEST DESCENT option (see Maddison, 1991; Swofford, 1991). This final step yielded 500 equally parsimonious, weighted trees. Because the maximum prespecified number of trees was found, many others probably exist at the same length. Search I required approximately 200 hours to complete.

**Search II** was performed for three reasons. First, the likely existence of other islands of equal or greater parsimony prompted us to use a strategy that would be more likely to find shorter trees and perhaps a different topology. Second, we were concerned about the effects of the Albert et al. (1993) weighting scheme upon the resulting topology. Third, we wished to examine positions of additional taxa (and make use of updated sequences) that became available after Search I was completed; many of these belonged to previously unrepresented lineages. Differences between these two sets of trees could thus be due to different taxon sampling, corrections or completions of sequences after Search I was finished, or search strategy. We did not intend these two searches to be controlled, direct tests (i.e., with only one variable differing between them); we show them both, rather than simply the one that we judge to be better (Search II), because their similarities, despite variation in taxon composition and search strategy, are considerable. They each represent results of searches that in their own context are worthy of publication, and their differences should be viewed as reasons to be skeptical of both and as cause for future study with more *rbc*L data as well as other characters.

In Search II, we were able to save more trees at the shortest length found: 3,900 rather than only 500 trees. The initial starting tree was produced by using the CLOSEST addition sequence with the HOLD option set for five trees (this in effect permitted initial swapping on several different starting topologies). Approximately 120 hours were required merely to add all taxa in this manner. The initial search (i) used NNI swapping and STEEPEST DESCENT with MULPARS off. The shortest single tree found was then swapped on using (ii) TBR, which generally found a shorter tree, at which time (iii) NNI (with MULPARS) was used. When use of MULPARS resulted in 3,900 trees, which used up available RAM, a single tree was randomly selected (iv) to swap on with TBR (MULPARS off). If this resulted in a shorter tree being found, the search was then stopped and restarted (iii, again) using NNI and MULPARS and this shorter tree as starting point (iii and iv were repeated until no shorter trees were found). The shortest tree length found with this method was 16,305. Three randomly selected trees from the 3,900 saved at this length were swapped in succession to completion with TBR (no MULPARS), and no shorter trees were found. A strict consensus tree was computed, and branch lengths for one randomly selected tree were calculated using the ACCTRAN optimization. Search II thus used no relative weighting; it required approximately four weeks to complete.

## Caveats

Methodologically, these searches suffer from (i) uncertainty about maximum parsimony, (ii) unquestionable absence of many trees at the same level of optimality, (iii) identification of only a single topology, and (iv), in Search I, incomplete branch swapping on any of the shortest trees found. We would never recommend these search strategies for smaller data sets, but several options were seriously restricted by the number of taxa included (these are reputedly the largest PAUP analyses attempted to date). Specific sections of the general topologies, when analyzed in a more "localized" manner, provide different sets of relationships (see Michaels et al., 1993; Morgan & Soltis, 1993; both this issue). The broader taxon distribution of the general analysis (thus with far greater outgroup information) may be assessing character-state change on the immediate branch leading to a specific ingroup differently than in more restricted analyses. Greater outgroup information could "improve" the ingroup analysis or add spuriousness to it; it is generally best to implement tree searches both with and without outgroups to examine their effects. If more restricted analyses differ from those pre-

sented here, we would certainly favor the former because of increased confidence in finding parsimonious solutions. We nonetheless view these analyses as instructive about seed-plant relationships and the utility and limits of *rbc*L information (see Discussion).

The major limiting factor in our studies is clearly matrix size. When confronted with the largest molecular database relevant to seed plants, computational trade-offs inevitably arose. The amount of time spent on these approximations may not be directly proportional to the time taken to generate all the *rbc*L sequences, but no method exists to predict how many trees at how many steps shorter might have been found after additional months or even years of continuous computation. We have opted for the approximations presented here rather than commit ourselves to an open-ended experiment.

Potential effects of errors in autoradiogram reading and data entry should be considered. We detected a number of internal stop-codons in sequences used in these analyses, and other workers have reported errors of various kinds. Most of these were corrected in the matrix used in Search II. Certainly the potential for errors is present, but the effects of such mistakes should not be extensive because they are likely to be random.

Identification of some taxa in this analysis has been questioned due to peculiarity of placement. One example of this has been now identified among the species used in Search I. We have not expunged it from the illustrations; the results represent the outcome of real tree searches and are instructive for that reason. The sequence analyzed was an actual member of the clade into which it was placed, but it was not the species to which it had been attributed. The material sent by a botanical garden and labeled as *Kirengeshoma* was evidently misidentified. It was almost certainly a member of the *Parnassia* group (Saxifragaceae sensu lato; the position it occupies in Fig. 11A) rather than a member of Hydrangeaceae. Sequencing of another specimen of *Kirengeshoma* and subsequent data analysis revealed the expected placement of this genus with other Hydrangeaceae (Xiang & Soltis, unpublished). Other "surprising" results also have been checked by obtaining another sample of the taxon in question and re-sequencing *rbc*L. The original sequence of purportedly saxifragaceous *Montinia* (which nested in Solanales) was checked and found to be accurate. Still others (such as *Sargentodoxa* among Fabaceae) are still being reassessed. Most workers have tried to make vouchers for each species in this study (see Appendix). Many tissue samples were provided by botanical gardens, and, if vouchers are not included with samples, investigators are dependent upon identification of these plants by the respective organizations (see Goldblatt et al., 1992; it is critical that a voucher sample taken from the same plant used for DNA extraction be included at the time of collection; accession numbers or vouchers taken previously are subject to later events, such as lost labels or collector mistakes). Because a number of the samples used in these two analyses are unvouchered (see Appendix), reproducibility is compromised. In cases with multiple species from a family, we should be able to recognize grossly misidentified samples (but this is true for only 37% of the 265 families represented).

## Results

For display purposes, we show here the combinable component consensus (Bremer, 1990) of the 500 equally parsimonious trees found in Search I (Figs. 1–15, A series). Because these are character-state weighted trees, tree lengths and tree statistics (e.g., consistency index, etc.) are not comparable to those of Fitch trees and are not given here. For Fitch trees found in Search II, the length was 16,305 with a consistency index (C.I., excluding unique substitutions and constant characters) of 0.102 and a retention index (R.I.) of 0.632. The branch lengths, again with ACCTRAN optimization, are shown on one of the 3,900 trees selected at random (Figs. 1–15, series B). Branches that collapse in the strict consensus tree are indicated by arrows on the B series (Figs. 3–15B).

First we will summarize the topology found in Search I ("A" series of figures). The results of Search II ("B" series) have been interdigitated with those of Search I to facilitate comparisons. After describing the results of Search I, we briefly examine major differences between the two results. Note that all figures in the A series are from the combinable component consensus tree, whereas in the B series, Figures 1B and 2B are the strict consensus tree (branch lengths in Fig. 2B, however, were taken from a single tree) and the remainder (Figs. 3B–15B) are a single tree randomly selected from 3,900 equally parsimonious Fitch trees (this may be confusing; for example, whereas the polytomy among monosulcate clades in Figs. 1B and 2B is due to variation among the 3,900 trees for branches in this portion, the topology shown in 3B is resolved because it is resolved in the single tree selected). To indicate branches of the B series that are absent in the strict consensus tree of the 3,900,

we have placed arrows to their right. The branch lengths presented in the B series should under no circumstances be interpreted as meaningful measures of support; thus, in the example of Hamamelidae provided, branches that decay at one step less parsimonious have lengths that range from 2 to 16 steps, whereas those that decay at four steps less parsimonious range from 7 to 14 steps (Fig. 16). The sole reason for providing branch lengths in the B series is to permit readers to estimate roughly relative degrees of divergence and to identify cases in which long terminal branches are connected to short internal branches (a situation in which adding related taxa often radically alters hypothesized relationships).

**Search I**. Unless stated otherwise, we have used the taxonomic circumscriptions of Cronquist (1981) for dicots and Dahlgren et al. (1985) for monocots, although we acknowledge that other recent systems fit these results better. We arranged the unrooted trees of both searches with cycads sister to all other seed plants (Figs. 1–3) in accord with recent results of several non-molecular cladistic studies (Crane, 1985, 1988; Doyle & Donoghue, 1986, 1992). In Search I, conifers are paraphyletic, but some trees (not shown) found in Search II have a monophyletic conifer lineage; the strict consensus tree from Search II is unresolved regarding conifers (Figs. 1B, 2B; we have cited in this section the B series of figures along with the A series if they include the same general set of taxa). The three genera of Gnetales, *Ephedra*, *Welwitschia*, and *Gnetum*, are highly divergent from all other seed plants but were nonetheless identified as sister of the angiosperms (Fig. 3A, B), within which *Ceratophyllum* (Ceratophyllaceae) alone is sister to and highly divergent from the rest (Fig. 4A, B). The major feature of flowering plants (exclusive of *Ceratophyllum*) is their separation into two major groups; these correspond well with distributions of the two major angiospermous pollen types, uniaperturate (monosulcate and monosulcate-derived) and triaperturate (tricolpate and tricolpate-derived). *Ceratophyllum* has inaperturate pollen (Cronquist, 1981). The major exception to this split is the presence of tricolpate pollen in Illiciaceae and Schisandraceae, which fall among the monosulcate taxa (Fig. 4A, B; see Qiu et al., 1993, this issue). No morphological support for monophyly of the monosulcate clade has been recognized in the literature (their pollen type exists among nonflowering seed plants and thus must be considered plesiomorphic).

Three monophyletic lineages within uniaperturate magnoliids were identified, and these correspond closely, although not exactly, to (i) Magnoliales, (ii) Laurales, and (iii) "paleoherbs" (here defined as composed of Aristolochiales, Piperales, and Nymphaeales; Fig. 4A). Monocots (also with uniaperturate pollen and sometimes included in "paleoherbs"; Donoghue & Doyle, 1989) represent a fourth member of this clade. Among the paleoherbs are also nested several problematic families: Illiciaceae, Schisandraceae (both Illiciales), Amborellaceae (Laurales), and Austrobaileyaceae (Magnoliales). Chloranthaceae are also allied cladistically with the paleoherbs, but *Chloranthus* does not form a monophyletic group with other Piperales.

Monocots are a well supported monophyletic group (see Duvall et al., 1993, and Qiu et al., 1993, both this issue) and are derived from within monosulcate Magnoliidae; the paleoherbs are their immediate sister group (Fig. 4A). Within monocots (Fig. 5A, B), Aranae plus *Pleea* (of polyphyletic Melanthiaceae; Lilianae) are basal-most, followed by Alismatanae plus *Burmannia* (Burmanniaceae) and *Aletris* (Melanthiaceae). Lilianae form a paraphyletic series of three lineages that correspond well to Dioscoreales, Liliales, and Asparagales of Dahlgren et al. (1985), except in the placement of certain families (Iridaceae, Orchidaceae, and Smilacaceae) and genera (*Chamaelirium* of Melanthiaceae: Melanthiales). *Vellozia* (Velloziaceae: Bromelianae), *Freycinetia* (Pandanaceae: Pandananae), and *Sphaeradenia* (Cyclanthaceae: Cyclanthanae) together form a monophyletic clade that is collectively sister of the Liliales. The "commelinoid" group of monocots (Fig. 6A, B) incorporates all of those that Harris & Hartley (1980) found to exhibit fluorescing cell-wall phenolics. In both searches, this commelinoid clade includes monophyletic Arecanae and Zingiberanae and polyphyletic Bromelianae and Commelinanae (Fig. 6A, B). Cyclanthaceae have the same phenolic biosynthetic pathway but do not accumulate end products; they are not members of the commelinoid assemblage (Clark et al., in prep.).

The two orders of Magnoliidae with triaperturate pollen, Ranunculales and Papaverales, form a clade that is sister to the rest of "eudicots" (Fig. 7A, B). The term "eudicot" has been variously defined in the literature, but we use it here to refer to all angiosperms with triaperturate or triaperturate-derived pollen (Donoghue & Doyle, 1989; Doyle & Holton, 1991). This is one of the best supported clades among angiosperms (Qiu et al., 1993, this issue). Two other basal clades within the eudicots (Fig. 7A, B) consist of some Hamamelidae (Trochodendraceae and Tetracentraceae) and Platanaceae, Sabiaceae, Nelumbonaceae, and Proteaceae.

Within eudicots, two large sister clades are iden-

tified, one that corresponds roughly to Asteridae and the other to Rosidae (Figs. 1, 2). Membership in both lineages is considerably expanded with respect to their circumscription by Cronquist (1981), although less so with respect to the circumscriptions of Dahlgren & Bremer (1985) and Thorne (1992). These two major clades (Fig. 2A, B) reflect the division of eudicots into two major groups (Young & Watson, 1970): sympetalous/tenuinucellate and polypetalous/not tenuinucellate (asterids and rosids, respectively, in our figures). The "crassinucellate" condition actually consists of several different states. Exceptions to this generalization exist, but these traits appear much less homoplastic here than in most systems of classification. The basalmost lineage within Rosidae includes Saxifragaceae sensu stricto and Crassulaceae besides lower hamamelids such as *Cercidiphyllum* and *Hamamelis* (Fig. 8A; see Morgan & Soltis, 1993, this issue, for a discussion of Saxifragaceae sensu lato). The next-most-basal group contains Caryophyllidae (including Plumbaginaceae and Polygonaceae; Rettig et al., 1992) plus Droseraceae, Nepenthaceae (Nepenthales, Dilleniidae; see Albert et al., 1992b), Dilleniaceae (Dilleniidae), and Vitaceae (Fig. 9A).

The remaining Rosidae are split into two large sister groups (Figs. 2A, 10A, 11A). In one (rosid I) are several families of higher Hamamelidae, Euphorbiales, Fabales, Linales, Polygalales, and Rosales (Fig. 11A). Other members of this clade include a number of dilleniid families: Ochnaceae (Theales), Datiscaceae, Passifloraceae, and Violaceae (all Violales). Ordinal boundaries of this group of Rosidae (sensu Cronquist, 1981) are largely unsupported; this assemblage is particularly heterogeneous. The largest polytomy in the consensus tree from Search I occurs at the base of this group, and sampling of the families that potentially belong to this clade is the most sparse in this analysis. The other major lineage of Rosidae (rosid II; Fig. 10A) includes orders Myrtales (see Conti et al., 1993, this issue) and Sapindales, for which ordinal boundaries are reasonably intact. Malvaceae (Malvales; Dilleniidae) and all but one of the mustard-oil families (those in Capparales plus others in Dilleniidae; see Rodman et al., 1993, this issue) are associated with Sapindales. Geraniaceae are also members of this clade, although other members of Geraniales appear elsewhere (Oxalidaceae with a group of families in Rosales, Fig. 11A; Balsaminaceae with Ebenales, Fig. 13A, B; and mustard-oil-producing Limnanthaceae and Tropaeolaceae with Capparales, Fig. 10A, B; Price & Palmer, 1993, this issue). Two members of Rosales, *Greyia* (Greyiaceae) and *Francoa* (Saxifragaceae), appear derived from within Geraniaceae, if *Viviania* is included in Geraniaceae (see also Price & Palmer, 1993, and Morgan & Soltis, 1993, this issue).

The tenuinucellate/sympetalous clade that terminates in Asteridae sensu Cronquist (1981) was also identified by Olmstead et al. (1992) in their efforts to circumscribe subclass Asteridae using *rbc*L sequences. This study greatly expands upon their sampling and identifies as members of the asterid clade two lineages of often polypetalous Rosidae (Figs. 2A, 12A): (i) Santalales plus Paeoniaceae and Gunneraceae and (ii) some families of Cornales plus Hydrangeaceae (see Xiang et al., 1993, this issue). The sister group of Asteridae is a clade (Figs. 2A, B, 13A, B; see Kron & Chase, 1993, this issue) that contains the dilleniid orders Ebenales, Ericales, Primulales, Diapensiales, plus some members of Theales (Actinidiaceae and Theaceae). Sarraceniaceae (Nepenthales; Dilleniidae) and *Roridula* (but not *Byblis* of Byblidaceae of Rosales: Rosidae) are also members of this lineage (Albert et al., 1992b). Polemoniaceae (Solanales: Asteridae) and Balsaminaceae (Geraniales: Rosidae) also belong to this ericalean/ebenalean group. (See also Olmstead et al., 1993, this issue, for a treatment of the Asteridae sensu lato.)

Asteridae sensu Cronquist split into two major sister groups. In one of these (asterid II; Fig. 14A, B) are families of Asterales, Calycerales, Campanulales, Dipsacales, and some Solanales (Menyanthaceae). Rosid taxa that are members of this clade include Apiales, Aquifoliaceae (Celastrales), some Cornaceae (Cornales), Pittosporaceae and Grossulariaceae (both Rosales). In the other major clade (Fig. 15A, B) fall orders Callitrichales, Gentianales, Lamiales, Rubiales, Scrophulariales, and most Solanales, although these ordinal limits are not always supported (see Olmstead et al., 1993, this issue). In this clade (Fig. 15A, B) is a group that includes rosids *Aucuba* (Cornaceae: Cornales) and *Garrya* (Garryaceae: Cornales) and hamamelid *Eucommia* (Eucommiaceae: Eucommiales), all of which accumulate aucubin (Cronquist, 1981) and share distinctive anatomical wood characteristics (E. Wheeler, pers. comm.). Thus the suite of floral characteristics that have been interpreted as support for the monophyly of Asteridae sensu Cronquist (1981) appears either (i) to have twice arisen independently from ancestors with rosalean and cornalean floral traits or (ii) to have undergone reversals in groups traditionally included in Rosidae (sensu Cronquist; Donoghue et al., 1992; Olmstead et al., 1992, 1993, this issue).

**Search II.** A number of taxa from Search I were removed from Search II (all marked with a "†" in the A series of figures) to accommodate the representatives of additional lineages in Search II.

Most of the removed taxa were from monophyletic families in which six or more species were present in Search I (for example, Asteraceae, Ericaceae sensu lato, Magnoliaceae, and Poaceae). Two others, *Burmannia* (Burmanniaceae) and *Hydrolea* (Hydrophyllaceae), were removed because they are highly sequence divergent from all other taxa; in separate, smaller analyses, these two appear to be involved in "branch attractions" and attach in radically different positions as other taxa are added or removed (other similarly divergent genera, for example, *Paeonia* and *Gunnera*, do not cause these problems and were kept; we admit to being relatively arbitrary in removing only these two taxa). *Burmannia* presents an interesting case. Members of Burmanniaceae are often achlorophyllous; in spite of being green, *Burmannia* may still derive a great deal of its nutrition through its mycorrhizal associate. In such cases in other families, a number of protein loci exhibit higher rates of sequence divergence (as measured by relative branch lengths when compared to completely autotrophic members of their lineages; C. dePamphilis, pers. comm.). Thus the high levels of sequence divergence, which make it difficult to place these taxa accurately, are a product of or at least associated with their partial heterotrophy.

For Search II, additional taxa were available (these species are marked with asterisks in the B series of figures). The placements of these are described first, and then different arrangements of taxa included in both searches are identified (the clades involved with major shifts of position are marked with an "§" in Fig. 2B). This last section describes only the major shifts of position, but many "minor" shifts also occur within clades (for example, 12 "minor" shifts take place among the taxa in Fig. 15, a clade in which only a few new species were added). What constitutes a "major" versus a "minor" alteration is, of course, a matter of personal perspective. We would therefore advise readers to examine carefully the trees from both searches for taxa of specific interest, which is one reason we presented and intercalated the results of both analyses.

*Positions of additional taxa.* *Ginkgo* (Ginkgoaceae) intercalates between cycads and conifers (Figs. 1–3B). *Taxus* (Taxaceae), *Cephalotaxus* (Cephalotaxaceae), and *Sciadopitys* (Taxodiaceae or in its own family) are members of the non-Pinaceae clade of conifers, with *Sciadopitys* sister to the rest of that clade (Fig. 3B). Within magnoliid angiosperms, *Lactoris* (Lactoridaceae) is sister to *Aristolochia* (Aristolochiaceae). Other new magnoliid species added in Search II represent additional members of families already present in Search I, and all of these form monophyletic units with other members of their respective families (Fig. 4B).

Sister to all other monocots is *Acorus* (Araceae; see Duvall et al., 1993, this issue). *Calochortus* (Calochortaceae) is sister to Liliaceae, *Hemerocallis* (Hemerocallidaceae) is sister to *Chlorophytum* (Anthericaceae), and *Lomandra* (Dasypogonaceae) is a member of the often arborescent clade composed of Agavaceae, Asphodelaceae, and Xanthorrhoeacae within Lilianae (Fig. 5B). Additional members of families in Search I are all placed as sister taxa to their respective family representatives. Among the commelinoid clade identified in Search I (Fig. 6A, B) are the following additional families: *Sparganium* (Sparganiaceae) sister to *Typha* (Typhaceae) and *Lachnocaulon* (Eriocaulaceae) among the graminoids.

Among eudicots (Fig. 7A, B), *Pachysandra* (Buxaceae) is sister to Trochodendrales (*Trochodendron* and *Tetracentron*). Composition of the various rosid clades is somewhat different in Search II (Fig. 2B; see below), but the following additional taxa are placed roughly among the rosid II (Fig. 10B) clade identified in Search I: *Shorea* (Dipterocarpaceae), *Theobroma* (Sterculiaceae), *Tilia* (Tiliaceae), and *Bombax* (Bombacaeae) are members of a malvalean clade (represented only by *Gossypium* in Search I). *Akania* (Akaniaceae) and *Bretschneidera* (Bretschneideraceae), both Sapindales, are members of the mustard-oil clade. Three additional members of Capparaceae, *Cleome*, *Koeberlinia*, and *Setchellanthus*, along with *Capparis*, create a polyphyletic Capparaceae (Fig. 10B; see also Rodman et al., 1993, this issue). *Hypseocharis* (Oxalidaceae) is sister to a clade containing many Geraniaceae (Fig. 10B; see Price & Palmer, 1993, this issue). Among members of rosid I (Fig. 11B, C) are representatives of the following new families: *Reinwardtia* (Linaceae) is sister to *Viola* (Violaceae); *Sargentodoxa* (Sargentodoxaceae) is imbedded in Fabaceae; *Humulus* (Cannabinaceae), *Trema* (Ulmaceae), and *Boehmeria* (Urticaceae) fall into an urticalean clade with *Morus* and *Ficus* (both Moraceae), but Ulmaceae are paraphyletic to Cannabaceae; *Coriaria* (Coriariaceae), *Begonia* (Begoniaceae), and three genera of Cucurbitaceae are placed with Datiscaceae; *Betula* (Betulaceae) and *Carya* (Juglandaceae) are members of the clade containing Fagaceae and Casuarinaceae; *Mouriri* and *Osbeckia* (Melastomataceae), *Punica* (Punicaceae), *Trapa* (Trapa-

ceae), and *Heteropyxis* (Myrtaceae) are members of a clade of (mostly Myrtales) that includes Onagraceae and Combretaceae (Fig. 11C). In asterid lineages, two additional families have been added: *Byblis* (Byblidaceae) and *Vahlia* (Saxifragaceae) are placed among Schrophulariales (Fig. 15B).

*Changes in placements of major clades.* At higher levels among the seed plants, Search II produced relatively few "major" differences in taxon placements from the topology of Search I. The conifers in some, but not all, 3,900 trees are monophyletic. Piperales–Aristolochiales were sister to all monosulcate angiosperms (Figs. 2B, 4B). The "paleoherb" clade of Search I (Fig. 4A) was thus split in two with the portion containing Chloranthaceae, Illiciales, Austrobaileyaceae, Amborellaceae, and Nymphaeales situated as sister to Magnoliales. Although these may seem to represent major shifts, extremely short branches separate these clades (Fig. 4B); thus neither topology has much internal support (Qiu et al., 1993, this issue). Within monocots, only shifts among the groups in Aranae, Alismatanae, and Lilianae occurred (Fig. 5B): Aranae (minus *Acorus*) are sister to Alismatanae; the clade containing Pandanaceae, Cyclanthaceae, and Velloziaceae is isolated and no longer sister to Liliales, and Dioscoreales are sister to the commelinoid taxa (the position of Asparagales in the trees from Search I). Among commelinoid taxa (Fig. 6B), *Stegolepis* (Rapateaceae) is sister to Bromeliaceae, Typhales are sister to Juncaceae–Cyperaceae, and *Flagellaria* is sister to the other graminoid clade.

Among eudicots, three major shifts of taxa present in Search I occurred. The first series of rearrangements involves the heterogeneous asterid V clade (Fig. 12A). *Gunnera* (Gunneraceae) intercalates as an isolated lineage (Fig. 7B) between Trochodendrales (plus *Pachysandra* of Buxaceae) and higher eudicots (asterids, caryophyllids, and rosids). Santalales, *Phoradendron* (Viscaceae), *Schoepfia* (Olacaceae), and *Osyris* (Santalaceae) become sister to Caryophyllidae–Droseraceae–Nepenthaceae (Fig. 9B), and this larger caryophyllid clade is shifted from a position within the rosid clade (rosid III; Figs. 2A, 9A) to sister to the larger asterid–rosid clade (Figs. 2B, 9B). The remaining member of asterid V, *Paeonia* (Paeoniaceae), is deeply imbedded within rosid III clade (Fig. 8B) as sister to Crassulaceae. We attach little significance to these shifts of position; internal branches of these groups are among the shortest supporting positions of major clades.

The second series of shifts occurs within rosids. Families of Myrtales (plus *Qualea* of Vochysiaceae, Polygalales) and the clade containing *Viviania*, *Wendtia* (both Geraniaceae), *Greyia* (Greyiaceae), and *Francoa* (Saxifragaceae) are shifted from rosid II to rosid I (Fig. 11B, C), and relationships of intermediate-level clades (containing several families, i.e., those of Urticales, Fagales, etc.) are somewhat modified from their position in Search I.

The third shift involves the two taxa that were sister to the expanded caryophyllid clade from Search I (Fig. 9A): *Dillenia* (Dilleniaceae) and *Vitis* (Vitaceae), which become sister to the rest of the larger asterid clade (Fig. 12B; *Vitis* and *Dillenia* in a sense exchanged positions with Santalales). Again, these groups have short internal branches, and these shifts would require little change of overall parsimony.

In several instances, the topology of Search II (which we favor because it was a more complete search) is more similar to that found in investigations of restricted nature (for example, outgroup relationships of Asteraceae are identical with those found by Michaels et al., 1993, this issue, and Olmstead et al., 1992, whereas those of Search I deviated in several ways).

## Discussion

Although *rbc*L sequences for several groups of spore-bearing plants are available (true mosses, hornworts, liverworts, *Equisetum*, *Isoetes*, *Lycopodium*, *Psilotum*, and both eu- and leptosporangiate ferns), their use as outgroups is complicated by extensive sequence divergence relative to that in the seed-plant ingroup. No other extant lineages of land plants are likely to have shared a common ancestor with seed plants for well over 350 million years, and a great deal of sequence change, much of it in the form of multiple, unrecoverable substitutions, has occurred. Analysis of these other land plant sequences produces topologies (not shown, but see Hamby & Zimmer, 1992, for similar results) that are radically different from all previous hypotheses of relationships (e.g., Bremer et al., 1987). In contrast, seed-plant relationships presented here are at least congruent in gross aspect with comparable morphological studies (Crane, 1985, 1988; Doyle & Donoghue, 1986, 1992; Loconte & Stevenson, 1991). Addition of highly sequence-divergent outgroups could be expected to increase ingroup homoplasy with unpredictable topological results (Felsenstein, 1978). In these analyses, we have chosen to use the more conservative approach of an unrooted ingroup analysis

of seed plants, which are almost certainly monophyletic (Doyle & Donoghue, 1986, 1992).

Likewise, effects of missing groups upon topologies may be profound (Donoghue et al., 1989) and unpredictable, and we expect the absence of the numerous extinct lineages of early land plants in molecular data matrices to pose potentially serious problems for elucidating relationships of extant lineages. Perhaps more conservative genes sampled for more of the sequence variation present within extant groups may be able to "bridge" gaps caused by extinction. Features of genome organization (such as gene and intron content and gene order; Downie & Palmer, 1992; Raubeson & Jansen, 1992) may offer more robust hypotheses than gene sequences for such questions, but these are likely to be too few to provide a fully resolved tree by themselves. A great deal more experimentation with combined data sets of morphological and molecular characters is obviously needed, and a number of these studies are underway (both with *rbc*L and rRNA/rDNA data). Consideration of these problems here is premature.

Sister-group status of angiosperms and Gnetales (Figs. 2A, B and 3A, B) is corroborated by other cladistic studies (Crane, 1985, 1988; Doyle & Donoghue, 1986, 1992; Loconte & Stevenson, 1991). The isolated position of *Ceratophyllum* as sister to all other angiosperms has been argued previously (Les, 1988; Les et al., 1991). In studies by Qiu et al. (1993, this issue) in which nonflowering seed plants were removed, this arrangement was made equivocal by the existence of another equally parsimonious island in which *Ceratophyllum* occurred in a radically different position. Hamby & Zimmer (1992; rRNA) also found a yet different placement for *Ceratophyllum* (but we suspect that the sparser sampling of their study may be responsible for most of the differences from those found with *rbc*L). In instances in which a taxon's morphology and anatomy are as divergent and potentially modified as those of *Ceratophyllum*, its position becomes difficult to address adequately in cladistic studies. *Ceratophyllum* has been absent from many morphological cladistic studies, such as those of Doyle & Donoghue (1986, 1992), so corroboration is currently precluded.

The general groupings of angiosperms (exclusive of *Ceratophyllum*) identified in these two analyses are highly similar to each other and to those of most recent taxonomic schemes, particularly those of Dahlgren (1980), Dahlgren et al. (1985), and Thorne (1992; this last has admittedly incorporated results of several molecular investigations). Furthermore, results of *rbc*S (Martin & Dowd, 1991) and ribosomal studies (Hamby & Zimmer, 1992) are quite similar to ours as well. How these larger groupings (clusters of families and in some cases orders) are inter-related is the point at which their similarity diverges. Although having quite different implications for angiosperm origins and evolution, the preferred hypothesis in one of these studies is not vastly different in relative parsimony from those favored in other investigations. For example, with mostly morphological data, Doyle & Donoghue (1986) discovered a "paleoherb rooting" at one step less parsimonious. Constraining a paleoherb rooting for angiosperms, at Nymphaeales (as in Hamby & Zimmer, 1992), was also only slightly less parsimonious in the subset of angiosperm *rbc*L sequences studied by Qiu et al. (1993, this issue). When examined to address basal angiosperm relationships, all these data appear to lack a strong historical signal.

A number of phenomena have been suggested to be capable of confounding molecular phylogenetic studies. We consider below several of these factors and examine their potential to affect studies of *rbc*L sequence variation and then address some additional concerns about future directions of molecular systematic study.

### EFFECTS OF PARALLEL NUCLEOTIDE SUBSTITUTIONS IN INDEPENDENT LINEAGES

An effect of unrecoverable (due to extinction) or unobserved (due to insufficient sampling) character-state changes is the introduction of spurious similarities, which may result in treatment of independently derived nucleotides at a given base position as homologous (see Albert & Mishler, 1992). Such mistaken interpretations of independent events can lead to "branch attractions" if an analysis includes a great number of such assessments (Felsenstein, 1978). Adequate taxon sampling, sometimes referred to as appropriate "taxon density," is one means of reducing potentially inaccurate assessments of similarity, but determining at what point sampling is sufficient has so far only been addressed in an a posteriori manner.

The improvement afforded to assessments of character-state change by increased taxon sampling is counterbalanced by a decrease in computational speed and ability to ascertain how near results are to maximum parsimony. Intrafamilial studies are not as likely to be affected severely by these problems because, in general, numbers of taxa are not as great and evenness of sampling is better. At higher taxonomic levels within seed plants, a paradoxical impediment to progress arises: if taxon number is great enough to assess character-

state changes accurately, then one reasonably can expect to reach only suboptimal phylogenetic solutions, but if taxon number is restricted enough to gain confidence of the maximum parsimony of the trees found, spurious assessments of character-state identity could obscure all but the closest relationships.

To evaluate relationships of Plumbaginaceae and Polygonaceae to families of Caryophyllales, Giannasi et al. (1992) used a number of phenetic and "phylogenetic" methods, including a Fitch-Margoliash dendrogram based upon genetic distances (Kimura, 1981; Felsenstein, 1990), maximum parsimony (PHYLIP, Felsenstein, 1990; PAUP, Swofford, 1991), and maximum likelihood (ML; Felsenstein, 1981). All three methods produced the same lack of resolution concerning relationships of these families; to state that Plumbaginaceae and Polygonaceae are "not closely related" (meaning "closely similar") to Caryophyllales does not preclude them nonetheless from being closest relatives. From the perspective of results presented here (Fig. 9A, B), spurious similarities in the data analyzed by Giannasi et al. (1992) appear to affect equally results of all three tree-building methods: *Gossypium* simultaneously attracts higher asterids and magnoliids (in our trees *Gossypium* is well imbedded among rosids; rosid II, Fig. 10A, B). (See Olmstead et al., 1992, 1993, this issue, for an example and discussion of the effects of taxon sampling.)

Prospects for improvements of tree-building methods with greater numbers of taxa exist (Penny et al., 1992). In the example of Giannasi et al. (1992), none of the methods employed succeeded in eliminating what we interpret as branch attractions due to the small number of taxa sampled and use of distantly related outgroups. Phylogenetic studies using morphological characters for a closely related group of rosid or asterid families would likely be affected adversely by outgroups of magnoliids or monocots. This phenomenon is perhaps even more probable with nucleotide data in which homology is initially assessed only by nucleotide position and character states are restricted to the same four alternatives. Character "homology" for distantly related taxa can be easily determined with *rbc*L data (i.e., a given nucleotide position in this size-conserved gene; "primary homology," de Pinna, 1991), but this does not mean that assessments of character-state homology (synapomorphy) are less subject to homoplasy than with other data.

If phylogenetic analyses of nucleotide data cannot be expected to reveal relationships when sampled with manageable numbers of taxa (from the standpoint of computation of minimal trees) and if sampling with sufficient numbers of taxa precludes assessing the parsimony of results, then we have reached an impasse until improved methods of analysis are developed. An appreciation of this problem has led us to be skeptical of the overall topologies presented (Figs. 1, 2), and competing ideas of relationships should not be overlooked when performing more restricted analyses of these and other gene sequences.

### INTERNAL SUPPORT FOR THE BROAD TOPOLOGY: AN AD HOC ANALYSIS OF SUBCLASS HAMAMELIDAE

For purposes of suggesting an appropriate manner to examine internal support of families traditionally recognized as a natural group, we selected one of the most controversial subclasses, Hamamelidae sensu Cronquist (1981), for which we have data from 18 of 24 families. Numerous phylogenetic and systematic studies of the Hamamelidae have been completed (see various authors in Crane & Blackmore, 1989). The morphological features suggesting a close relationship among these families are largely those associated with the temperate amentiferous syndrome, and these clearly could be the result of parallel modification in unrelated lineages. In their developmental characteristics and wood anatomy, families of Hamamelidae are particularly heterogeneous (Cronquist, 1981; Crane & Blackmore, 1989). In performing the broad analysis, we sought to avoid a priori ideas about what constituted monophyletic subgroupings of angiosperms, but for this heuristic example we have accepted ad hoc the outgroup relationships found in the general study.

We selected 72 species that included all members of Hamamelidae and their immediate sister taxa as identified in trees from both searches. No attempt was made to select species that would reproduce the particulars of the general topologies. A tree search under the Fitch (equal weights) criterion using 2,000 random sequence additions, MULPARS, STEEPEST DESCENT, and NNI branch-swapping (but permitting only 10 trees to be held at each step) found only one island at maximum parsimony (i.e., all trees could be found by single branch swaps using any one of them as a starting tree; cf. Maddison, 1991). Additional as well as shorter islands could still exist but are unlikely after 2,000 repetitions (this type of search required about 24 hours to complete on a Macintosh Quadra 950 with 20 MB of RAM). After random addition searches were completed, the trees

found were used as starting points in a single analysis with MULPARS on and TBR swapping to completion; this process should find all equally parsimonious trees in the single island identified. Our search found 36 equally parsimonious Fitch trees, three of which were optimal under the weighting criterion of Albert et al. (1993, this issue; see Materials and Methods). One of these was randomly selected and is shown with Fitch branch lengths (ACCTRAN optimization; Fig. 16). The tree length was 2,234 steps, the C. I. was 0.288 (excluding unique characters), and the R. I. was 0.532. The maximum parsimony trees also were used to search for trees up to five steps less parsimonious under the Fitch criterion; the FILTER TREES option was used to identify trees at each length, and a strict consensus tree at each step was computed. The number of steps less parsimonious at which each topological component decayed was recorded (Fig. 16; "decay values" are shown below the branches: "d0" indicates that the branch is a polytomy in the strict consensus of the maximum parsimony trees, "d1" indicates that the branch is a polytomy in the consensus tree at one step less parsimonious, etc.).

This analysis identified eight lineages into which members of Hamamelidae fell (Fig. 16): *Eucommia*, clade A, sister to *Aucuba* (Cornaceae) and *Garrya* (Garryaceae) and nested within an asterid clade; Hamamelidaceae, Cercidiphyllaceae, etc., clade B, in a series paraphyletic to Saxifragaceae–Grossulariaceae; Fagales, etc., clade C, sister to Fabaceae–Polygalaceae; Urticales, clade D, sister to Rosaceae; *Leitneria*, clade E, nested within families of Sapindales; isolated Trochodendrales, clade F, sister to Buxaceae; *Platanus*, clade G, situated in a heterogeneous group; and the last, *Euptelea*, clade H, situated among Ranunculales. Many of these clades are well supported internally, decaying at three or more steps less parsimonious (some, such as Trochodendrales Buxaceae and the *Platanus* assemblage are weakly supported as monophyletic lineages but clearly are not members of other well supported groups, leaving them in isolated positions apart from other Hamamelidae).

Results of this restricted analysis are congruent with the topology found in the broad searches (Figs. 1, 2) and indicate the level of internal support demonstrated by *rbc*L data. Future studies could combine morphological data with this molecular matrix and perform constraint experiments in which various rearrangements of these taxa are examined for their relative degrees of parsimony. The general conclusion from this example is that the Hamamelidae do not form a monophyletic lineage; they are shown to be grossly polyphyletic. Besides the amentiferous syndrome, the major trait of Hamamelidae is the presence of tannins, which is likewise compatible with a relationship to the other tannin-containing families, Fabaceae, Rosaceae, Saxifragaceae sensu stricto, and Crassulaceae. Many authors (e.g., in Crane & Blackmore, 1989) have discussed these families in terms of which are "lower" and which are "higher" families. This distinction finds some support from these results; the "lower" groups either stand in an isolated position near the base of the eudicots (Eupteleaceae, Platanaceae, and Tetracentraceae–Trochodendraceae) or basal within rosids (rosid IV, Fig. 2A; Daphniphyllaceae, Hamamelidaceae, and Cercidiphyllaceae), whereas most "higher" hamamelids (Casuarinaceae, Fagaceae, Moracae, Ulmaceae, and Urticaceae) demonstrate a well supported relationship to Fabaceae or Rosaceae ($d > 5$ on two branches at the base of the largest clade in Fig. 16). The position of *Leitneria* in Sapindales near Burseraceae is corroborated by a shared suite of secondary compounds and presence of intercellular resin canals.

The example presented above is not intended to be more than a superficial phylogenetic treatment of families traditionally referred to Hamamelidae. It is meant to serve as an example of how the general topology, which itself is suspected of being suboptimal and presently cannot be examined by decay analysis because of its size, may identify a relevant analysis within which questions of optimality and relative support can be addressed. We are pleased that general relationships found in the broad analyses hold up well when addressed in this and other more restricted investigations, none of which have found vastly different topologies.

### ON THE INFORMATIVENESS OF ALL SUBSTITUTIONS

The majority of character-state changes in protein-coding genes have been demonstrated to occur at third positions within codons, and numerous empirical studies have shown third position substitutions to be more abundant in this and other data sets. Some workers have experimented with discarding third position substitutions from their analyses or analyzing nucleotide sequences inferred from amino acid data (which standardizes all synonymous substitutions; Martin & Dowd, 1991). In several studies (Conti et al., 1993, this issue; Donoghue et al., 1992; Kim et al., 1992; Smith et al., 1993, this issue), all three codon positions have been found to exhibit similar levels of homoplasy (and perhaps similar rates of change per site as

well). It has generally been assumed that, for most genes at some unspecified higher taxonomic level, third positions become saturated and therefore are more likely to be uninformative or even misleading (Swofford & Olsen, 1990), hence the "logic" for discarding third positions and using only nonsynonymous substitutions. In the empirical studies cited above, multiple substitutions apparently have occurred at certain first and second positions at low taxonomic levels (i.e., within families). Variable third positions appear as consistent on average as variable first or second positions, thus making them as reliable at reconstructing relationships (as a class perhaps they are better because they are more numerous; Donoghue et al., 1992).

Whether factors such as codon usage (tRNA biases known to favor only a subset of the possible third position nucleotides for a given amino acid) might contribute to the relatively higher consistencies of some synonymous substitutions is a topic that should be investigated. Codon usage is usually studied in a pairwise fashion, but it would be better examined from a phylogenetic perspective. Most molecular models, including the one (a modified version of that of Kimura, 1980) that is the basis for the weighting scheme used here (Albert et al., 1993), are arguably too simplistic in their assumptions concerning patterns of nucleotide substitutions. Ultimately, we could imagine that knowledge of processes, specific to *rbc*L, responsible for the higher consistencies of some synonymous substitutions might permit construction of alternative weighting models that would extract more historical signal from *rbc*L (Albert et al., 1992a). Until we better understand evolutionary constraints on all positions within a coding sequence, it seems most prudent to use methods that do not eliminate any evidence of the underlying process.

### BRANCH LENGTH INEQUALITIES AND UNEQUAL RATES

The fossil record suggests an early, and perhaps rapid, diversification of angiosperms (e.g., Doyle & Hickey, 1976). Several different categories of specialized flowers appeared nearly simultaneously in geological terms. These included strobiloid types characteristic of Magnoliales, simpler forms similar to those of Laurales, highly reduced sorts like those of Piperaceae and Chloranthaceae, and catkin-bearing specimens comparable to those of lower hamamelids (i.e., eudicots like Platanaceae; Schwarzwalder & Dilcher, 1991). Most of the segments are short in the basal portion of the *rbc*L trees (but not the branches of monocots or eudicots; Fig. 2A, B), which could be interpreted as support for hypotheses that production of diverse flower types took place rapidly and early in angiosperm evolution.

Nonetheless, other explanations could explain patterns of uneven distribution of character-state changes identified by this and many other analyses of molecular data (e.g., Jansen & Palmer, 1988). These include episodic changes of rates of sequence divergence and effects resulting from an uneven distribution of sampled taxa that could cause certain character-state changes to be assigned to several more terminal branches rather than to a single, more internal one. The latter effect could be explained if subsequent substitutions over the long history of groups obscured or even eliminated evidence of synapomorphic character states for these groups. Greater sampling of variation within terminal groups may result in character states being optimized to a single, more basal branch, with reversals and further changes in terminal lineages, as opposed to being optimized to appear as independently arising in several terminal groups. Several other factors, including the specific method of optimization and interpretation of the robustness of groups with "weak" character-state support, are considerations relevant to the distribution of homoplasy. This is another area in which future emphasis should be placed because advances (supported by theoretical considerations) in understanding the effects of character-state optimization could improve evaluation of critical innermost branches.

Lineage-specific rate asymmetry, a potential contributor to spurious branch attractions (Hendy & Penny, 1989; Albert et al., 1993, this issue), is significant for *rbc*L (Bousquet et al., 1992), yet may not be extensive enough between lineages to be problematic. Initial estimates of total sequence divergence rate per year produced a range of $5–7 \times 10^{-10}$ for (i) panicoid versus pooid grasses (Doebley et al., 1990), (ii) *Petunia* versus *Tobacco*, and (iii) *Colchicum* versus *Lilium* (Wendel & Albert, 1992, from data presented in Albert et al., 1992a). Subsequent studies of woody magnoliid taxa with austral disjunction patterns (and for which plate tectonics suggest appropriate divergence times) have indicated divergence rates ranging between $4–5 \times 10^{-11}$ and $1.4–1.7 \times 10^{-10}$ (V. A. Albert, unpublished; note that all rates presented are for lineage pairs, and so the average rate for each lineage is half the figure shown). Only the lowest of these rates is approximately an order of magnitude different from the herbaceous taxon comparisons. Wilson et al. (1990) indicated slightly slower rates for palms. Recent work on monocots

using relative rate tests (Gaut et al., 1992) demonstrated five-fold variation for *rbc*L, which still falls within the range cited above. Although 5–10-fold differences in rates would appear potentially to contribute enormous branch-length differences, the small overall rates involved mean that great divergence times would be a more important factor. In addition, differences in rates appear to be highly lineage-correlated (for example, in graminoids; Gaut et al., 1992) rather than random, and if more extensive sampling at lower taxonomic levels is possible in these "fast" clades, then effects of rate differences can be offset.

Most if not all *rbc*L rates will probably exist within a relatively narrow "window," perhaps approximating the range illustrated above ($10^{-10}$–$10^{-11}$, V. A. Albert, M. W. Chase & J. F. Wendel, unpublished). If that is correct, lineage-specific rate inequalities are unlikely to be a primary factor in branch attraction; rather, asymmetrical divergence times would be implicated because the product of rate and time is the central parameter in considerations of potential systematic errors (see Albert et al., 1993, this issue). Thus uneven sampling or extinction of lineages may present greater problems than do differences in rates.

### EFFECTS OF LATERAL GENOME TRANSFER, ANCESTRAL POLYMORPHISMS, AND DIFFERENT MODES OF INHERITANCE

The trees presented here represent only information from a single gene, and factors peculiar to its evolution could lead to erroneous results. Several of these phenomena are discussed below, but we feel that their impact is likely minimal. Genome transfers would result in all or parts of a genome being phylogenetically coherent (transferred as a unit) at the time transit occurs (Doyle, 1992; Rieseberg & Soltis, 1991), but before and after movement most characters within genomes evolve independently (although still linked if on the same chromosome) and ought to be expected to contain historical evidence. Hybridization is unlikely to influence phylogenetic analyses except at lower taxonomic levels. Even matings between divergent parents still occur within portions of families (and usually among closely related species in a genus) rather than between families. Parental taxa at the time of an ancient hybridization also were likely closely related, and in these genomes highly conserved loci, such as *rbc*L, would have been similar or even identical.

Ancestral polymorphisms (Pamilo & Nei, 1988; Wu, 1991; Doyle, 1992) also affect only closely related taxa, and, like the effects of ancient hybridization, those of ancient polymorphisms would likely be minor relative to subsequent genetic divergence. If lineages that contain polymorphisms diverged in a closely spaced manner and uneven sorting did take place, it is unlikely that any evidence of such variation within a progenitor could be identified as such over the great amounts of time involved in this study. Furthermore, polymorphisms are short-lived and are undocumented for conservative, single-copy loci, such as *rbc*L. At most these effects would be highly localized among groups of closely related terminal taxa and, with adequate taxon sampling, would not be expected to perturb greatly the results.

Lateral transfers not involving exchange of gametes (by unknown mechanisms) may have occurred between major lineages in the past (i.e., of *rbc*L from a purple bacterium to a red algal ancestor; Morden et al., 1992). Such transfers presently appear rare among land plants and seed plants in particular; furthermore, artificial transformations are relatively difficult and often have a destabilizing or transient effect on transformed plants. While we must admit that this is an unknown area that could have played a role in certain anomalous placements in the *rbc*L trees (e.g., *Montinia* and *Vahlia* of Saxifragaceae sensu lato among asterids; Fig. 15), at the same time we are not prepared to advocate it as a scenario until trees based on other data demonstrate a pattern consistent with such hypotheses (as in the example of Morden et al., 1992). Using evidence from studies of secondary chemistry and development, Morgan & Soltis (1993, this issue) build strong cases for the highly dispersed groupings found in their study of Saxifragaceae sensu lato. Furthermore, many of their findings were also congruent with recent investigations of non-molecular characters. Rather than resorting to explanations involving lateral transfers of chloroplasts by mechanisms about which we can only speculate, we would prefer first to examine specific cases from a cladistic perspective rather than from that of current taxonomic schemes.

An *rbc*L tree is not solely a maternal tree. Although chloroplast transmission is principally maternal and uniparental, several groups exhibit a paternal (e.g., conifers) or biparental pattern (Neale et al., 1986; Szmidt et al., 1987; Whatley, 1982; Wagner et al., 1987; Corriveau & Coleman, 1988; White, 1990; Owens & Morris, 1991). Others that have been thought most probably maternal, such as *Liriodendron* and *Magnolia* (Corriveau & Coleman, 1988), consistently exhibit 5–15% paternal inheritance (Sewell et al., 1993). The potential

effects of a mixed pattern of inheritance on gene trees are also unlikely to affect studies at interfamilial levels and above.

## GENES VERSUS TAXA

One of the more persistent controversies surrounding molecular phylogenetic studies has centered on whether results, at a given taxonomic level, will be "improved" more by adding additional taxa sequenced for the same gene or by adding sequence analyses of additional genes for the same set of taxa (analyzed simultaneously or each performed independently for assessments of congruence; Pamilo & Nei, 1988; Wu, 1991). From the standpoint of corroboration, phylogenetic studies of other data sets are absolutely crucial. Nevertheless, it seems quite clear from our work on these data sets that ideas of relationships have changed considerably as more taxa have been added. We suspect that no single gene sequence can provide reasonable hypotheses of relationships of seed plants when sampled uncritically and superficially, but perhaps erroneous results from one locus would be "corrected" by stronger signals present in the others. Data to evaluate this most critical question do not exist: would separately analyzing 20 gene sequences for the same set of 25 to 30 taxa produce well supported relationships?

We are convinced that adding representatives of the still numerous and diverse families absent from this analysis has the potential to enhance assessments of relationships at all levels (despite obvious computational complications). A great deal of the variation present within the gene still remains to be sampled taxonomically. Studies in several groups of plants indicate that *rbc*L often can be valuable at rather low taxonomic levels (Albert, in press, in the slipper orchids; S. Graham, B. Morton & S. Barrett, unpublished, in *Eichhornia*; R. Price & J. Palmer, unpublished, in *Pelargonium*; S. Williams & M. Chase, submitted, in *Drosera*; Xiang et al., 1993, this issue, in *Cornus*). What can be concluded from these studies is that although it is absolutely critical that more genes be studied to provide corroboration, it is unlikely that any of these studies will make a contribution to understanding seed-plant relationships if the level of sampling is too sparse. Only empirical studies will ultimately resolve the "genes versus taxa" controversy. We estimate that by the time this paper is in print, more than 1,200 sequences of *rbc*L from seed plants will exist, and future studies will undoubtedly benefit from this enormous database.

An additional implication of adding more taxa is that the results presented here may not be stable or reflective of those of an analysis of two, three, or four times as many sequences. We point to two regions of the general topology that are morphologically quite heterogeneous and that we believe are possibly generated by undersampling: hamamelid II (Figs. 2A, B, 7A, B) and rosid I (Figs. 2A, B, 11A, B, C). In the former, the critical taxa needed to provide more appropriate relationships could be some of the still-unsampled families, but these groups (represented by *Lambertia*, *Nelumbo*, *Platanus*, and *Sabia*) could just as likely represent the isolated relicts of now largely extinct lineages. In the case of rosid I, only a small percentage of the families has been sampled (for instance, only 7 of 24 families in the Violales: Dilleniidae), and it is in such a case that we might predict "curious" sister-group relationships. Topological instability often occurs in cases where long terminal branches are next to short internal branches, that is, hypothesized relationships are drastically altered by the addition of related taxa that "break up" long branches. Two surprising pairs of sister taxa from Search I, *Erythroxylum–Viola* and *Ochna–Drypetes*, are quite divergent and connected to each other by relatively short branches (Fig. 11A; branch lengths shown only in 11B). In Search II, the addition of *Reinwardtia* displaced *Erythroxylum* from *Viola* to *Drypetes*, leaving *Ochna* to stand isolated from any other taxon (Fig. 11B). In such situations, assessments of relationships are difficult, but, as more closely related species are added, distinguishing synapomorphies for families and groups of families as distinct from autapomorphies for individual species will become more reliable. We would not argue that the relationships found for rosid I are "better" in Search I than in Search II (or vice versa), but rather point these out as areas of the trees that require additional sampling and in which many of the relationships suggested by these analyses of *rbc*L have little or no morphological support.

## VALUE OF THE BROAD ANALYSIS

We view the relatively robust internal support found by evaluations of portions of the broad analysis as an indication that *rbc*L sequences contain information relevant to the evolutionary history of angiosperms (Fig. 16, on Hamamelidae and most of the other papers in this issue; in particular see Conti et al., 1993, and Rodman et al., 1993, for which comparable cladistic analyses of non-molecular data are also available and compared). Well-

characterized families and groups of families (as evidenced in several more restricted studies of morphology, anatomy, and secondary chemistry; e.g., Rodman, 1991a, b; Hufford, 1992) are largely congruent with our results. Other evidence supports the monophyly of the angiosperms (Doyle & Donoghue, 1986, 1992), monocots (Dahlgren et al., 1985), and eudicots (Donoghue & Doyle, 1989). Likewise, the position of *Ceratophyllum* as sister to the rest of the angiosperms compares favorably with the fossil record (Les, 1988; fossil fruits from 120 million years ago are identical to extant fruits, D. Dilcher, pers. comm.). The status of the families of the Papaverales–Ranunculales collectively as sister to the rest of the eudicots (Figs. 1, 2) also finds ample external support (Donoghue & Doyle, 1989, among others).

The results reported here do find some "surprising" relationships. Several families, such as Chenopodiaceae (Fig. 9A, B) and Berberidaceae with only two representatives each in our studies, are paraphyletic to other families. These results do not surprise us because sampling has been demonstrated repeatedly to be a major factor, and insufficient or uneven sampling can generate anomalous relationships. Concomitantly, our results emphasize the need for studies of familial limits to include much better taxon sampling than is generally the case in these two analyses. Some of these instances of paraphyly may be accurate; many pairs of temperate, herbaceous/woody, tropical families have long been suspected of being unnatural (for example, Lamiaceae are derived within Verbenaceae and Brassicaceae within Capparaceae in our studies).

Other "major" findings of this study, although discordant when viewed from the perspective of various taxonomic treatments, find support from recent studies of non-molecular characters. For example, the placement of Ericales as sister to asterids (Figs. 1, 2) was also found by Hufford (1992), and the monophyly of most mustard-oil families (Fig. 10A, B) was previously suggested by Rodman (1991b). Other sets of relationships are unique to this analysis and require more thorough morphological and molecular studies. These include: (i) the position of several families with polypetalous corollas and supposed affinities to Saxifragaceae among each major lineage of Asteridae (requiring a hypothesized reversal of the sympetalous condition in *Escallonia*, *Montinia*, *Phyllonoma*, and *Vahlia* (all Saxifragaceae sensu lato); (ii) nesting of dilleniid orders Capparales, Malvales, Theales, and Violales among rosid clades (the systems of both Dahlgren, 1980, and Thorne, 1992, treated these groups in a manner somewhat similar to our topology); (iii) relationships of Nepenthaceae and Droseraceae to Caryophyllidae sensu lato (Fig. 9A, B); and (iv) specific associations of numerous problematic genera like *Dillenia* (among rosids near Caryophyllidae, Fig. 9A, or near the base of the asterids, Fig. 12B; see Olmstead et al., 1993, this issue), *Impatiens* (near members of Ebenales and Ericales; Fig. 13A, B), and *Nelumbo* and *Lambertia* (among lower hamamelids; Fig. 7A, B). Placement of most of these genera and families has varied substantially among recently proposed classifications (although no one has suggested the relationships found here), and their positions in this study will undoubtedly add to the controversies.

Because additional lineages were present in Search II and different methods were used to construct the trees, it is impossible to evaluate whether the topology found in Search II represents a different island of trees. Indeed, multiple islands of equally parsimonious trees were found in other studies in this issue: Morgan & Soltis (1993), Olmstead et al. (1993), and Qiu et al. (1993). Certainly shifts of some taxa, especially *Paeonia* from a basal asterid to sister of Crassulaceae and Saxifragaceae sensu stricto, suggest a radically different explanation of the distribution of at least some characters. *Paeonia* is well supported internally in its new position (its sister status to *Ribes* does not decay even at five steps less parsimonious; Fig. 16). Shifts of *Dillenia*, *Gunnera*, Santalales, and *Vitis* seem, at first glance, to be major alterations of position, but branches are so short near the split between asterids and rosids that these could not involve many additional steps in either topology (Fig. 2B).

Although the trees of Search II are preferred to those of Search I because some of them were swapped on to completion and therefore are more likely to represent at least a local optimum, taxonomic conclusions based on either search are untimely. When faced with the fact that large numbers of angiosperm families are still unrepresented in the *rbc*L data set, we would argue that a valid assessment of the most appropriate positions of many taxa, such as *Dillenia*, *Gunnera*, and *Vitis*, grossly premature. Some conclusions, polyphyly of Hamamelidae and Dilleniidae, for example, seem well supported now.

This study is noteworthy not only for its scope but also for the large number of contributors whose unpublished sequences made up the bulk of the data analyzed. This wide collaboration was advantageous to all workers; many found that taxa sequenced by other laboratories supposedly working

on distantly related groups (in recent taxonomic schemes) fell into or near their group of interest. Prime examples of this are the close phylogenetic relationship of Nepenthaceae and Droseraceae to families of Caryophyllidae, Pittosporaceae to Apiaceae–Araliaceae, Malvales and Capparales (both "dilleniids") to Sapindales, and *Corokia* (Cornaceae) to Asteraceae.

Broad analyses are thus important in providing evaluations of a priori assumptions about appropriate sets of study taxa for more focused and rigorous studies; they should be formalized so that someone takes the initiative to perform them. Governmental funding agencies should facilitate studies, such as the one presented here, that are well beyond the scope of individual laboratories. This study demonstrates the potential of this kind of analysis, but no single individual or laboratory could have received formal support for sampling this diverse set of taxa and performing the phylogenetic analysis; it would have been deemed by reviewers too broad and too unfocused. Although extramural funds supported most of the other studies in this issue, no support was received specifically for the broad analysis. It is the investment in individual studies that justifies a further expenditure to support syntheses that supply an essential overall perspective, even though they may be necessarily approximate.

The benefits of performing this largest-yet phylogenetic study of seed plants lie not only in support of specific relationships hypothesized by other studies (e.g., the sister group status of the Ericales and higher asterids proposed by Hufford, 1992) and in identification of previously unhypothesized monophyletic groups. This study also presents a comprehensive, explicit hypothesis for higher level relationships, permitting and encouraging initiation of studies evaluating other character systems that may show congruence with the major lineages of seed plants described here. We have performed none of the essential experiments that these results suggest (topological constraints, removal of characters, combining morphological with molecular data, etc.) and have not developed implications these topologies may have for specific character transformations in seed plants or molecular evolution of *rbc*L or RuBisCO. Believing that serious consideration of the significance of these general topologies is best handled at the more manifest level of other papers published here (and elsewhere), we have chosen instead to emphasize reasons for caution. We are content to present the findings of these studies as examples of potential benefits and pitfalls of such exercises. At the least, these analyses represent an attempt to improve both our understanding of seed-plant evolution and methods of phylogenetic inference. Corroboration by other data sets analyzed in a similar fashion is by far the most significant measure of relationships proposed here, and we hope this process of evaluation will be innervated by our efforts.

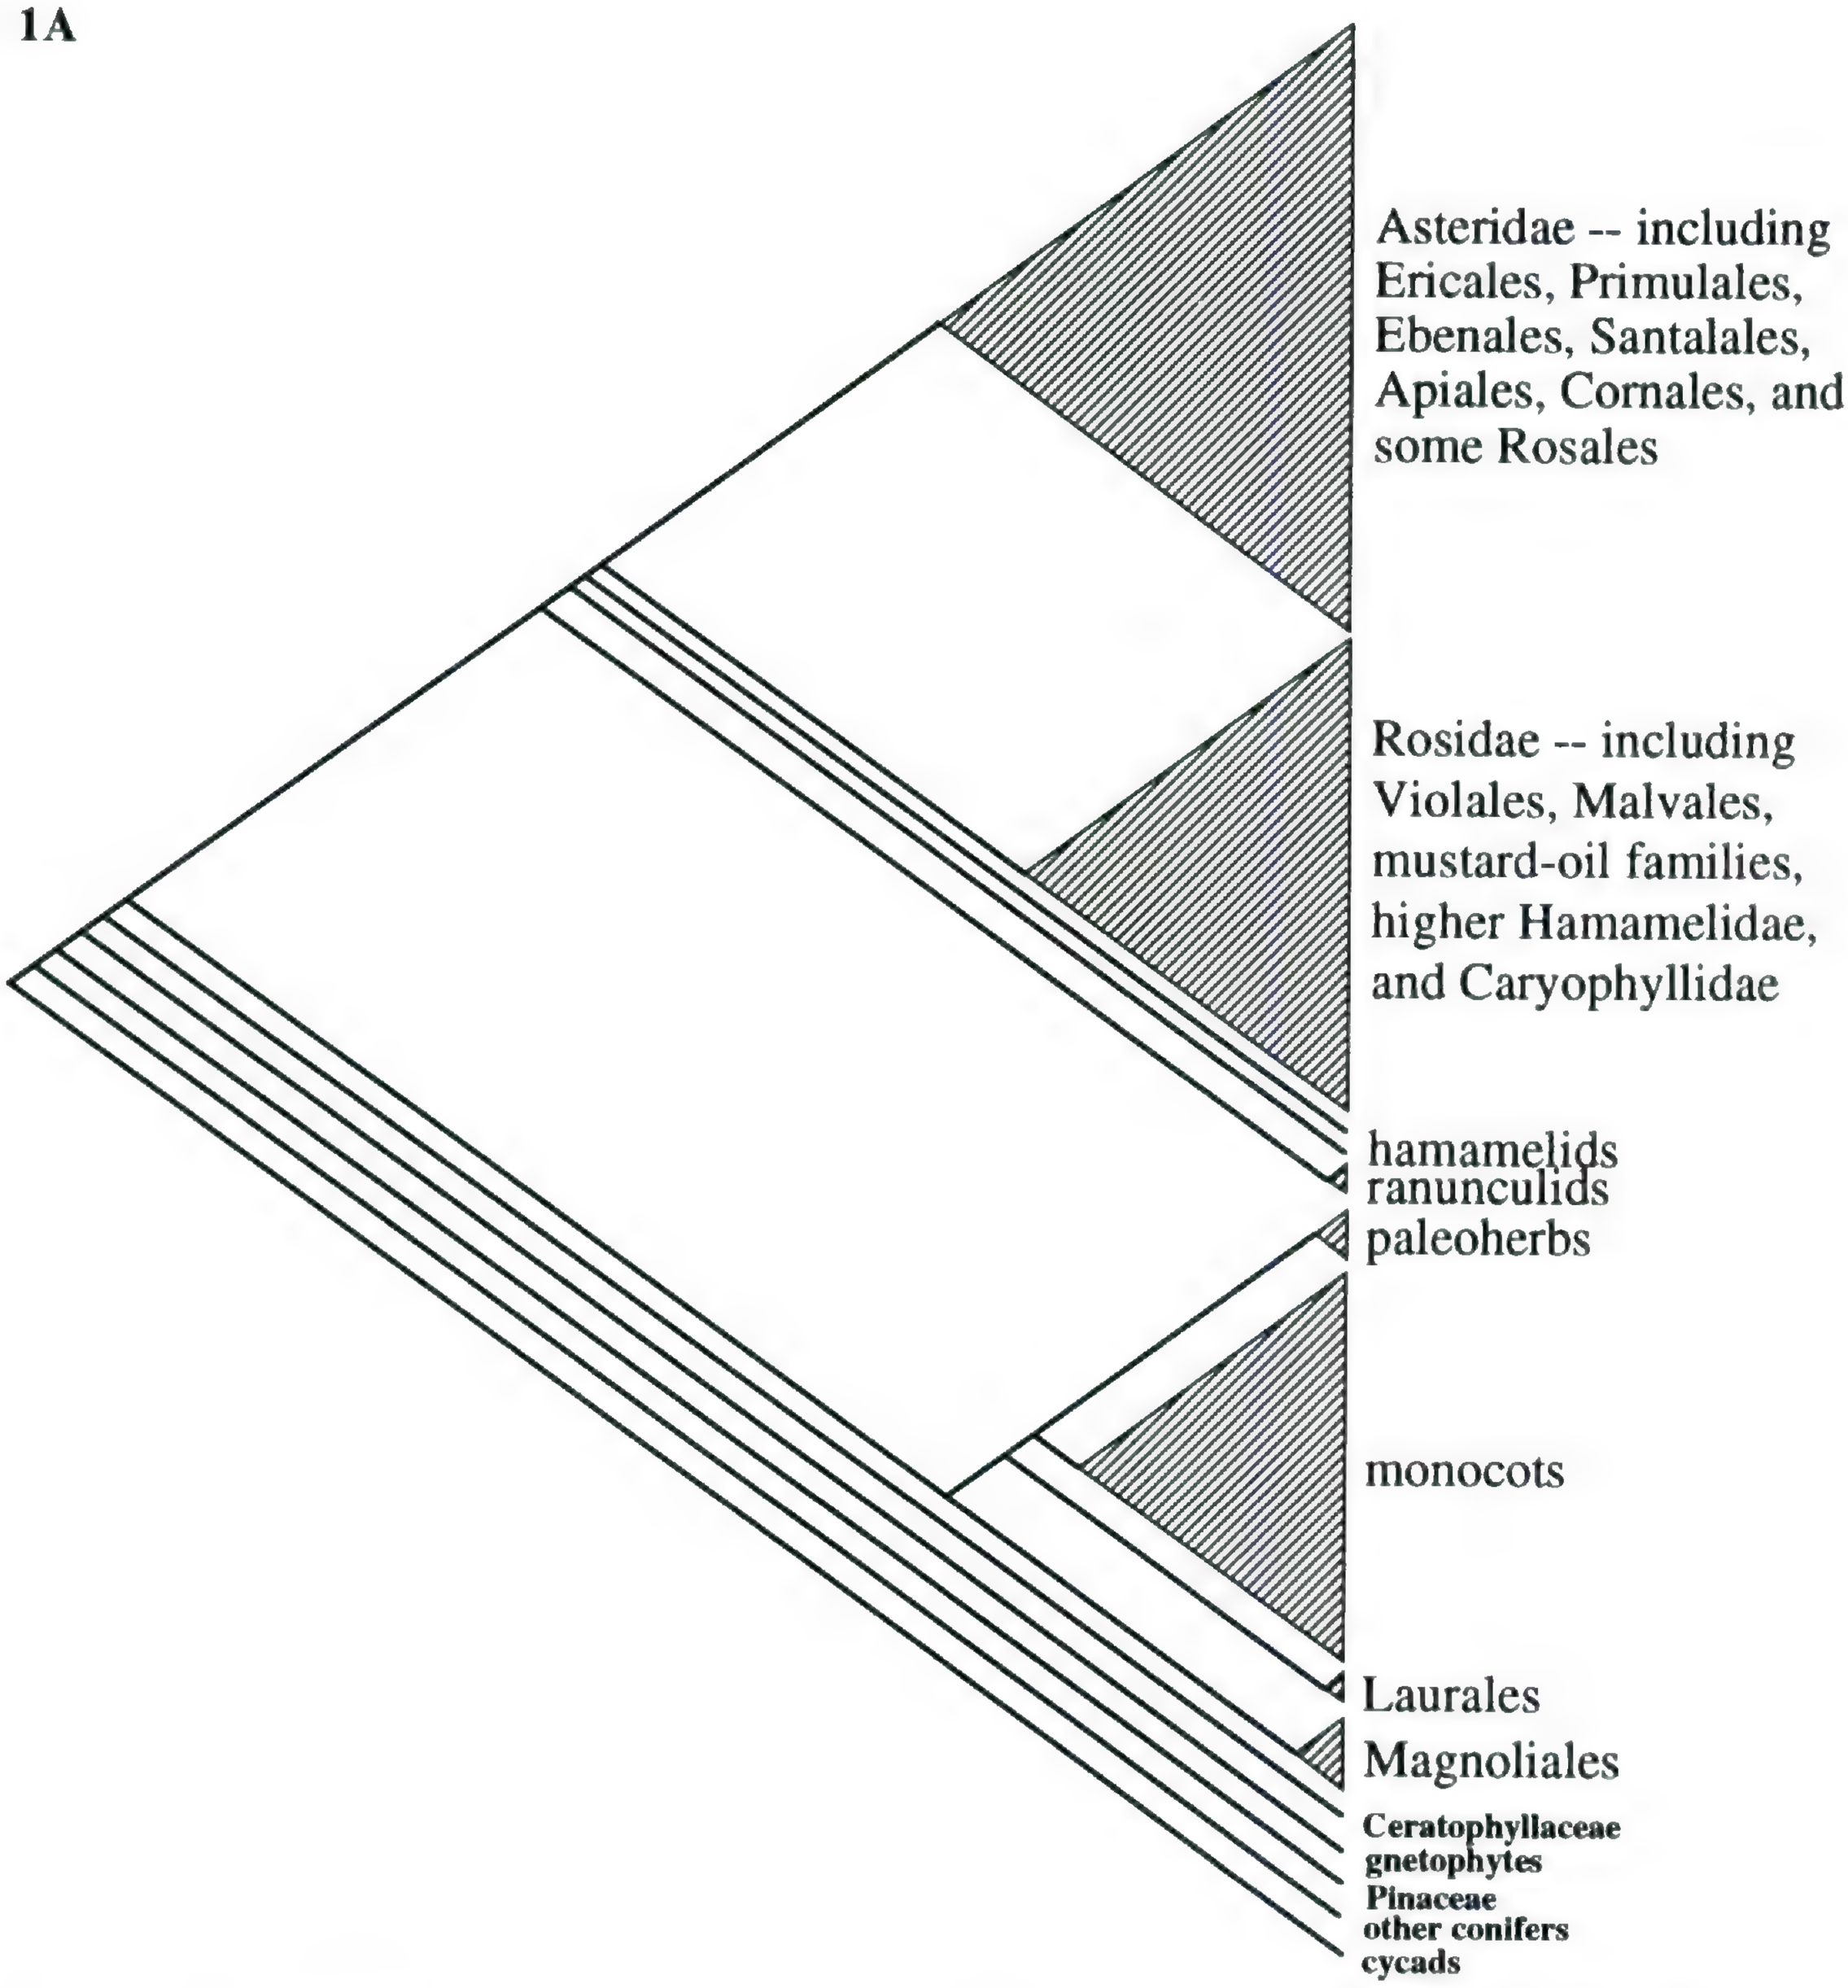

FIGURE 1. Summaries of the major clades identified in: (A) the combinable component consensus tree of 500 equally parsimonious trees found for 475 taxa using the character-state weighting method of Albert et al. (1993, this issue); and (B) the strict consensus tree of 3,900 equally parsimonious trees for 499 taxa found using the Fitch (even weights) criterion. These are ingroup networks arranged arbitrarily with the cycads sister to all other seed plants.

2A

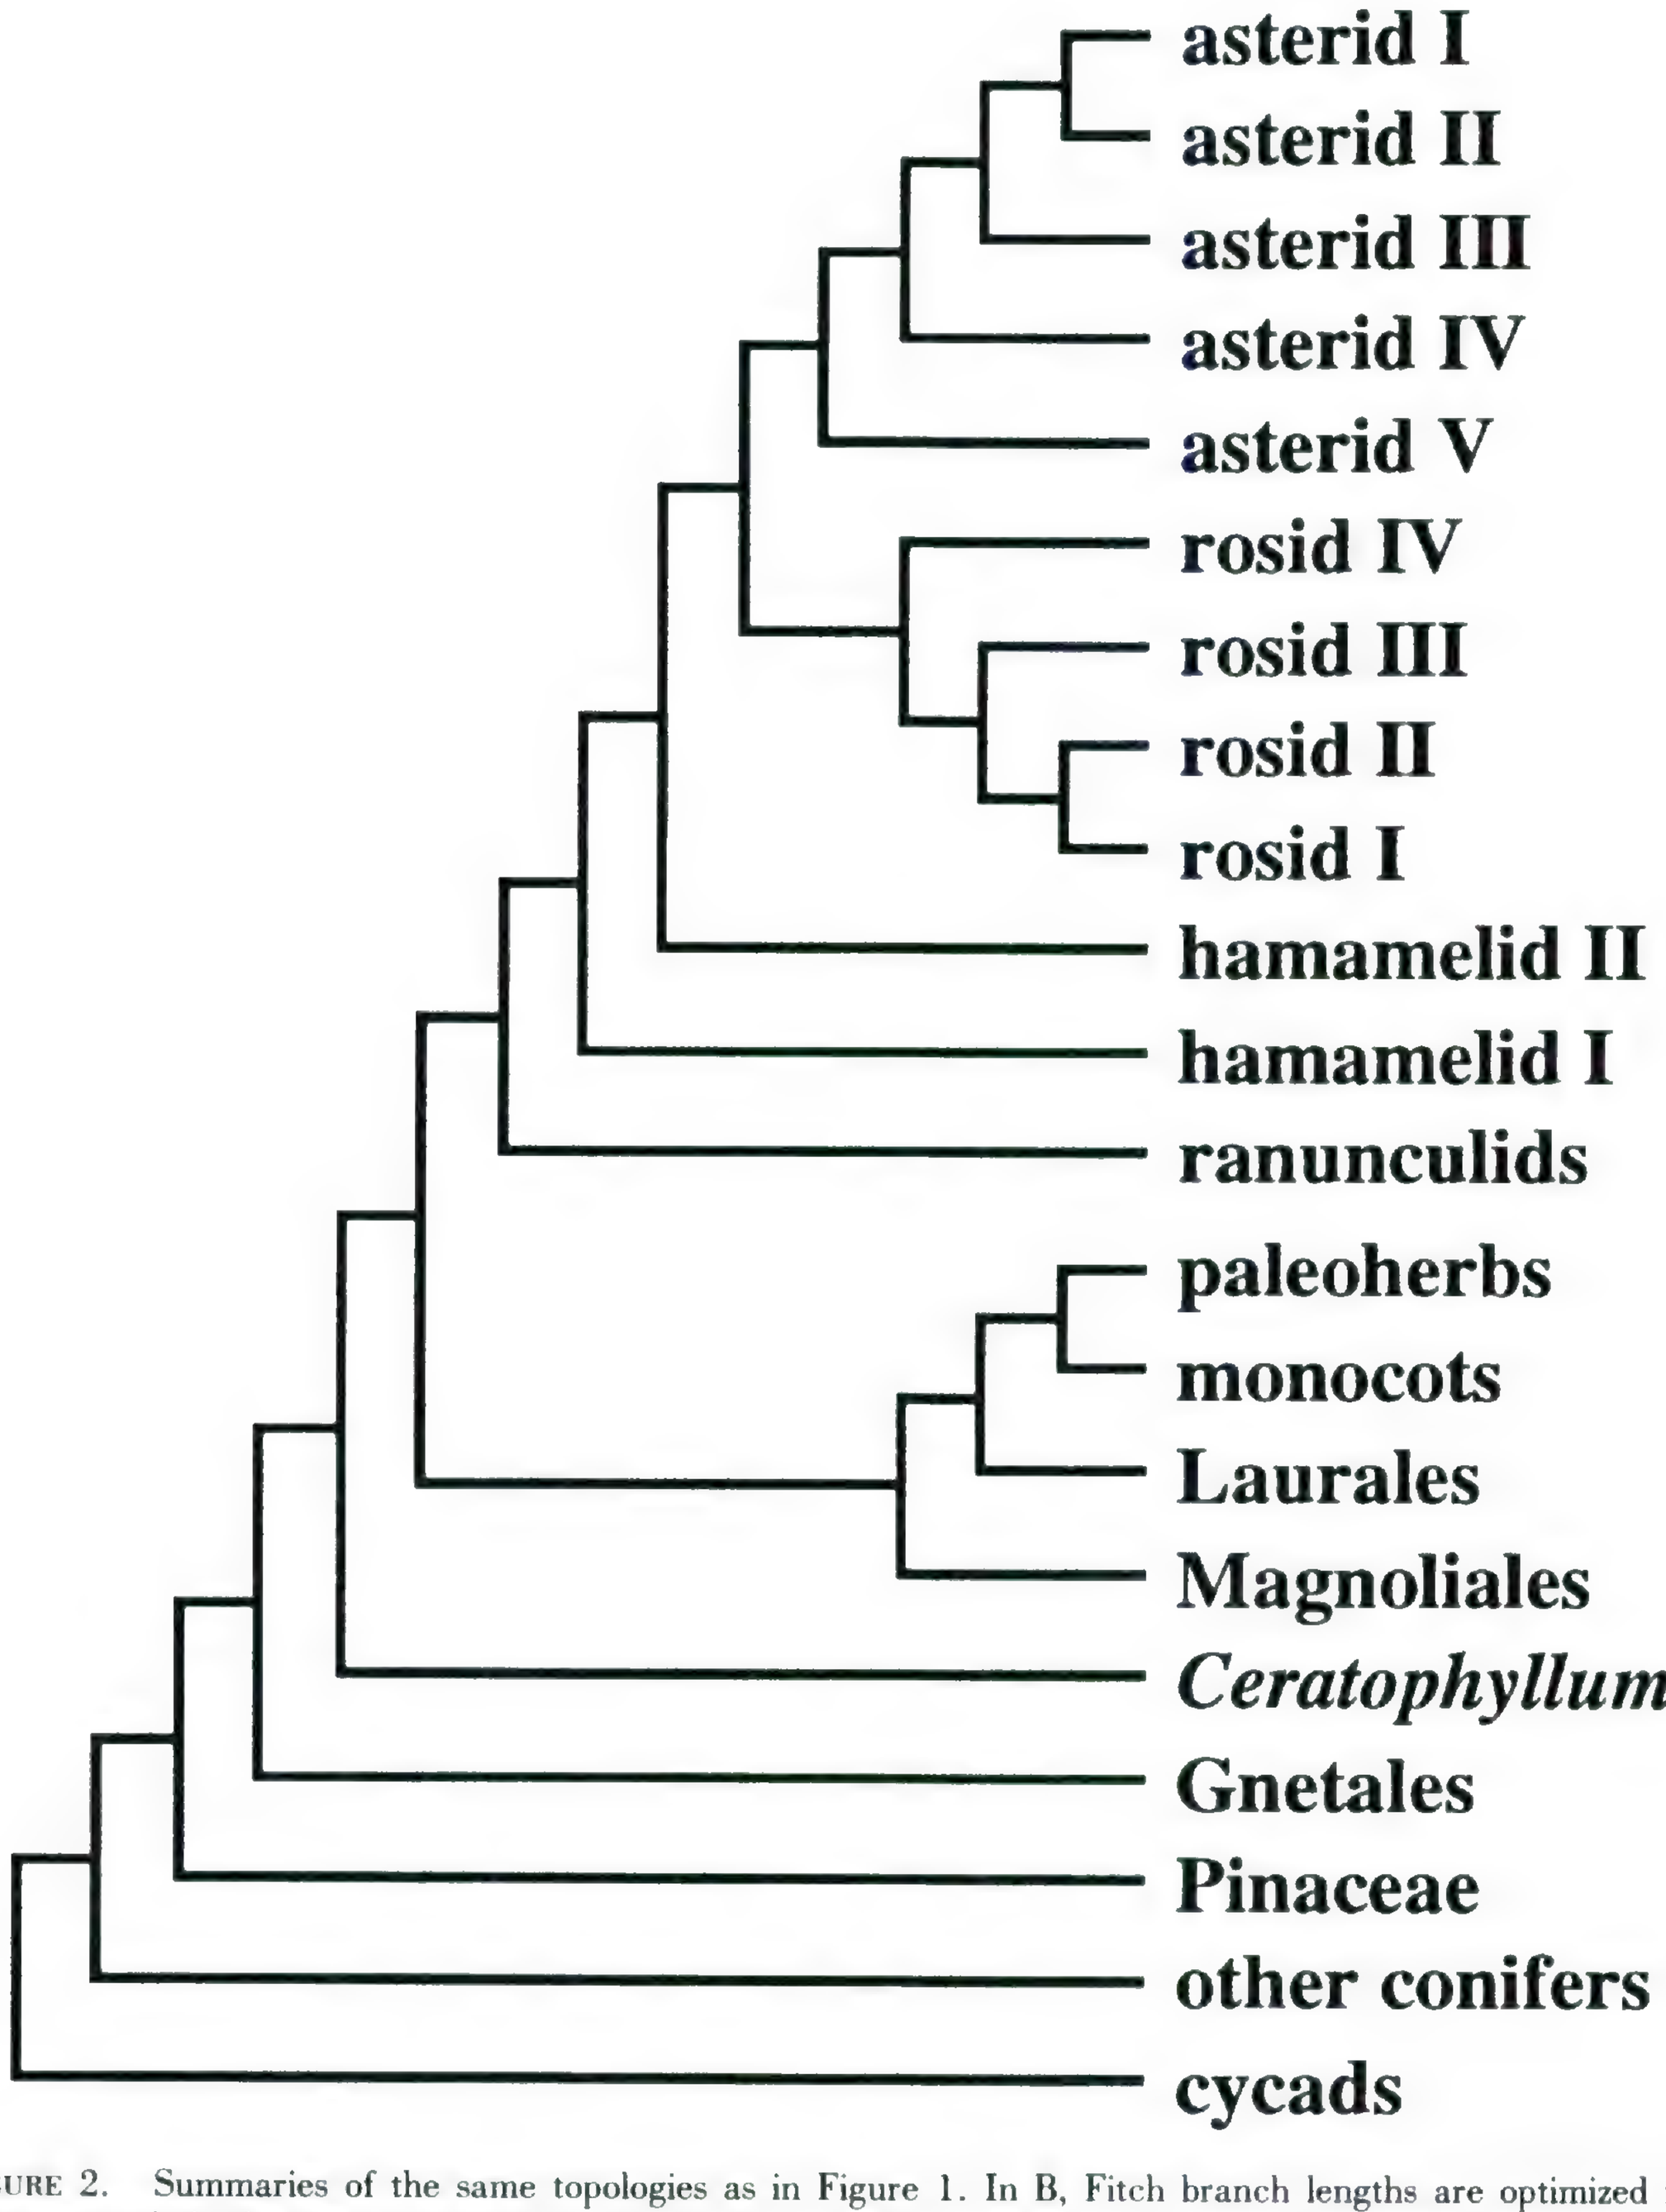

FIGURE 2. Summaries of the same topologies as in Figure 1. In B, Fitch branch lengths are optimized from a single tree; optimization on consensus trees is likely to overestimate branch lengths. Names of the specific clades identified do not conform to the composition of families used in most taxonomic schemes, but rather are designated with respect to the components of the major lineages (i.e., by the subclass name for the majority of taxa included, except for the heterogeneous hamamelid I, which is so designated because of its position and inclusion of Platanaceae). Names of each clade correspond to groups shown in Figures 3–15. Clades marked with a "§" in B are those that differ significantly in position or composition from A.

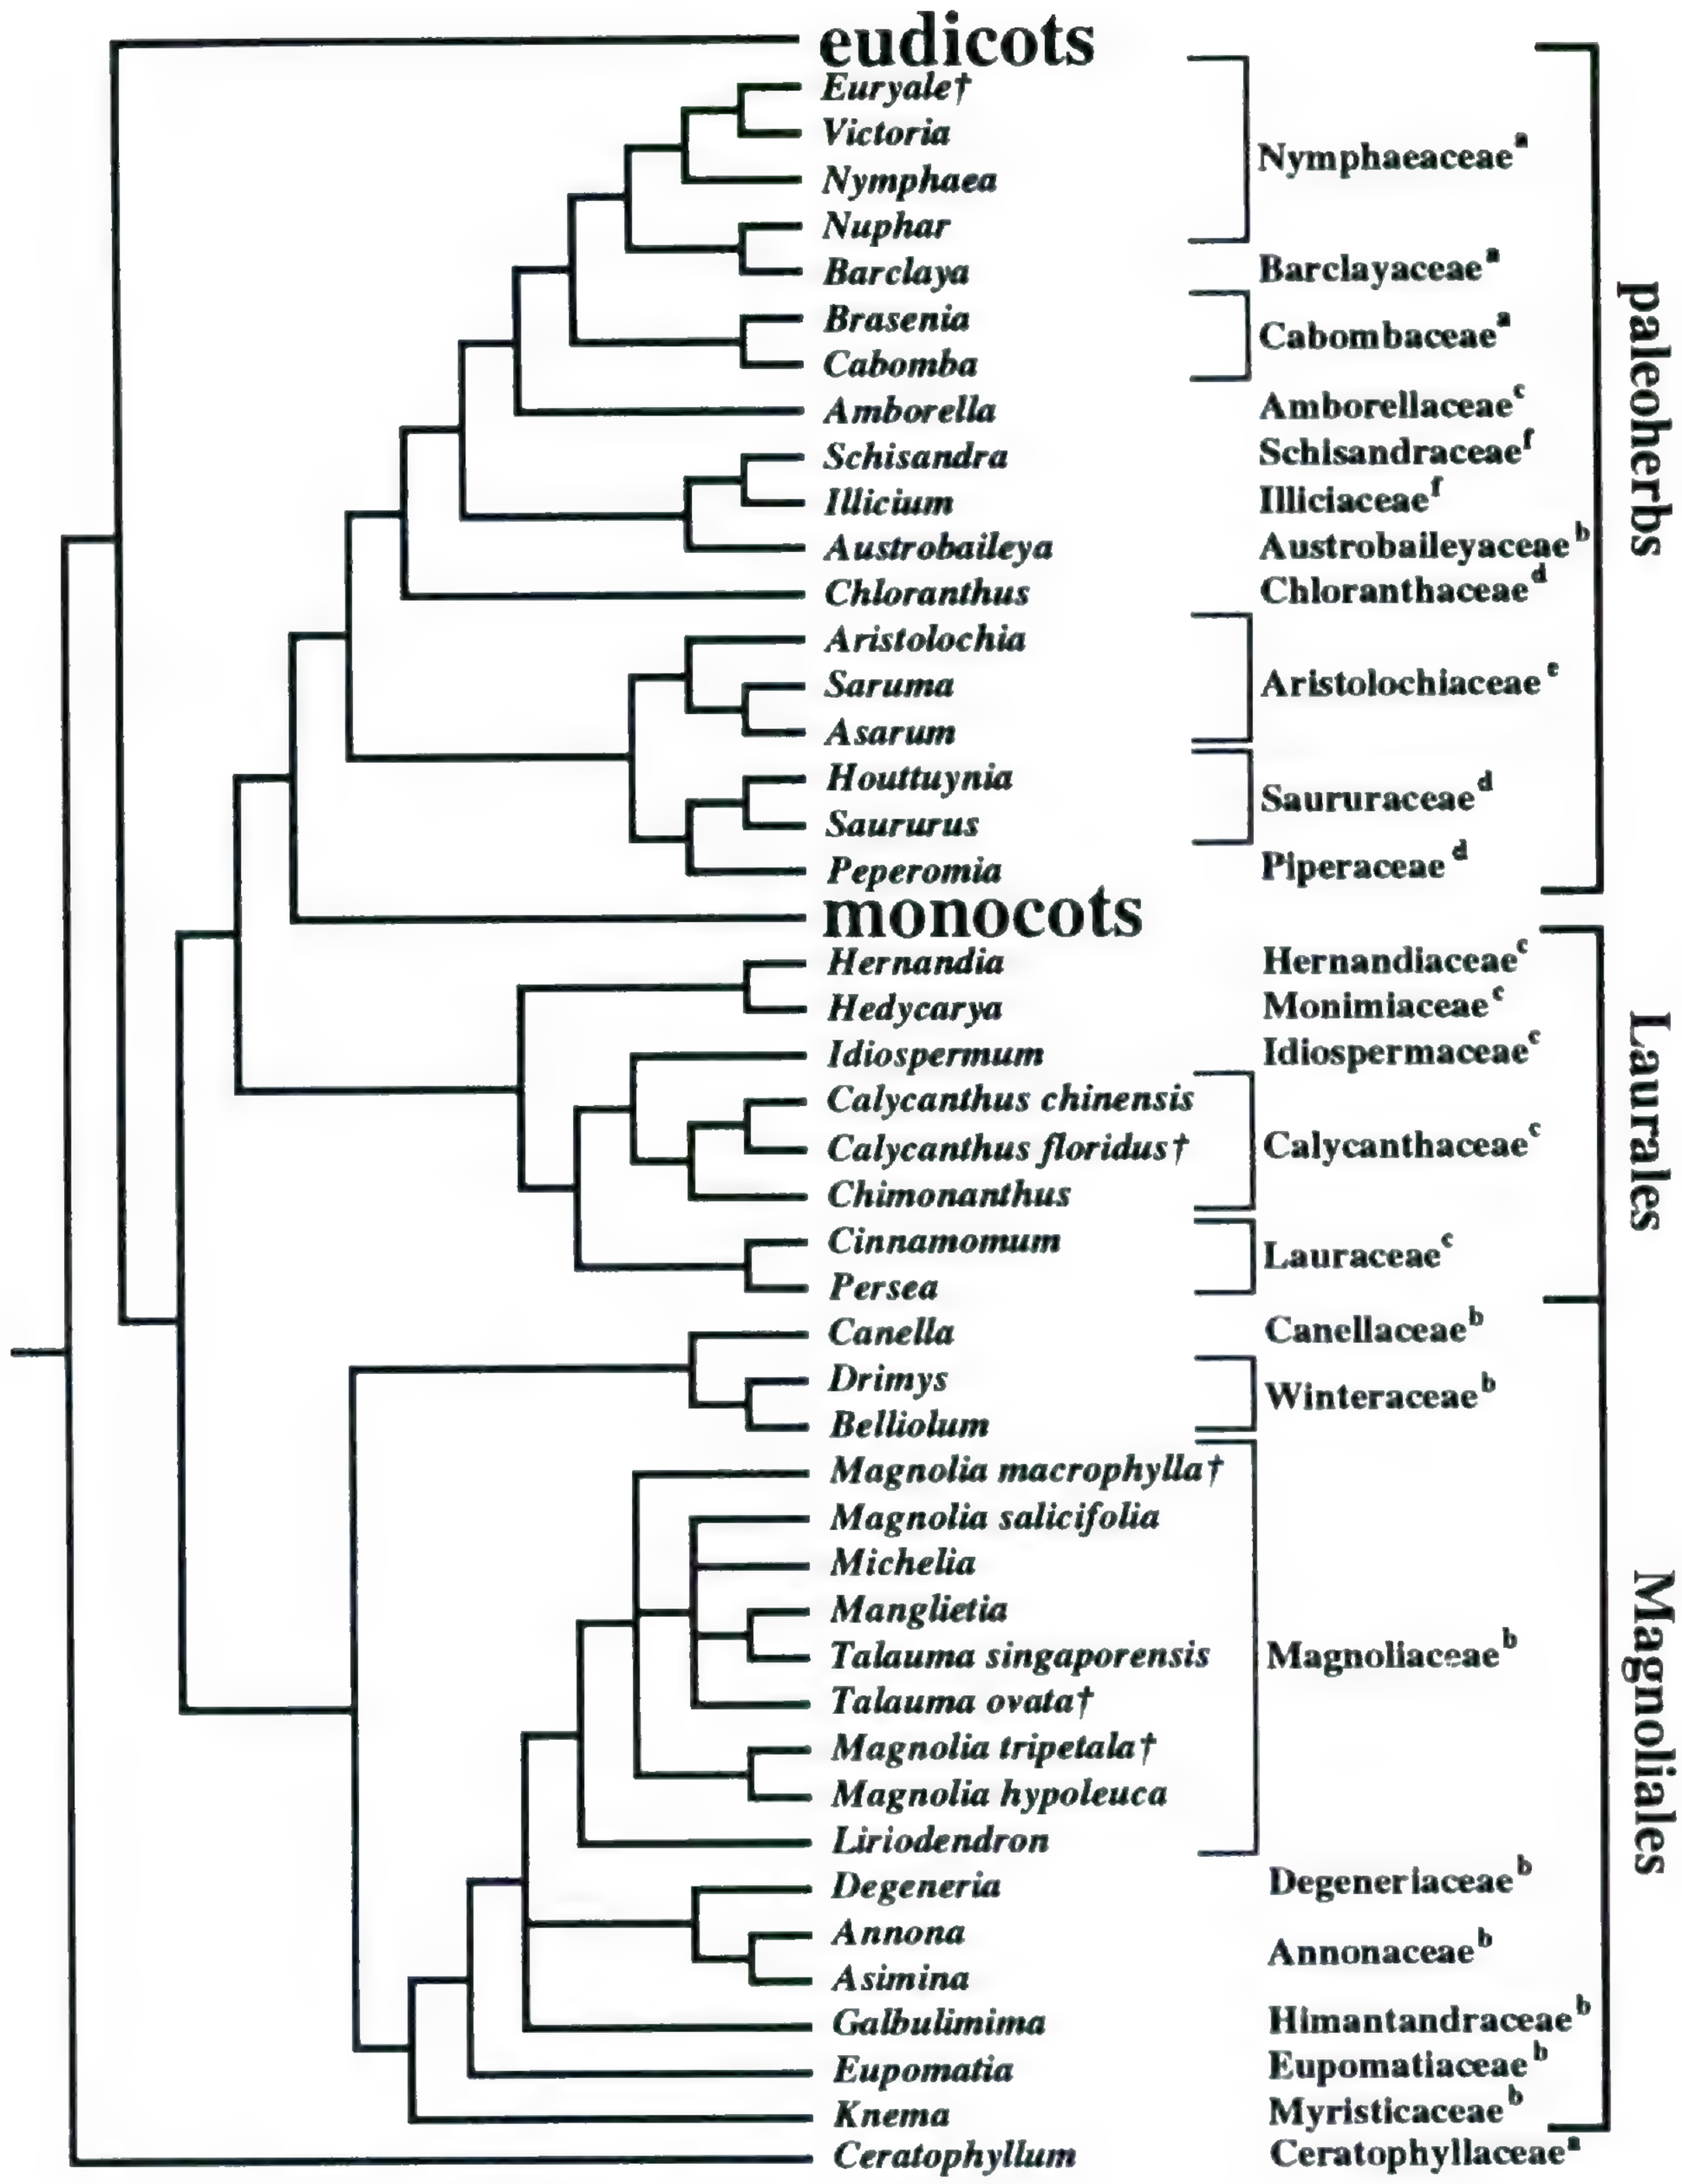

FIGURE 4. Basal portion of the overall analysis showing the positions of Ceratophyllaceae (inaperturate pollen), monocots (uniaperturate pollen), eudicots (dicots with triaperturate pollen), and the three clades of "primitive" dicots (monosulcate pollen). Note that, exclusive of *Ceratophyllum*, the angiosperms form two sister groups marked by the general pollen aperture number (one versus three). (Numbers above the branches in B are the numbers of substitutions optimized onto one tree randomly selected from the 3,900 saved in Search II.) Genera marked with a "†" in A were omitted from Search II; genera marked with an asterisk in B were not available for Search I. The "*Canella*" in this figure represents the position of two sequences amplified from a total cellular DNA template (see Materials & Methods). Note that A is the consensus tree of Search I, whereas B is a single tree with branches not present in the strict consensus of Search II marked by an arrow.

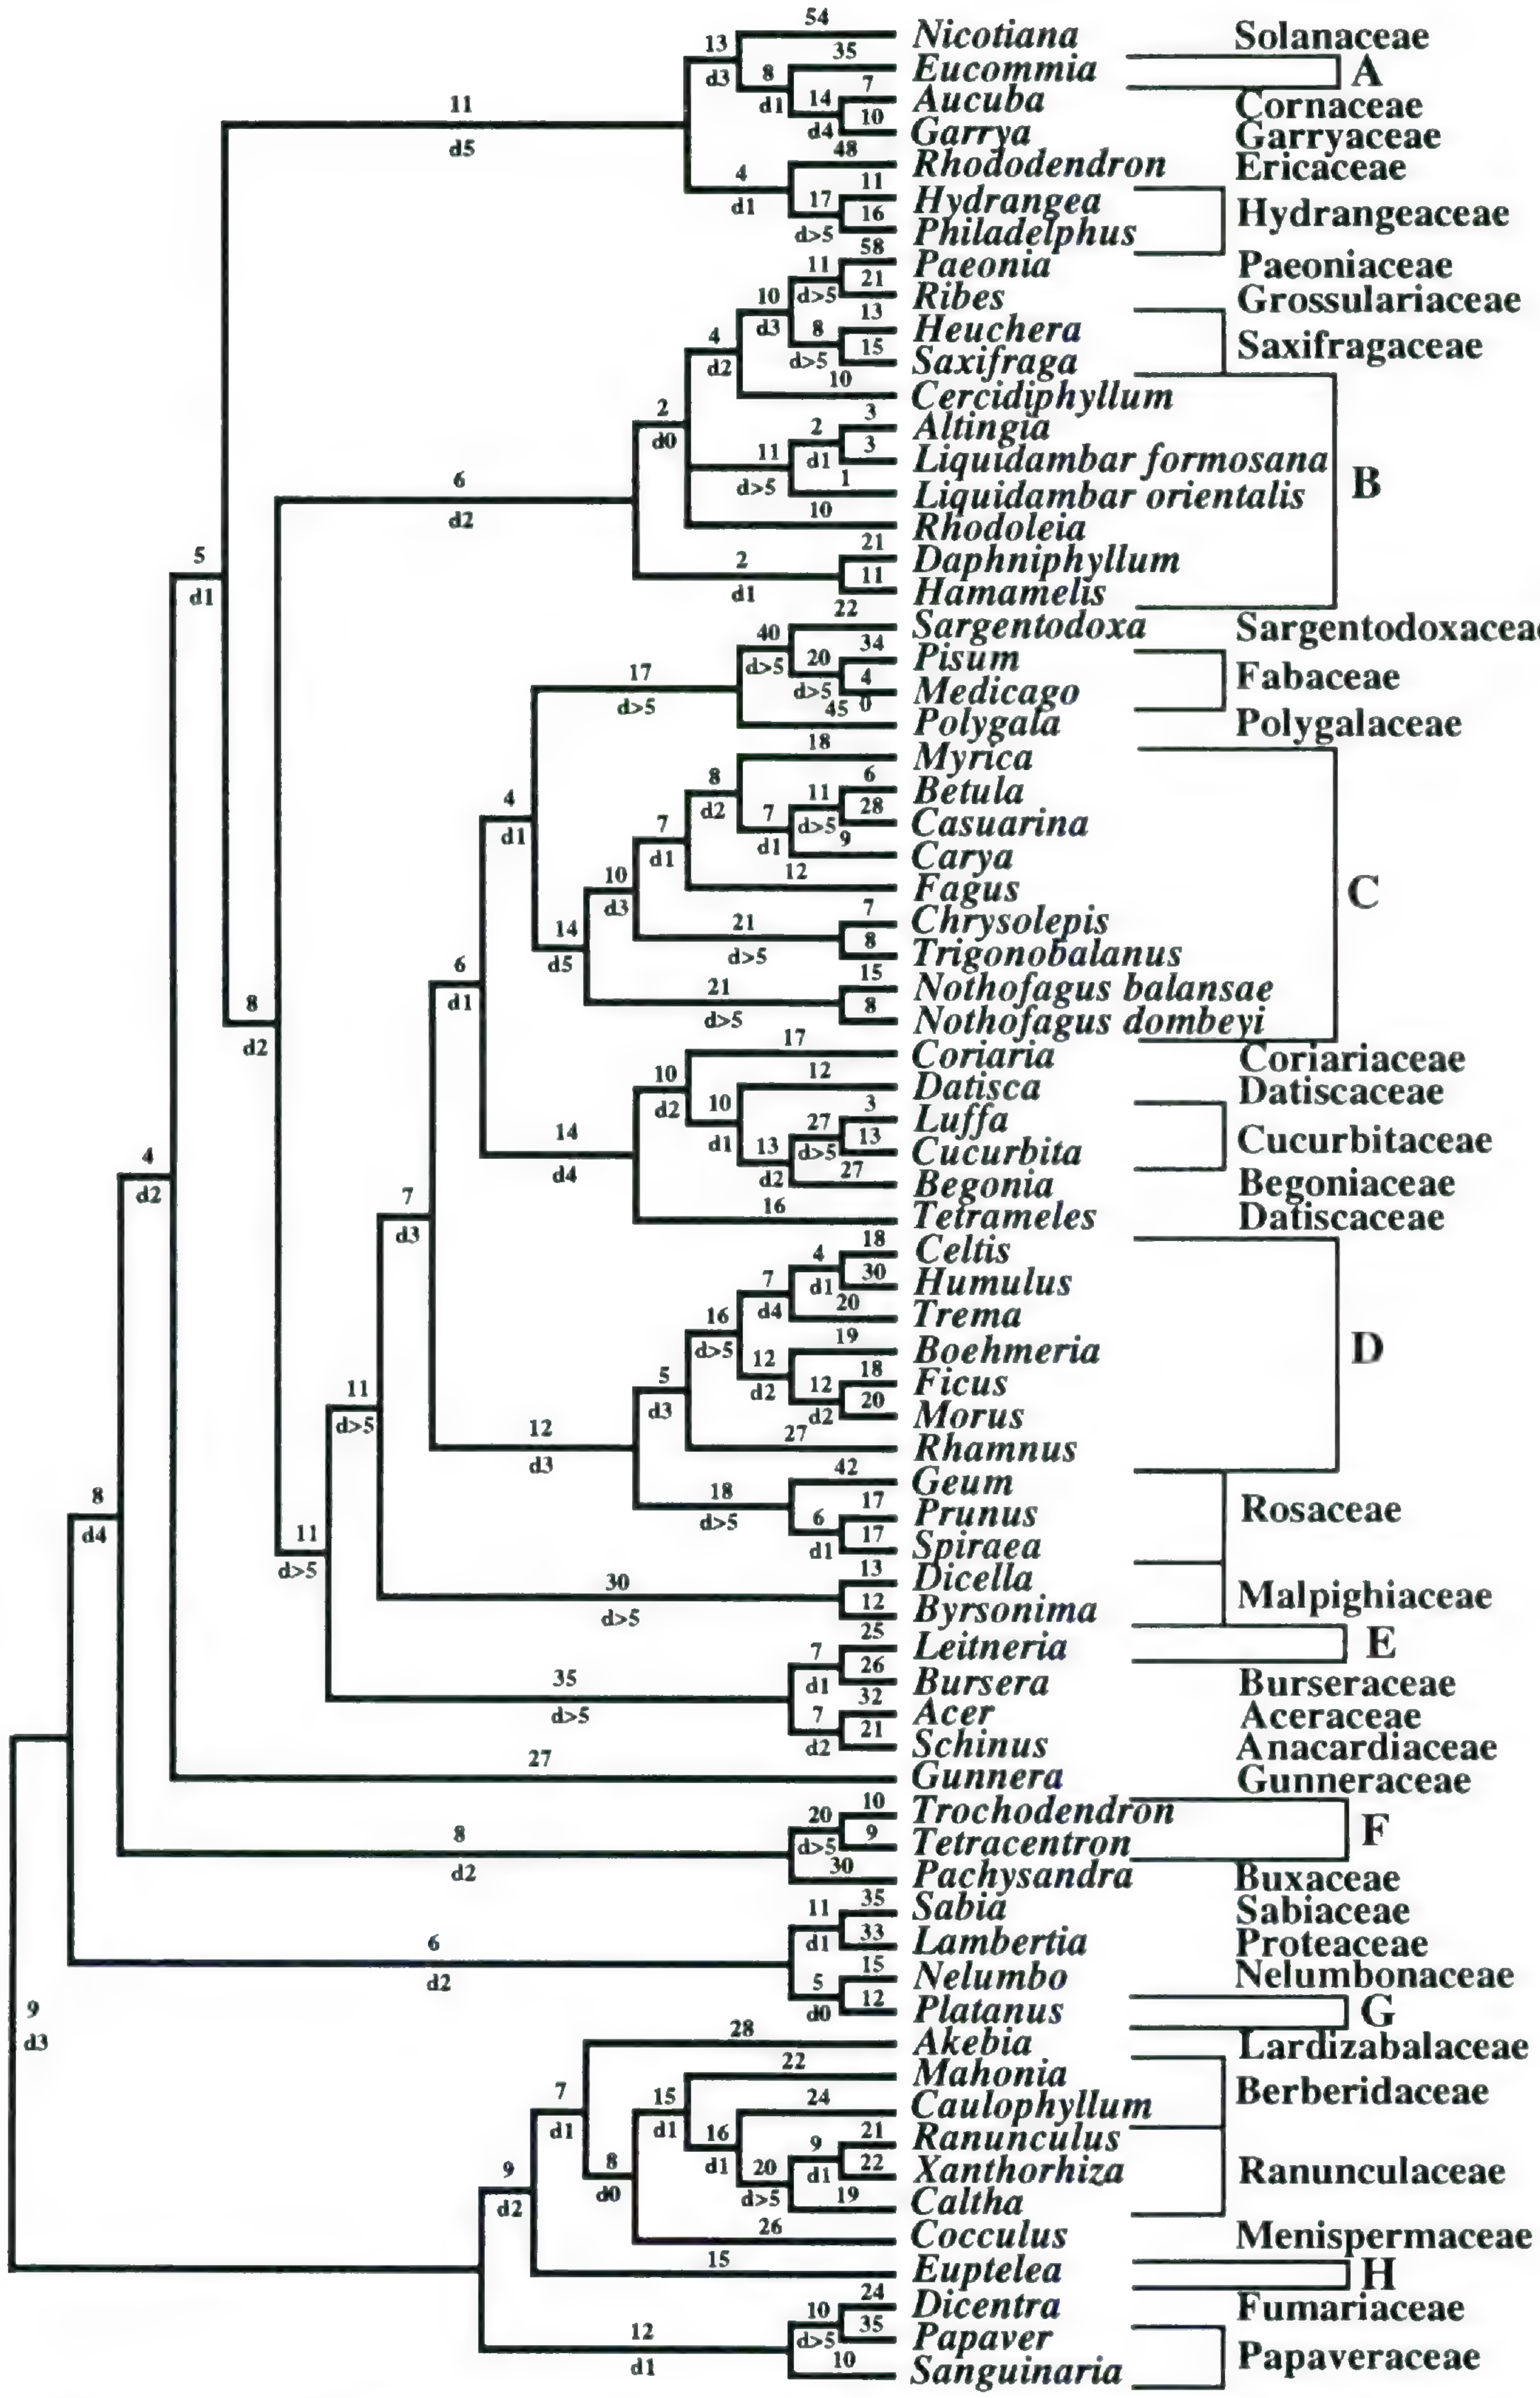

FIGURE 16. An example of using the general analysis to focus a narrower study of internal support for a polyphyletic Hamamelidae. Numbers above the horizontal lines indicate the number of substitutions optimized (ACCTRAN) onto one of the most parsimonious trees found using character-state weighting (i.e., these are Fitch steps, equal weighting). The numbers below the horizontal lines (preceded with a "d") are the number of steps less parsimonious at which a branch becomes a polytomy with the branch interior to it. Branches that are not present in the strict consensus of most-parsimonious Fitch trees are indicated by "d0," signifying that they "decay" at maximum parsimony. Groups of taxa often considered to be members of Hamamelidae are bracketed and lettered to designate putatively independent lineages (for further explanation see text).

# AN ANALYSIS OF RELATIONSHIPS WITHIN THE CUPRESSACEAE SENSU STRICTO BASED ON *rbc*L SEQUENCES[1]

*Paul A. Gadek and Christopher J. Quinn*[2]

ABSTRACT

The analysis of *rbc*L sequences of representative species of 13 of the 20 genera of the Cupressaceae sens. str. has produced a cladogram that agrees with data derived from other sources. The monophyly of the family is well supported. The cladogram provides support for the recognition of a basically northern subfamily (Cupressoideae) and a southern subfamily (Callitroideae), but the boundary between the subfamilies needs to be realigned by moving *Tetraclinis* from the Callitroideae to the Cupressoideae. The tribal arrangement of Li is largely artificial: the Libocedreae, Cupresseae, and Thujopsideae are clearly paraphyletic.

While there is evidence from morphology, leaf and wood anatomy (Eckenwalder, 1976; Hart, 1987; Quinn & Gadek, 1988), and seed proteins (Price & Lowenstein, 1989) to support the monophyly of the Cupressaceae sensu stricto, the data for some of these characters, as well as for leaf biflavonoids (Gadek & Quinn, 1983, 1985), wood anatomy (Quinn et al., unpublished), and immunological comparisons of seed proteins (Price, pers. comm.), have not correlated well with the widely accepted intrafamilial classification of Li (1953; Table 1). Cladistic analyses of the database have shown a high level of homoplasy (Gadek & Quinn, unpublished). We therefore initiated an analysis of *rbc*L sequences in representative taxa in the hope of obtaining evidence of a more conservative nature that will permit estimates of relationships within the family.

## MATERIALS AND METHODS

Species from which *rbc*L sequence data were obtained are listed in Tables 2 and 3 and are drawn from genera in both subfamilies and all six tribes (Table 1). Sequences will be lodged in Genbank on completion; they are also available from the authors.

Total DNA was isolated using the CTAB method (Doyle & Doyle, 1990). A series of synthetic oligonucleotide primers based on the *rbc*L sequences of *Nicotiana tabacum* and *Zea mays*, as well as one provided by M. W. Chase (designed by Helen Michaels and Jeff Palmer), were used for cyclic DNA amplification initially to produce a double stranded product containing the *rbc*L gene and subsequently to obtain single stranded products of both strands. The latter were sequenced by the standard dideoxy chain termination method. Sequences have been verified by sequencing both strands. The primer at the 5′ end included the first 16 bases of the gene, while that at the 3′ end was outside the coding portion of the gene. Hence, sequences start from the first complete codon (position 19) and terminate at the end of the stop codon (position 1428), a total length of 1,410 bp.

Sequences of *Glyptostrobus* and *Cryptomeria* (unpublished, Soltis et al., pers. comm.) were included as representatives of the Taxodiaceae, the generally accepted sister group for the Cupressaceae sens. str. Phylogenetic analyses were performed with PAUP version 3.0g (Swofford, 1991) using both the default character-state weightings as well as the model of Albert et al. (1993). The default weightings give equal weighting to all character states, while the Albert model invokes a tree-searching procedure that differentially weights

[1] We acknowledge the assistance of the following: W. D. Clark, Arizona State University, for advice on sequencing and analysis and help in gaining access to unpublished sequence data; D. Soltis, P. Soltis, and S. Brunsfeld, Washington State University, for access to unpublished sequences of *Glyptostrobus* and *Cryptomeria*; M. W. Chase, University of North Carolina (now at Royal Botanic Gardens, Kew, England), for 3′ primer; M. T. Clegg, University of California, Riverside, for the SE program; R. C. Crozier, Ching Crozier, and G. de Couet for assistance with techniques in the initial stages of this work; and N. Skelton and D. Crayn for technical assistance. This work is supported by Australian Research Council grant no. AD9031851.

transversions over transitions within characters, and codon positions 2>1>3 among characters. Output trees from PAUP were also transferred into MacClade (Maddison & Maddison, Harvard University) and manipulated to test other topologies.

## RESULTS

The 5′ end of the sequences for several species are still incomplete, approximately 40 bases missing from the start of *Cupressus* and *Thuja*, and 30 from *Diselma*. Percentage sequence divergence was calculated, using the available homologous sequence data, for all taxon pairs (Table 2). There are quite low levels of divergence between some pairs of species: viz, *Juniperus conferta* and *Cupressus sempervirens* (0.7%), *Thuja occidentalis* and *Thujopsis dolobrata* (0.6%), *Platycladus orientalis* and *Microbiota decussata* (0.9%), and *Diselma archeri* and *Widdringtonia cedarbergensis* (0.9%). *Callitris rhomboidea* is clearly the most divergent species, showing divergences ranging from 5.1% (with *Calocedrus decurrens*) to 3.6% (with *Libocedrus bidwillii*). The levels of sequence divergence among the taxa indicate that the gene has the potential to be informative about relationships within the family.

Two trees were found by PAUP branch and bound analysis using the unweighted (default) character assumption and TBR swapping option. These trees differed only in placing *Calocedrus* either basal to, or as part of an unresolved trichotomy involving *Cupressus* + *Juniperus* and *Platycladus* + *Microbiota*. The tree with the lowest f-value is shown in Figure 1. The Cupressaceae sens. str. are monophyletic, and there are two monophyletic clades representing northern and southern genera. *Tetraclinis* appears with *Thuja* + *Thujopsis*, in a clade basal to the remaining northern genera, while *Chamaecyparis* is basal to the unresolved trichotomy referred to above. *Libocedrus* is basal to a clade containing all the remaining southern genera.

PAUP identifies in this data set 14 apomorphs that characterize Cupressaceae sens. str., of which 10 are unique synapomorphs. The clade comprising the southern genera is supported by seven unique synapomorphs (positions 459, 693, 1071, 1194, 1203, 1308, and 1363), and there are potentially three more synapomorphs at positions

that are undetermined in a single species (33, 450, and 1227). Three additional apomorphs showing parallelisms elsewhere in the cladogram are also identified. The clade comprising the northern genera is supported by three apomorphs, of which two are unique synapomorphs (positions 237 and 339). There is only weak apomorphic support for other northern groupings within this clade, although *Juniperus* + *Cupressus* is characterized by three unique synapomorphs (168, 318, and 507) and *Microbiota* + *Platycladus* by one (1047).

The data set was then subjected to bootstrapping (PAUP, 100 replicates), and this provided strong support for the monophyly of the southern taxa (95%) and within it the grouping of *Diselma* + *Widdringtonia* (97%). The northern taxa, including *Tetraclinis*, clustered at the 75% level, and there was strong support for the clades comprising *Thuja* + *Thujopsis* (80%) and *Juniperus* + *Cupressus* (79%), while *Microbiota* clustered with *Platycladus* at the 63% level. The placement of *Tetraclinis* within this group was more equivocal: it clustered with *Microbiota* + *Platycladus* in 33% of trees and with *Thuja* + *Thujopsis* in 27%.

When the Albert et al. model of character-state weightings was invoked, PAUP heuristic analysis found three trees, all one step longer than the most parsimonious trees found using the equally weighted character option. All the Albert trees clustered *Tetraclinis* within the clade of *Microbiota* and *Platycladus*, and placed *Calocedrus* basal to *Chamaecyparis* (Fig. 2). The position of *Chamaecyparis* is determined by a single nonsynonymous 2nd codon position change, at position 284, for which there is considerable homoplasy within the cladogram.

## DISCUSSION

The molecular estimate of the phylogeny presented here gives strong support for the monophyly of the Cupressaceae sens. str. Monophyly of the family is also supported by the opposite and decussate phyllotaxis, the absence of a germination papilla and the compound nature of the sexine in the pollen (Ueno, 1959; Hart, 1987), and apparently also in the basipetal sequence of protoxylem differentiation within the leaves (Quinn & Gadek, 1988). There are further characters cited by Hart (1987) that show reversals or parallelisms.

Although the sampling of genera in this study is still quite limited, especially among the southern genera, some assessment of the support given to the present intrafamilial taxonomy (Table 1) by the sequence data is already possible. The southern genera form a strong clade but there is no support for the inclusion of the North African genus *Tetraclinis* within the mainly southern Callitroideae. The subfamily distinction (Li, 1953) was based on a single character, ovulate cone scales imbricate or valvate, which has been inconsistently scored in several genera by different authors (cf. Buchholz, 1948; Janchen, 1950) and which de Laubenfels (1965) described as "spurious." Independent ev-

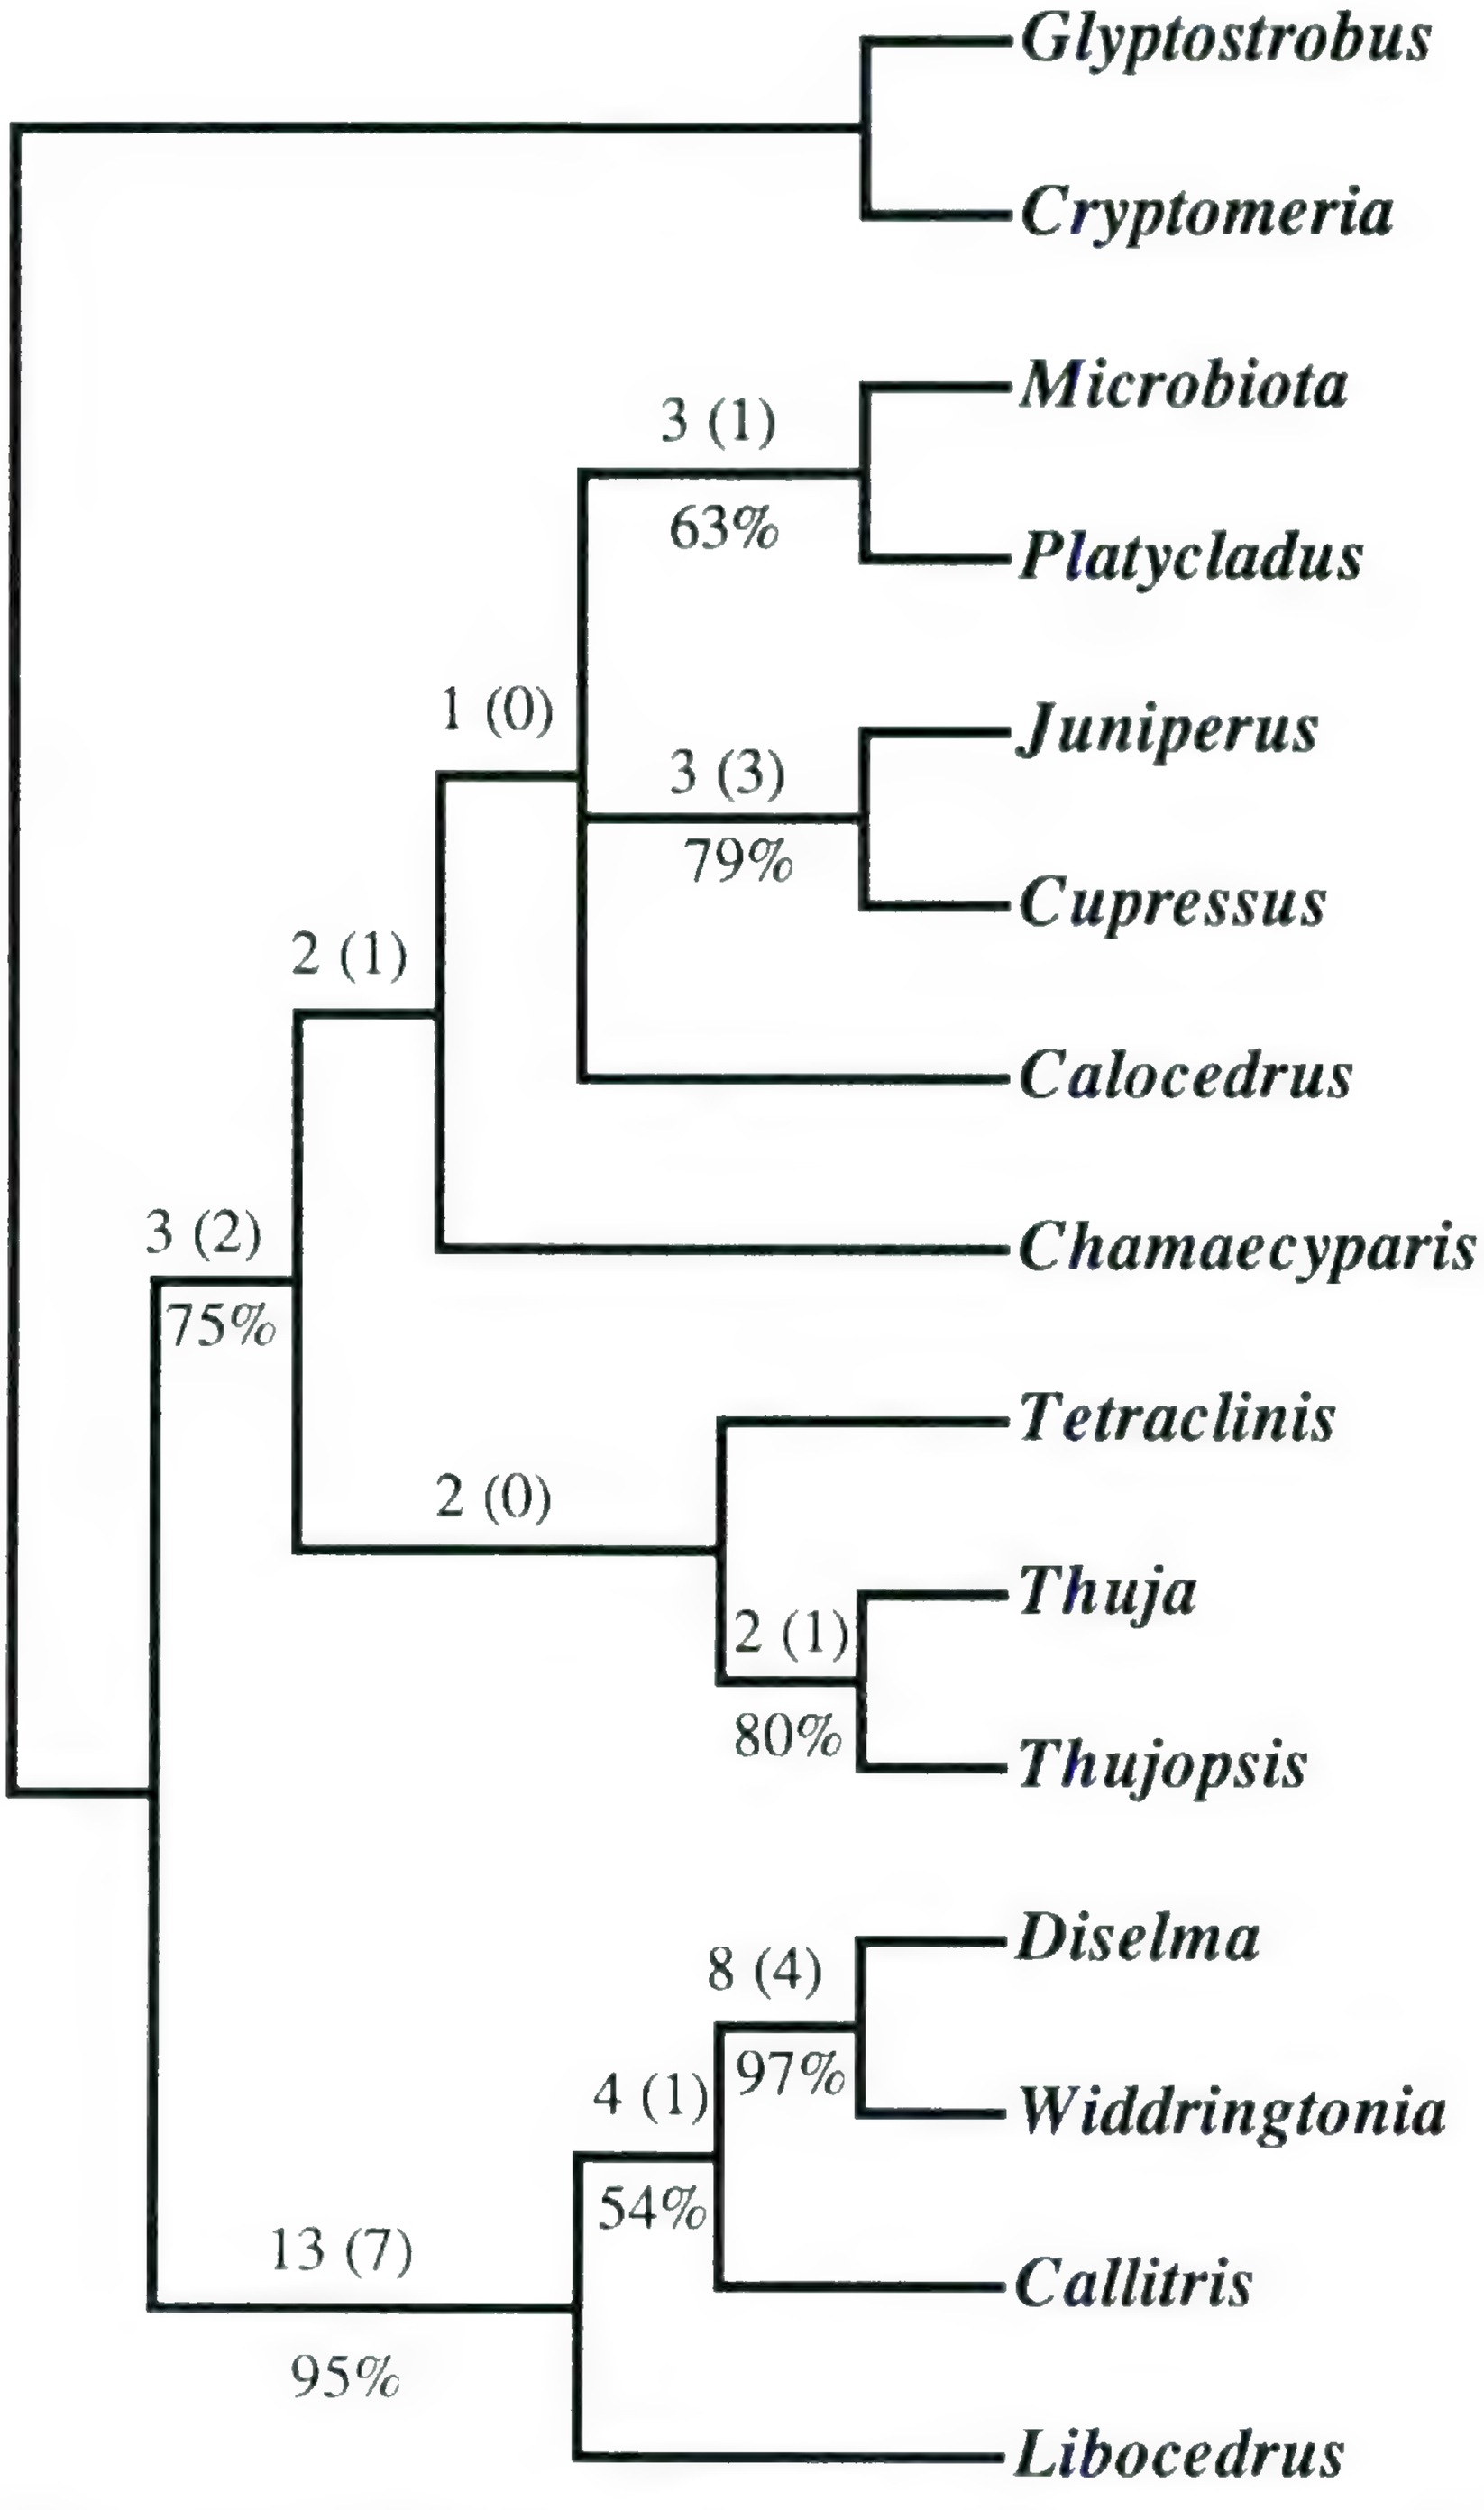

FIGURE 1. One of two shortest trees found by PAUP branch and bound analysis, arranged with *Glyptostrobus* and *Cryptomeria* (Taxodiaceae) as the outgroup. The tree shown is that with the lowest f-value. Apomorphic support as identified by PAUP is indicated above the branches, with the number of unique synapomorphs in brackets. Frequency of occurrence in bootstrap replicates of groups of taxa to the right of the branch are indicated as a percentage below the branch.

idence of an affinity between *Tetraclinis* and certain northern genera, especially *Cupressus* and *Juniperus*, has come from recent work on seed proteins (Price, pers. comm.), leaf biflavonoids (Gadek & Quinn, 1985), and transfusion tracheids (Gadek & Quinn, 1988).

The pattern of relationships within the northern and southern clades (Fig. 1) is strikingly at variance

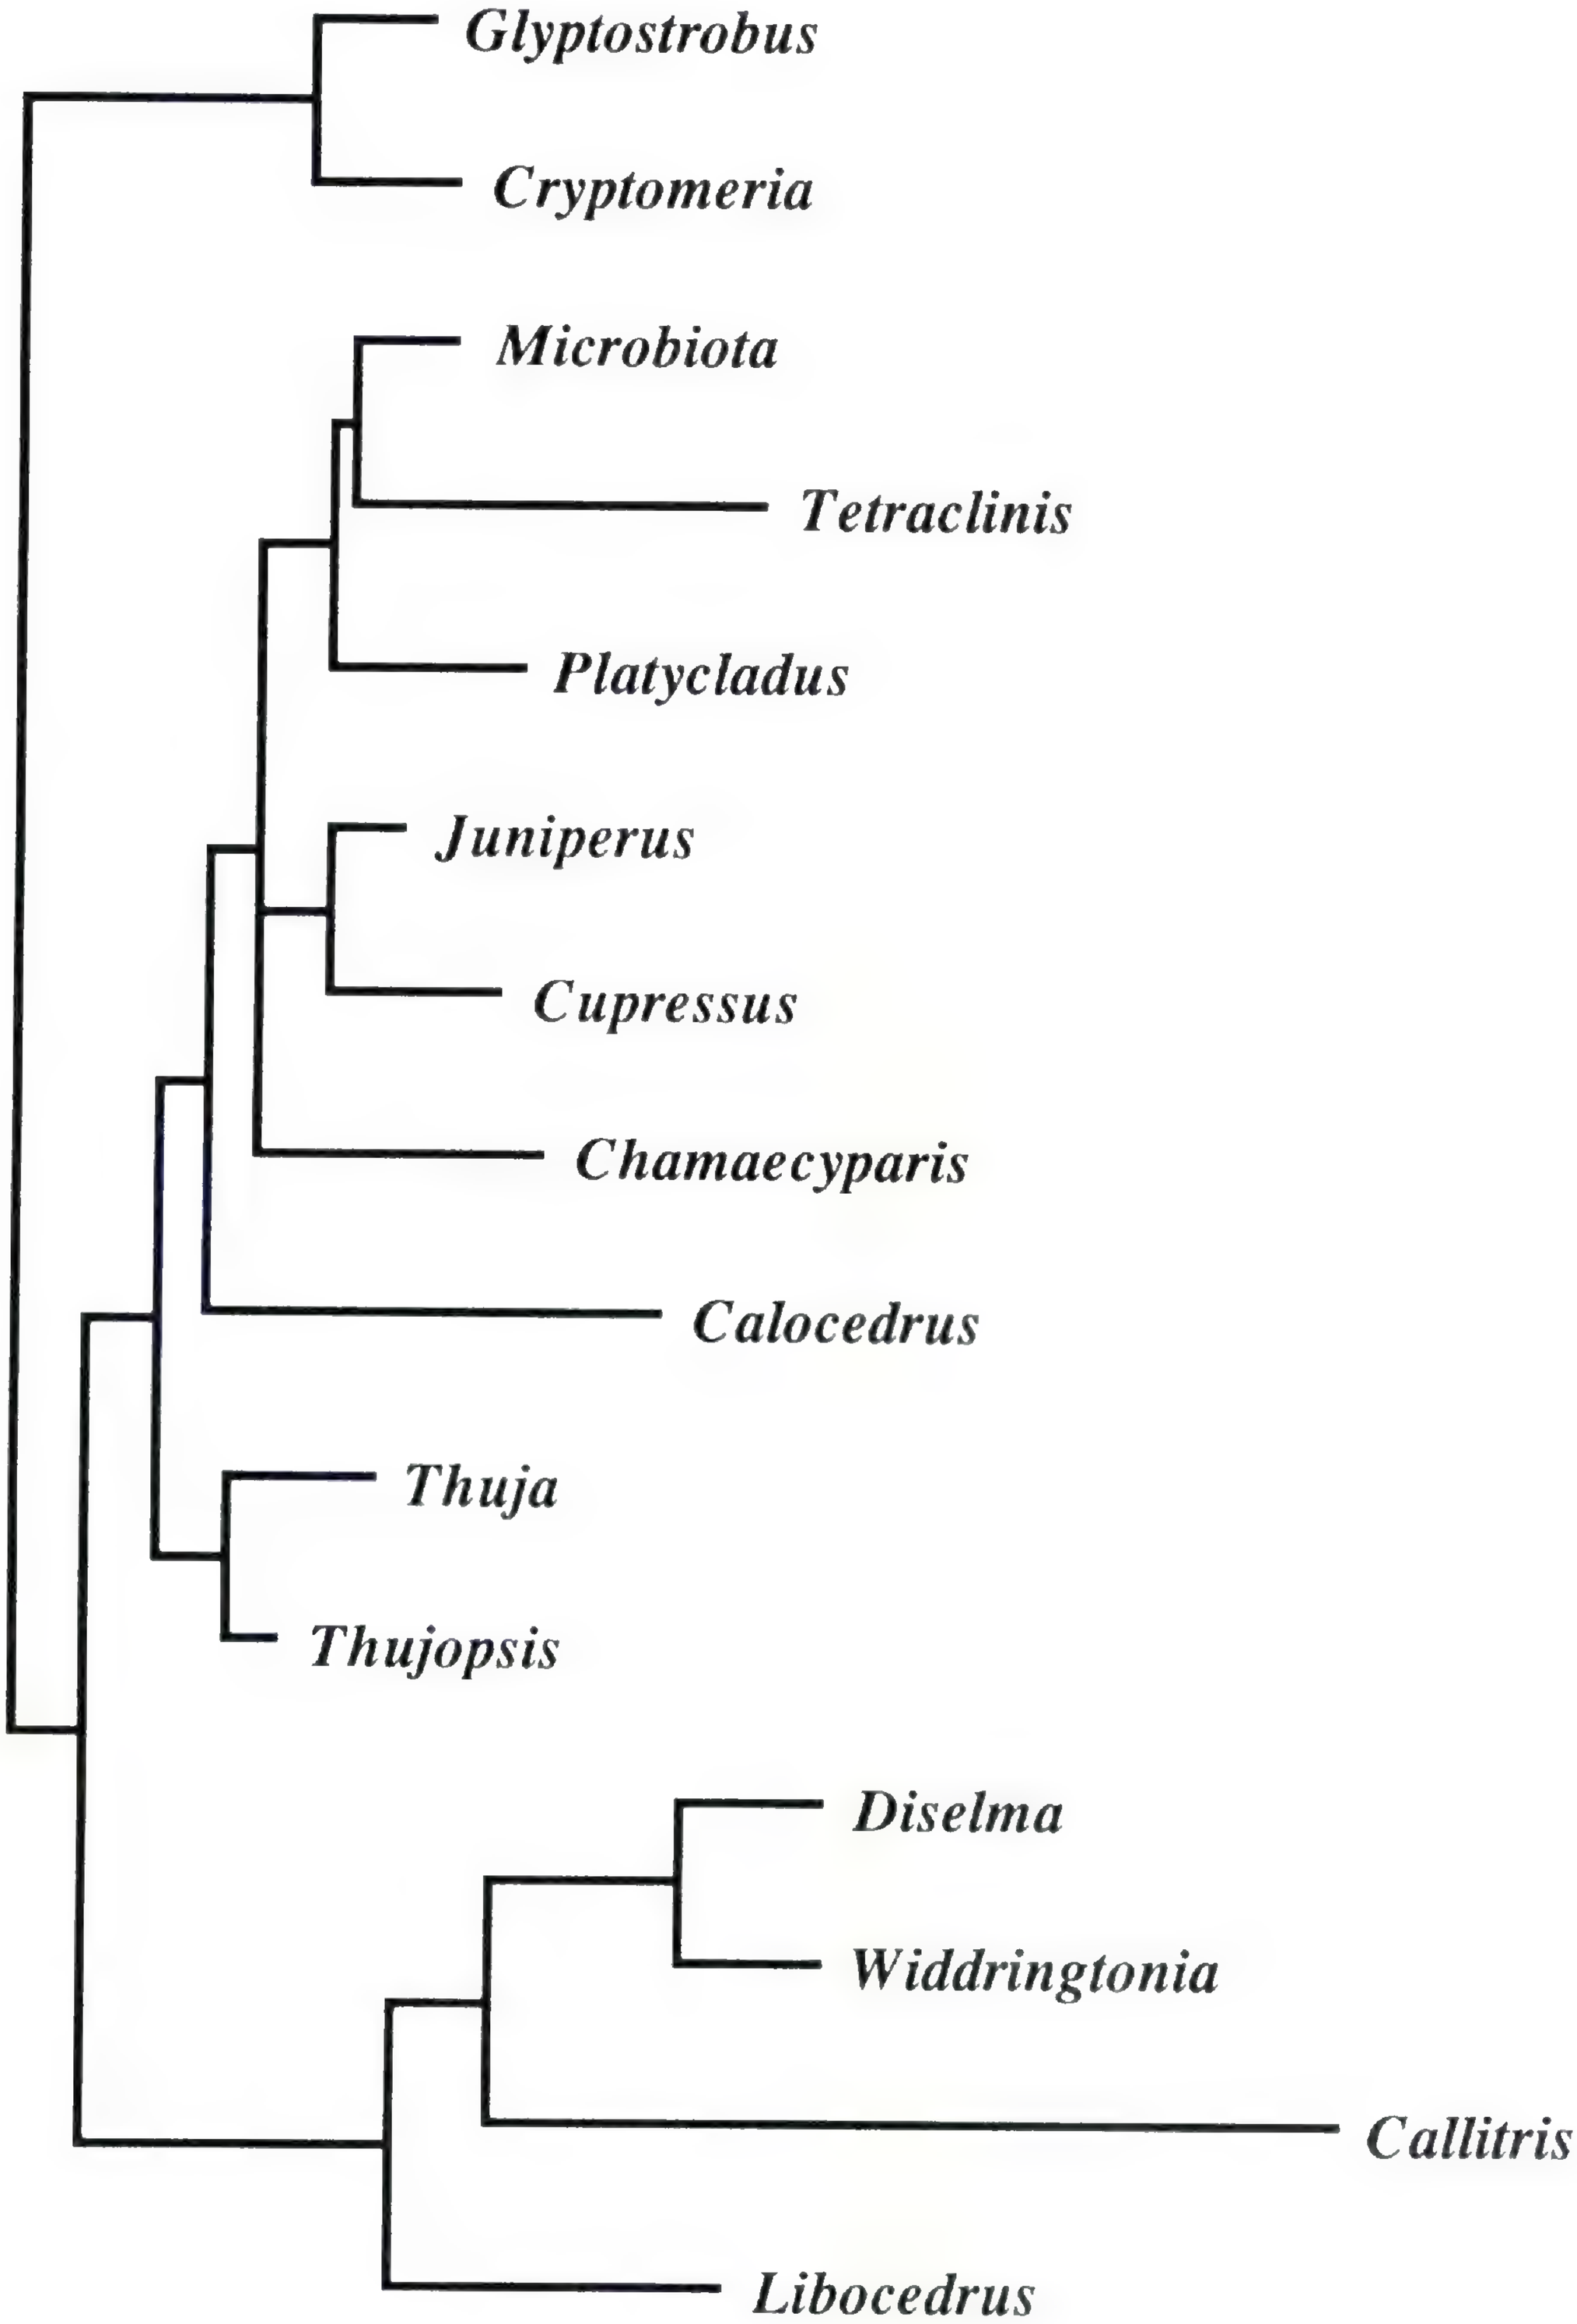

FIGURE 2. One of three shortest trees found using PAUP after invoking the character weighting assumptions of Albert et al. (1993), shown with relative branch lengths. The other two trees resolve the trichotomy by placing *Chamaecyparis* either basal to the other two clades, or basal within the *Juniperus–Cupressus* clade. In each case, PAUP assigns a relative branch length of zero to these internodes. The tree shown is one step longer than that in Figure 1.

with the tribal groups of Li (1953). The placement of *Callitris* (Actinostrobeae) as sister group to *Diselma* + *Widdringtonia* (Libocedreae) renders the latter tribe paraphyletic. The monophyly of neither the Cupresseae (*Cupressus* and *Chamaecyparis*) nor the Thujopsideae (*Thuja*, *Thujopsis*, *Calocedrus*, *Platycladus*, and *Microbiota*) is supported by the sequence data. Indeed, all the trees derived from PAUP using either default or Albert et al. character-state weightings, and from the bootstrap analysis, contain the same three strong clades within the northern genera: *Juniperus* + *Cupressus*, *Microbiota* + *Platycladus*, and *Thuja* + *Thujopsis*. The position of the other northern genera is equivocal on these sequence data, but there is some evidence from the Albert trees, and the bootstrap analysis, for the association of *Tetraclinis* with the first two of these clades. Such an affinity is supported by both chemical and anatomical data: *Tetraclinis* possesses the same leaf biflavonoid pattern that distinguishes *Cupressus* and *Juniperus* (mainly parental biflavonoids with cupressuflavone a major constituent) and all five genera accumulate cupressuflavone (Gadek & Quinn, 1985; unpublished). Cupressuflavone derivatives also occur in *Calocedrus decurrens*, but are not found in the species of *Chamaecyparis* or *Thujopsis* sampled here. *Tetraclinis*, *Platycladus*, *Cupressus*, and *Juniperus* all possess trabeculate pitting in their transfusion tracheids, a state not found in *Chamaecyparis*, *Thuja*, or *Thujopsis*, while the intermediate state of barred pits occurs in *Calocedrus* (Gadek & Quinn, 1988). These same characters support the grouping of *Cupressus* with *Juniperus*, which Li (1953) assigned to a separate tribe (Table 1), rather than with *Chamaecyparis* to form the Cupresseae. They also support the separation of *Platycladus* from the *Thuja* + *Thujopsis* clade with which it has long been associated. The close association of *Thuja* and *Thujopsis* accords with other available data, and their divergence from the other northern genera finds some support from wood characters (Hart, 1987). The lack of a robust resolution of affinities between these clades and other northern genera, however, particularly with regard to the placement of *Chamaecyparis*, *Calocedrus*, and *Tetraclinis*, is a reflection of the low evolutionary rate of divergence of the *rbc*L gene within this group. Sequence data from a faster-evolving gene may help resolve the cladogram.

## Conclusions

The analysis of *rbc*L sequences of representative species of 13 of the 20 genera of the Cupressaceae sens. str. has produced a cladogram that finds considerable support from data derived from other sources. The monophyly of the family is well supported. The cladogram provides support for the recognition of a basically northern subfamily (Cupressoideae) and a southern subfamily (Callitroideae), but the boundary between these subfamilies needs to be realigned by moving *Tetraclinis* from the Callitroideae to the Cupressoideae. The tribal arrangement of Li (1953) is largely artificial: the Libocedreae, Cupresseae, and Thujopsideae are clearly paraphyletic. Although some robust clades are recognized (viz, *Diselma* + *Widdringtonia*, *Juniperus* + *Cupressus*, and *Thuja* + *Thujopsis*), the present database will not provide a robust resolution of relationships among the genera because of the low evolutionary rate of divergence of the *rbc*L sequences, especially within the northern subfamily.

# MOLECULAR PHYLOGENETICS OF THE MAGNOLIIDAE: CLADISTIC ANALYSES OF NUCLEOTIDE SEQUENCES OF THE PLASTID GENE *rbc*L[1]

*Yin-Long Qiu,*[2] *Mark W. Chase,*[2,3] *Donald H. Les,*[4,5] *and Clifford R. Parks*[2]

## Abstract

Nucleotide sequences of the plastid protein-coding gene *rbc*L from 64 species of 36 families in subclass Magnoliidae sensu Cronquist and representatives of all other major seed plant groups were analyzed by parsimony in a series of four analyses. *Ceratophyllum* (Ceratophyllaceae) was found to be sister to all other angiosperms. Other magnoliids formed five major groups, roughly corresponding to the Magnoliales, Laurales, Aristolochiaceae/Piperales, Nymphaeales, and Ranunculales/Papaverales. Four magnoliid lineages, those with monosulcate or monosulcate-derived pollen (Magnoliales, Laurales, Aristolochiales/Piperales, and Nymphaeales), and the monocots (with the same type of pollen) formed a weakly supported monophyletic group. The Illiciales (Illiciaceae and Schisandraceae), with a unique type of tricolpate pollen, also fell into this monosulcate clade. Relationships among these major lineages were resolved in all trees, but with low levels of support. Magnoliidae with tricolpate and tricolpate-derived pollen, Ranunculales Papaverales and Nelumbonaceae, fell into the other large clade of angiosperms, which have sometimes been termed the eudicots. Monophyly of this large tricolpate clade was strongly supported. These results demonstrated a high degree of congruence with the major groups identified in other studies, but they differed in the general relationships of these groups, particularly the monophyly of the monosulcate taxa and the sister-group relationship of angiosperms with the two general pollen types. They also deviated in the specific taxon composition of some major clades.

The dicotyledonous subclass Magnoliidae (Cronquist, 1981) contains most of the putatively primitive angiosperms. A thorough phylogenetic understanding of the complex is critical for study of the origin and reconstruction of the phylogeny of angiosperms. The Euanthial Theory of angiosperm evolution (Arber & Parkin, 1907) postulates that angiosperms with large strobiloid flowers such as Magnoliales are more primitive than those with diminutive, simple flowers (e.g., Piperales and Chloranthaceae). Over the past two decades, however, paleobotanists have accumulated a large body of fossil evidence which suggests that, during their early evolution, angiosperms with small and simple flowers might have paralleled or preceded those with large and complex flowers (Dilcher, 1979; Upchurch, 1984; Crane et al., 1986; Friis et al., 1986; Crane, 1989; Taylor & Hickey, 1990; Pedersen et al., 1991). A similar challenge has come from studies of extant plants (Burger, 1977, 1981; Hamby & Zimmer, 1992; Taylor & Hickey, 1992). Furthermore, which particular groups of Magnoliidae are related to the monocots and eudicots (the dicots with tricolpate and tricolpate-derived pollen

[1] We thank the following people for help in obtaining plant material for this study: W. Barthlott, H.-D. Behnke, D. J. Crawford, S. Dayanandan, W. C. Dickison, P. K. Endress, H. Forbes, L. Goff, G. Kappeler, B. Keller, K. A. Kron, L. Lee, Q.-X. Liu, D. G. Long, J. M. Miller, J. C. Ralston, D. E. Stone, T. F. Stuessy, E. P. Tay, C. M. Taylor, T. Terrazas-Salgado, L. B. Thien, J. L. Ward, K. J. Wurdack, and Y. Xia. We also thank H. G. Hills, C. F. Wimpee, D. K. Garvin, M. Bennett, and S. E. Williams for technical assistance, V. A. Albert and B. D. Mishler for assisting with part of the data analysis, P. G. Gensel and J. R. Massey for helpful discussion, and many other individuals for sharing unpublished sequences. J. A. Doyle, P. R. Crane, and J. W. Walker critically reviewed the manuscript; their suggestions and insightful comments are gratefully acknowledged. This research was supported by the W. C. Coker fellowship and a fellowship from the Graduate School, University of North Carolina to Y. Qiu and NSF grants BSR-8906496 to M. Chase and BSR-8817992 to D. Les. Publication of this paper is partially supported by the A. E. Radford and Laurie S. Radford Trust for Publication in Systematic Botany.

types, exclusive of Illiciales, cf. Walker & Doyle, 1975; Doyle & Hotton, 1991) remains a debatable issue (Dahlgren & Clifford, 1982; Dahlgren et al., 1985; Walker & Walker, 1984; Donoghue & Doyle, 1989; Doyle & Hotton, 1991).

The Magnoliidae have been known as the ranalian complex, Ranales, or Polycarpicae. In the classification scheme of A. P. de Candolle (1824), their prototype first appeared; it included key families of Magnoliales (Magnoliaceae, with *Illicium* of Illiciaceae and *Drimys* and *Tasmannia* of Winteraceae; and Annonaceae, with *Kadsura* of Schisandraceae), Nymphaeales (Nymphaeaceae, with *Nelumbo* of Nelumbonaceae), and Ranunculales/Papaverales (Ranunculaceae; Menispermaceae, with *Lardizabala* of Lardizabalaceae; Berberidaceae; Papaveraceae; and Fumariaceae). These taxa were placed sequentially at the beginning of the system, which covered only dicots and gymnosperms, but no collective name was given to this aggregation of families. Lindley (1833) was the first one to erect two taxa, Ranales and Anonales, to cover this group of plants. In *Genera Plantarum*, Bentham & Hooker (1862) followed de Candolle's treatment for this complex, except for addition of a lauralean family, the Calycanthaceae; they placed all these taxa together under Ranales. Situating these families at the beginning of the classification systems antedated formulation of the Euanthial Theory by Arber & Parkin (1907), which equated flowers of the Magnoliales to Bennettitalean strobili and provided a theoretical explanation for recognizing Magnoliidae as the primitive angiosperms. Eichler (1890) and Engler & Prantl (1891), despite advocating Amentiferae as the primitive angiosperms, also made a significant contribution to development of the ranalian concept by adding to the complex the major lauralean families, Hernandiaceae, Lauraceae, and Monimiaceae, and several other taxa such as Lactoridaceae and Trochodendraceae (also including *Cercidiphyllum* of Cercidiphyllaceae and *Eupteleа* of Eupteleaceae). In his 1915 paper, often regarded as the first truly phylogenetic classification, Bessey brought to the ranalian complex the piperalean families (Piperaceae, Saururaceae, and Chloranthaceae). By early this century, the Magnoliidae were conceptually mature and comprised five major lineages: Magnoliales, Laurales, Piperales, Nymphaeales, and Ranunculales/Papaverales.

Modern systematists (Takhtajan, 1987; Cronquist, 1988; Dahlgren, 1989; Thorne, 1992) have agreed upon the basal position of Magnoliidae in angiosperms and recognition of the five major lineages; nonetheless, their opinions differ widely on relationships among these lineages. Takhtajan (1987) divided the complex into two subclasses, placing monosulcate lineages in Magnoliidae and tricolpate lineages in Ranunculidae (but Illiciales and Nelumbonaceae were in the former). Dahlgren's (1989) treatment of the complex resembled that of Takhtajan (1987), but no higher categories were given to the two assemblages, Magnolianae/Nymphaeanae and Ranunculanae (cf. fig. 1 in Dahlgren, 1989). In the monosulcate assemblage, Dahlgren placed Piperales with Nymphaeales, rather than with Magnoliales and Laurales as in Takhtajan's (1987) scheme. A major difference between Cronquist's (1981, 1988) and Takhtajan's (1980, 1987) systems is that Cronquist did not recognize Ranunculales/Papaverales as a separate subclass. Thorne (1992) divided the complex into three superorders, Annonanae (including most monosulcate families plus Ranunculales/Papaverales), Nymphaeanae, and Rafflesianae (the latter two narrowly defined).

Relationships of several isolated families, Austrobaileyaceae, Ceratophyllaceae, Chloranthaceae, Illiciaceae/Schisandraceae, Lactoridaceae, and Nelumbonaceae, have been extensively debated. These taxa are either included in one of the major lineages of Magnoliidae or treated as independent minor groups, but their affinities are typically stated to be uncertain.

Recently, several cladistic studies of morphological, phytochemical, and molecular data have attempted to answer some of the questions concerning the phylogenetics of Magnoliidae (Dahlgren & Bremer, 1985; Donoghue & Doyle, 1989; Loconte & Stevenson, 1991; Martin & Dowd, 1991; Hamby & Zimmer, 1992; Taylor & Hickey, 1992). These efforts have met with only partial success due to: (i) widespread homoplasy in primitive angiosperms, (ii) problems of choosing appropriate ingroups and outgroups, (iii) difficulty of coding characters in morphological cladistic studies, or (iv) insufficient sampling (a major problem in the molecular investigations).

Protein-coding genes have been shown to reflect the genealogical history of organisms (Atchley & Fitch, 1991), though to what degree and at what taxonomic level this is true awaits further study. Evolutionarily conservative genes, such as *rbc*L, which codes for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), are considered suitable for study of relationships among taxa of higher rank (Ritland & Clegg, 1987; Zurawski & Clegg, 1987; Palmer et al., 1988). They provide new characters that permit an in-

dependent evaluation of phylogenetic relationships among plant groups uninfluenced by previous ideas of transformation of morphological characters and putative relationships among taxa. In the present study, we perform parsimony analyses of *rbc*L sequences from species representing almost all magnoliid families and endeavor to (1) evaluate the concepts of Magnoliidae, (2) identify major lineages in the subclass, investigate relationships within these major lineages, and assess affinities of several problematic taxa, (3) determine the relative phylogenetic positions of the major lineages within Magnoliidae, and (4) examine relationships of the Magnoliidae to monocots and eudicots.

## Material and Methods

Well aware of the pitfalls caused by inadequate sampling of sequence variation (Albert et al., 1993; Chase et al., 1993), we sampled at least one species from each family (this of course does not address adequately the putative monophyly of these families). Thus 64 species from 36 families representing all orders of the Magnoliidae were included (we follow the classification scheme of Cronquist, 1981, unless otherwise indicated). These taxa are listed in the Appendix at the end of this issue. Several sequences have been published previously (Golenberg et al., 1990; Les et al., 1991). Missing families are Circaeasteraceae, Gomortegaceae, Trimeniaceae, Hydnoraceae, and Rafflesiaceae (Takhtajan, 1987; Dahlgren, 1989; Thorne, 1992). It is likely that the last two, which are achlorophyllous, lack *rbc*L, as was found in other parasitic plants (dePamphilis & Palmer, 1990).

Total cellular DNA was extracted using the modified CTAB method (Doyle & Doyle, 1987) from 0.6–2.0 g fresh or silica gel-dried leaves (Chase & Hills, 1991) collected from a single plant (in the case of *Hernandia ovigera* L., the leaf was removed from a 22-year-old herbarium specimen). All DNAs were purified by CsCl-ethidium bromide gradient centrifugation. A fragment containing the gene *rbc*L was amplified using a thermo-stable DNA polymerase and two synthetic 26-mer primers based on the *rbc*L sequences from *Zea mays* L. and *Nicotiana tabacum* L. The amplified fragment was ligated into Bluescript vector and cloned with standard recombinant techniques. Sequencing was performed using Sequenase 2.0 (US Biochemical, Inc.) for dideoxynucleotide chain-termination reactions, and sequences were obtained from both strands. For several species, the gene was directly sequenced from the amplified fragment without cloning.

Sequence data were analyzed using PAUP 3.0s (Swofford, 1991). Several searches were conducted to approach problems at different scales and with different techniques.

**Search A.** All 65 magnoliid sequences were analyzed together with 434 other seed plant *rbc*L sequences (see Chase et al., 1993) to identify major lineages in the Magnoliidae, determine relative position of these lineages, and examine relationships of the subclass to monocots and eudicots. Two sequences of *Canella winterana* (L.) Gaertner, both with intact reading frames, were obtained from the DNA sample extracted from a single plant. They differ by 57 base pairs; 24, 15, and 18 of these differences occur at the first-, second-, and third-codon position, respectively. Both sequences were used in all analyses; one of them may be a "pseudogene." Due to the magnitude of the data set and the limitation of the software, the level of parsimony of this broad search was not certain (see Chase et al., 1993, for a more detailed explanation and discussion of the result of this larger analysis). This search helped us select a smaller number of taxa for a "manageable" analysis to examine internal support.

**Search B.** We performed another analysis with all monosulcate magnoliid sequences plus selected gymnosperms, monocots, and eudicots that served as place-holders for their respective groups identified in Search A. An analysis under the Fitch criterion (equal weights for all substitutions; Fitch, 1971) using 2,000 random sequence additions, STEEPEST DESCENT, MULPARS (but permitting only 10 trees to be held at each step), and NNI (nearest-neighbor interchange) found only one island of trees. All trees within this island were recovered by using the trees found in the random searches as starting points with MULPARS and TBR (tree bisection-reconnection) until swapping was completed.

**Search C.** To examine the effect of distant outgroups such as Gnetales on the ingroup network, we conducted an ingroup-only analysis of flowering plants. Again, this analysis was performed under the Fitch criterion using 2,000 random sequence additions in the same manner as described above. In addition to the same set of monosulcate magnoliids and monocots as were used in Search B, representative species of all families in the Ranunculales/Papaverales were included to investigate interfamilial relationships within this group. Two islands of equally parsimonious trees were found, and all of the trees in each of those islands were recovered by the same method as in Search B (swapping to completion with MULPARS and TBR).

To gain a measure of the robustness of the topology, decay of parsimony (Bremer, 1988) was examined. All maximum parsimony trees of both islands were used as starting trees to search for trees up to five steps less parsimonious; the FILTER TREES option was used to identify trees at each length, and a strict consensus tree was computed at each step. The number of steps less parsimonious at which a branch collapsed was recorded as the decay index. The larger the number, the more robust a branch. A decay index of 1 indicates that the branch is present in all maximum parsimony trees but collapses at maximum parsimony plus one step.

**Search D.** There has been great interest in recent cladistic studies to determine the basalmost lineage of angiosperms. The Nymphaeales are often claimed as a sister group to all other angiosperms (Donoghue & Doyle, 1989; Hamby & Zimmer, 1992), but our results did not place them in such a position. To evaluate the hypothesis of Nymphaeles being the basalmost angiosperms, we performed a topology constraint experiment using the same set of taxa as in Search B, but with the Nymphaeales constrained to be sister to all other angiosperms (using the CONSTRAINTS option of PAUP). The search was conducted under the Fitch criterion using 2,000 random sequence additions in the same manner as described in Search B. This is a more accurate means to determine the loss of parsimony associated with an alternate topology; merely constraining the topology based on the shortest trees found overall without performing branch swapping is likely to result in an inaccurate assessment of tree length because it does not permit character transformations to be optimized on different branches than in the unconstrained trees.

## Results

**Search A.** A strict consensus tree was computed from 3,900 equally parsimonious trees at a length of 16,305 steps (Chase et al., 1993). These trees have a consistency index (C.I.; for potentially synapomorphous characters) of 0.102 and a retention index (R.I.) of 0.638; a summary of this tree is shown in Figure 1 (for the detailed version of the strict consensus tree, see Chase et al., 1993). Exclusive of *Ceratophyllum*, which is sister to all other flowering plants, the angiosperms are split into two clades that correspond to the two general pollen types, monosulcate and tricolpate (for the sake of convenience, we refer to angiosperms with monosulcate and monosulcate-derived pollen types as the "monosulcates" and those with tricolpate and tricolpate-derived pollen types as the "eudicots," the latter in accord with Doyle & Hotton's, 1991, use of that term). Five major lineages are identified among the Magnoliidae; they are roughly equal to the Magnoliales, Laurales, Piperales (including Aristolochiaceae and Lactoridaceae), Nymphaeales (excluding Nelumbonaceae but including Amborellaceae, Austrobaileyaceae, Chloranthaceae, and Illiciales), and Ranunculales (excluding Coriariaceae, Sargentodoxaceae, and Sabiaceae but including Eupteleaceae, Fumariaceae, and Papaveraceae). (We will use these ordinal circumscriptions throughout the rest of this paper; i.e., under Piperales we will include Aristolochiaceae and Lactoridaceae, unless stated otherwise.) The four magnoliid lineages with monosulcate pollen types, (i) Magnoliales, (ii) Laurales, (iii) Piperales, and (iv) Nymphaeales, plus the monocots (with the same type of pollen), form a clade. The Illiciales, which have anomalous tricolpate pollen (see below), also fall into this monosulcate clade. The Piperales are sister to all other monosulcates; Magnoliales/Nymphaeales, Laurales, and monocots form an unresolved trichotomy in the strict consensus tree. The Ranunculales, Nelumbonaceae, and Sabiaceae, all of which have tricolpate pollen, together with other angiosperms possessing the same pollen type, form a monophyletic group. This large clade corresponds to Walker & Doyle's (1975) nonmagnoliid dicots or Doyle & Hotton's (1991) "eudicots." The Ranunculales are sister to the rest of the eudicots. In another basal lineage of eudicots are Nelumbonaceae and Sabiaceae (with Platanaceae and Proteaceae; hamamelid I, Fig. 1). The Coriariaceae and Sargentodoxaceae are not affiliated with the Magnoliidae, the former being sister to the clade of Cucurbitaceae/Begoniaceae/Datiscaceae and the latter imbedded in the Fabaceae (both in rosid I, Fig. 1; also see fig. 11B in Chase et al., 1993).

**Search B.** A single island of 46 trees at a length of 3,414 steps with C.I. of 0.275 (unique substitutions excluded) and R.I. of 0.566 was found. One of these maximum parsimony trees favored by the weighting criterion (Albert et al., 1993) is shown with Fitch branch lengths optimized on it (ACCTRAN optimization; Fig. 2). Even though far fewer taxa (82 species) were used in Search B, the same general topology as Search A was obtained.

**Search C.** Two islands of 89 and 3 trees respectively, at a length of 2,674 steps with C.I. of 0.346 (unique substitutions excluded) and R.I. of 0.531 were found. For illustration, one tree from each island was selected using the weighting criterion of Albert et al. (1993). The trees in the

Summary of the strict consensus tree of 3,900 equally parsimonious trees at a length of 16,305 for *rbc*L sequences from 499 species of seed plants using Fitch (1971) parsimony (branch lengths are from one of the trees). The ingroup network is arranged with the cycads sister to all other seed plants. The five major lineages of the Magnoliidae identified are underlined. Nelumbonaceae and Sabiaceae are in hamamelidae I; Coriariaceae and Sargentodoxaceae are in rosid I. For a detailed explanation of the composition of all clades in this figure, see Chase et al. (1993).

larger island (Fig. 3), though less resolved, are congruent in the general topology with the trees from Search B (Fig. 2). In contrast, the trees of the smaller island (Fig. 4) are different from those found in Search B; *Ceratophyllum* allies with *Canella* in the Magnoliales rather than being situated in an isolated position. These trees were arranged to agree with the results of two previous searches (i.e., with the eudicots sister to the monosulcates).

Many parts of this topology (Fig. 3) do not demonstrate strong internal support (decaying at two or fewer steps less parsimonious). At the level of the relationships among the major groups identified, all are weakly supported (even though the monophyly of some of the orders themselves are strongly supported; see below). The shift of *Ceratophyllum*, which is the only taxon with a different position in the two islands of trees, demonstrates its low level of internal support. It would appear that the use of distant outgroups such as Gnetales may be introducing homoplasy such that the smaller island does not exist at maximum parsimony in Search B (we cannot evaluate the degree of parsimony of the trees or the existence of other islands of equally parsimonious trees in Search A because of the size of the data set). Groups with moderate to strong support (decaying at three or more steps less parsimonious; Fig. 3) are eudicots, monocots, Laurales, "core" Magnoliales (excluding Canellaceae and Winteraceae), Nymphaeales (including the associated woody families, but excluding Chloranthaceae), Piperales, and Ranunculales.

**Search D.** A single island of 186 trees at a length of 3,425 steps with C.I. of 0.274 (unique substitutions excluded) and R.I. of 0.565 was found. One of the maximum parsimony trees chosen by the weighting criterion is shown in Figure 5. Compared with the trees from Search B (length of 3,414 steps; the same taxa are present in both), the trees recovered in this search are only slightly less parsimonious: 11 steps or only 0.32% longer.

Although relationships among the four monosulcate magnoliid lineages, monocots, and eudicots are resolved with only low levels of support, these clades are consistently identified, and relationships within the clades remain unchanged in the series of analyses (Figs. 1, 2, 3, 4). Even though the constraint experiment makes the group related to the Nymphaeales paraphyletic to all other angiosperms, it leaves them in near proximity to each other and otherwise identifies the same major lineages as in the previous searches. *Ceratophyllum* is the single taxon that shifts wildly with each treatment.

## Discussion

### 1. Phylogenetic evaluation of the Magnoliidae

From the review of historical development of the ranalian concept and the treatment of the complex in several modern classification systems presented in the introduction, it is clear that five major lineages, Magnoliales, Laurales, Piperales, Nymphaeales, and Ranunculales, were consistently recognized. In this study, we obtained clades that are roughly equal to these traditionally recognized lineages, and they occupy basal positions among angiosperms. Our analyses were conducted only under the criterion of parsimony, and we did not rely on any previous hypothesis concerning evolution of morphological characters or putative relationships among these taxa. The high degree of correspondence between the clades identified in this study and those traditionally recognized categories provides support for these lineages (even though support for several of these was weak in our study) and is an indication that *both* morphology and *rbc*L sequences are informative for phylogenetic reconstruction.

The split of the angiosperms, exclusive of *Ceratophyllum*, into a monosulcate and eudicot clade in our results was unexpected. Monophyly of the monosulcates has never been suggested, and at present we know of no unequivocal morphological or phytochemical characters to define the clade. Possession of monosulcate pollen is not a synapomorphy because this pollen type is also found in nonflowering seed plants. The ethereal oil cells could be a potential synapomorphy for the monosulcates; they occur in all component lineages (at least in some basal members) of this clade and absence of these cells in Amborellaceae/Nymphaeales and most monocots (basal monocots such as *Acorus* have the ethereal oil cells, Cronquist, 1981) can be interpreted as due to secondary loss. A close relationship between the Magnoliidae and the monocots has been proposed by Huber (1977), Hegnauer (1977), and Kubitzki & Gottlieb (1984),

but they relied on what are probably symplesiomorphic features. Currently available fossil evidence indicates that monosulcate angiosperms antedate eudicots (Doyle, 1969; Muller, 1970, 1981, 1984; Doyle & Hickey, 1976; Hickey & Doyle, 1977; Friis & Crepet, 1987; Hughes & McDougall, 1990; Doyle & Hotton, 1991), and it has been postulated that the latter were derived from the former (Walker & Walker, 1984). Crane & Lidgard (1990), after examining palynological diversity in the Cretaceous, suggested that the monosulcates probably represent an evolutionary grade rather than a clade. Three different scenarios may explain the discrepancy between our results and these previous hypotheses. First, the fossil evidence is most certainly incomplete, and future paleobotanical exploration may find older evidence for eudicots. Second, the weakly supported monosulcate clade is perhaps generated spuriously by high levels of sequence divergence among the monosulcates, eudicots, and gymnosperms (i.e., the monophyletic monosulcate clade is the result of "long branch attraction"; cf. Felsenstein, 1978). The third explanation postulates that two lines, both of which contained monosulcates, existed: one was paraphyletic to extant eudicots, and the monosulcate members of this line are now extinct; the other line included at the least all extant monosulcates. This third scenario implies the existence of yet unidentified lineages of monosulcates in the fossil record.

It has long been recognized by phylogenists that Magnoliidae sensu Cronquist are paraphyletic to monocots and eudicots. A cladistic study of basal angiosperms using morphological characters has corroborated this viewpoint (Donoghue & Doyle, 1989). Our study of *rbc*L sequences further demonstrates the paraphyly of the Magnoliidae. Takhtajan (1987) and Dahlgren (1989) removed the Ranunculales from the Magnoliidae and placed them in a higher category equal to the rest of the subclass. These plants lack several features used to define the Magnoliidae, e.g., spherical ethereal oil cells in the parenchymatous tissues and monosulcate pollen. In our analyses, the Ranunculales consistently fall into the strongly supported eudicot clade apart from the rest of the Magnoliidae sensu Cronquist.

The Nymphaeales are another member of the Magnoliidae that are often treated as an independent group of equal rank to the rest of the subclass (Thorne, 1992) or to all other monosulcate members of the subclass (i.e., excluding Ranunculales; Walker & Walker, 1984; Takhtajan, 1987). This study does not support such treatment. The Nymphaeales are only one of the major lineages in monosulcate Magnoliidae, and furthermore, several other taxa, Amborellaceae, Austrobaileyaceae, and Illiciales, share a close, unique phylogenetic relationship with them.

The enigmatic genus *Ceratophyllum* forms its own clade and is sister to all other angiosperms when outgroups to the angiosperms are included, but when only angiosperms are analyzed its highly divergent sequence is involved in two islands of equally parsimonious trees in which it occurs in radically different positions (Figs. 3, 4). The affinities of *Ceratophyllum* have been controversial, and most recent authors favored a relationship with *Cabomba* of the Cabombaceae (Cronquist, 1981; Takhtajan, 1980; Dahlgren, 1989). After a critical review of all the evidence, Les (1988) questioned this connection. The phylogenetic position of *Ceratophyllum* shown in this study largely corroborates Les's (1988; Les et al., 1991) proposition that the genus represents a vestige of the ancient angiosperms that diverged early from the line leading to most other modern taxa. From Aptian sediments in Victoria, Australia, and Albian and Cenomanian sediments in Kansas, North America, Dilcher (1989) reported fossil fruits similar to those of extant *Ceratophyllum* species; fossil leaves resembling those of modern *Ceratophyllum* were also found associated with the fruits. Possession of a suite of distinctive characters (partially sealed carpels, unitegmic ovules, branching pollen tubes, and lack of exine, vessels, and perianth) makes the genus anomalous among angiosperms.

No evidence, however, can be considered to give strong support for any of the placements of *Ceratophyllum* in our *rbc*L trees. The inclusion of distantly related outgroups (in particular, the highly divergent Gnetales) may be responsible for the placement of *Ceratophyllum* as sister to the rest of the angiosperms by introducing spurious synapomorphies. Nevertheless, in the search with nonflowering seed plants removed (Search C), *Cera-*

FIGURE 5. One of the 186 maximum-parsimony (Fitch) trees found in a constraint experiment in which the Nymphaeales were specified as the sister of all other angiosperms. These trees are only 11 steps less parsimonious than the most parsimonious, unconstrained trees found with the same data matrix. The branch lengths are Fitch optimizations (ACCTRAN).

*tophyllum* remains as an outlier to the monosulcates and eudicots in the trees of one island (Fig. 3). In the trees from the other island, the genus is allied with *Canella* in the Magnoliales (Fig. 4), which seems unsatisfactory, both from the perspective of the long branches of *Ceratophyllum* and *Canella* and lack of corroboration from other evidence. In the topology constraint experiment (Search D), *Ceratophyllum* again ends up in another position that is potentially spurious (Fig. 5). Our overall conclusion is that the *rbc*L analyses do not definitively resolve the phylogenetic relationships of *Ceratophyllum*, but they do suggest, in agreement with Les's hypothesis (1988, 1991), that it is distantly related to all other extant angiosperms and may represent an ancient and highly modified taxon allied to the oldest angiosperms, which is consistent with its long fossil history.

### 2. PHYLOGENETICS OF THE MAGNOLIALES, LAURALES, PIPERALES, NYMPHAEALES, AND RANUNCULALES

The isolated position of Winteraceae has been recognized for some time (Bailey & Nast, 1943; Ehrendorfer et al., 1968; Thorne, 1968; Walker, 1976a; Takhtajan, 1980), and the family is placed independently in several classification systems (Walker & Walker, 1984; Takhtajan, 1987; Dahlgren, 1989; Thorne, 1992). A morphological cladistic study showed that Winteraceae fall outside of the "core" Magnoliales (Donoghue & Doyle, 1989). The family has several features that are not compatible with other members of Magnoliales, e.g., vesselless wood, poorly organized leaf venation, and ulcerate pollen shed in permanent tetrads. The Canellaceae are another family not securely placed in the Magnoliales (Donoghue & Doyle, 1989). A relationship between these two families emerges from this study as well as previous work. Leroy (1977) suggested that Winteraceae are allied to Canellaceae via the anomalous Madagascan genus *Takhtajania*; both have a compound unilocular ovary, a type of gynoecium rare in the Magnoliales. The two families (plus the Illiciales) were found to be associated in some of the equally most parsimonious trees in Donoghue & Doyle's (1989) study. Gottlieb et al. (1989) found that among members of Magnolianae and Piperales sensu Dahlgren, Winteraceae and Canellaceae share sesquiterpenoids of the drimane and rearranged drimane type, and at least two representatives of the drimane type occur only in these two families. A recent study of 26S rDNA also showed that these two families are related (Suh et al., 1992).

The other families of the Magnoliales, Annonaceae, Degeneriaceae, Eupomatiaceae, Himantandraceae, Magnoliaceae, and Myristicaceae, are often recognized as "core" Magnoliales (Thorne, 1976; Walker, 1976a). Donoghue & Doyle's (1989) morphological cladistic study also identified this group. Our study of *rbc*L sequences offers moderate support for this group (Fig. 3). The Myristicaceae, traditionally regarded as an advanced member of Magnoliales (Walker, 1976b; Walker & Walker, 1984), occupy a weakly supported basal position in this clade (Fig. 3).

The anomalous magnoliaceous genus *Liriodendron* stands in an isolated position from the rest of the family, and its inclusion in the Magnoliaceae has been questioned by Barkley (1975). The relationship of *Liriodendron* to other magnoliaceous members is well supported in this study (Fig. 3). A reliable morphological character supporting monophyly of Magnoliaceae is their gynoecium, spirally arranged follicles on an elongate receptacle, which elsewhere is only found in Ranunculaceae. The mid-Cretaceous (Cenomanian) angiospermous fructification *Archaeanthus* provides evidence for a long history of this type of fruit (Dilcher & Crane, 1984). Another character defining the Magnoliaceae is their large stipules that enfold terminal buds. The rest of the Magnoliaceae are so homogenous that their taxonomy is notoriously difficult (Dandy, 1964; Law, 1984; Nooteboom, 1985), and *rbc*L sequences show little divergence among the genera (Qiu, Chase & Parks, unpublished).

In Laurales, *Hernandia* and *Gyrocarpus* have been placed in two unrelated families, Hernandiaceae and Gyrocarpaceae, by some (Walker & Walker, 1984; Takhtajan, 1987). Our study shows that the relationship between these two genera is strong even though their *rbc*L sequences are divergent (Fig. 3). Dahlgren's (1983, 1989) inclusion of these two genera in the Lauraceae is not supported by this study.

The Calycanthaceae and Idiospermaceae form a strongly supported clade, though resolution of their relationships to other lauralean families is poor. Interfamilial relationships within the Laurales are not well resolved (Fig. 3). Lack of several important taxa, such as *Trimenia*, *Gomortega*, *Atherosperma*, and other monimiaceous genera, may be a problem. Inclusion of these taxa in future studies should help to improve the resolution.

The relationship between Aristolochiaceae and Piperaceae/Saururaceae has not been consistently recognized. Takhtajan (1987) and Cronquist (1988) placed the two groups together, whereas Dahlgren (1989) and Thorne (1992) allied the Aristolochi-

aceae with the "core" Magnoliales rather than with the Piperales. Results from our study clearly favor association of the two groups.

The affinity of Lactoridaceae is an extensively debated issue. In the past, this family has been placed in the Magnoliales (Cronquist, 1981), Laurales (Takhtajan, 1980), Piperales (Walker & Walker, 1984; Thorne, 1992), or in its own order Lactoridales between the Magnoliales and Winterales (Dahlgren, 1989). A study of the family with numerical approaches suggested a magnolialean affinity (Lammers et al., 1986), but the proposition has been criticized by Carlquist (1990) on the basis of wood anatomy. Recent cladistic investigations using morphological data indicated a relationship to the Piperales (Dahlgren & Bremer, 1985; Donoghue & Doyle, 1989). A detailed comparative study of wood anatomy revealed that the Chloranthaceae, Piperaceae, and Lactoridaceae are similar in wood anatomy (Carlquist, 1990). In our analyses, support for a relationship of *Lactoris* to *Aristolochia* is weak, but alliance of the genus within Piperales is moderately supported (Fig. 3). *Aristolochia* has a rather divergent sequence, and more sampling in future studies may help to characterize better the affinities of the genus and *Lactoris*.

The Nymphaeales are distinct among primitive angiosperms in that they occupy a peculiar ecological niche and exhibit many characteristics of aquatic adaptation. How they are related to the rest of the Magnoliidae has been a long-standing issue in the phylogenetics of primitive angiosperms. In this study, we found the Nymphaeales are allied with several isolated taxa, Amborellaceae, Austrobaileyaceae, and Illiciales, whose relationships have also been widely debated. This topology is rather novel, but it is not drastically different from some previous ideas. Takhtajan (1980) and Cronquist (1981) suggested the Nymphaeales are derivatives of a woody ancestor with magnolialean features. The Austrobaileyaceae and Illiciales share many floral features with the Magnoliales and have been treated as members of that order in the past. The Amborellaceae are generally regarded as a basal member of the Laurales and have been placed near the Magnoliales (Cronquist, 1981). Hence, it is not unreasonable that these taxa form a group paraphyletic to Nymphaeales.

The Amborellaceae are a poorly studied monotypic family endemic to New Caledonia and have always been treated as a member of the Laurales. Bailey & Swamy (1948), however, found that the only species of the family, *Amborella trichopoda* Baill., lacks vessels and then questioned its placement in the Monimiaceae. Whether the angiosperms are primitively vesselless is an unresolved issue (Young, 1981; Donoghue & Doyle, 1989; Carlquist, 1992). It is possible that the Nymphaeales are secondarily vesselless (Cronquist, 1981). If vessellessness in primitive angiosperms is indeed due to secondary loss, this character may be of significant phylogenetic value in associating *Amborella* with the Nymphaeales. Another line of evidence supporting the relationship between *Amborella* and Nymphaeales is their lack of ethereal oil cells in parenchymatous tissues (Money et al., 1950; Cronquist, 1981). The ethereal oil cells are a characteristic feature of monosulcate Magnoliidae, and are otherwise found in all members. Finally, both Amborellaceae and Nymphaeales have granular pollen that has no or reduced endexine in the nonaperture regions of the exine, features that elsewhere are found only in the "core" Magnoliales, Trimeniaceae and some Chloranthaceae (Walker, 1976b). Although these "negative" characters need to be investigated further, they support a relationship between Nymphaeales and Amborellaceae.

The Illiciales stand as the only exception of a tricolpate pollen-bearing taxon among the monosulcate angiosperms. Previously, Walker & Doyle (1975) have highlighted their problematic aperture type. Huynh (1976, cited in Doyle & Hotton, 1991) revealed that the tricolpate condition in Illiciales is of a different type from that of eudicots; the three colpi are oriented according to Garside's rule, not Fischer's rule as in the latter. This implies that the tricolpate condition evolved independently in these two lineages. Our results support such interpretation. Leaf architecture (Hickey & Wolfe, 1975) and morphological cladistics (Donoghue & Doyle, 1989) also favor this hypothesis, though neither of these studies associates Illiciales with the particular group of monosulcate magnoliids as identified in this study. A relationship between Illiciales and Winteraceae has been proposed by some workers (Walker, 1976a; Donoghue & Doyle, 1989; Doyle et al., 1990) who relied partly on palynological evidence, yet such a relationship was not observed in investigations of chromosome number, leaf epidermis, and secondary compounds (Ehrendorfer, 1968; Baranova, 1972; Gottlieb et al., 1989). The one pollen character, coarsely reticulate and semitectate exine, that unites the two groups in Donoghue & Doyle's (1989) cladistic study has not been observed in *Walkeripollis*, the Early Cretaceous fossil pollen of putative winteraceous affinity (Doyle & Hotton, 1991).

The Austrobaileyaceae are yet another poorly studied family. They have been allied to Monimi-

aceae in Laurales (Bailey & Swamy, 1949) or Annonaceae of Magnoliales (Endress, 1980, 1983; Endress & Honegger, 1980). As noted by Cronquist (1981), the family has a combination of characters that make its placement in either order difficult: unilacunar nodes, opposite leaves, climbing habit, laminar stamens, hypogynous flowers, monosulcate pollen, and pluriovulate carpels. The relationship between Austrobaileyaceae and Illiciales identified in this study is supported by their similar sieve-element plastids (Behnke, 1988).

Given the extensive fossil record of Chloranthaceae (Couper, 1958; Kuprianova, 1967; Hughes et al., 1979; Muller, 1981; Upchurch, 1984; Walker & Walker, 1984; Friis et al., 1986; Chlonova & Surova, 1988), it may be safe to suggest that the family was more diverse in the past. A recent report of chloranthaceous fruits with anatropous ovules, instead of orthotropous ovules as in extant species, from Cenomanian sediments in eastern North America corroborates such a hypothesis (Pedersen et al., 1991). The modern family stands in a rather isolated position and has been placed in the Laurales (Thorne, 1992), Piperales (Cronquist, 1988), in its own order Chloranthales between Lactoridales and Piperales (Takhtajan, 1987), or between Winterales and Illiciales (Dahlgren, 1989). In this study, we found the Chloranthaceae are allied with Austrobaileyaceae, Illiciales, Amborellaceae, and Nymphaeales, but this position is weakly supported (Fig. 3). It has been suggested the Amborellaceae are related to the Chloranthaceae on the basis of floral morphology and anatomy (Endress, 1986a, 1987). Behnke (1988) also found Chloranthaceae share similar sieve-element plastids with Austrobaileyaceae and Illiciales.

Assignment of Ranunculales and other ranalian taxa such as Eupteleaceae, Nelumbonaceae, and Trochodendrales (Trochodendraceae and Tetracentracaeae) into two subclasses, the Magnoliidae (or Ranunculidae) and Hamamelidae by Takhtajan (1987) and Cronquist (1988) may have led to a belief that these taxa are distantly related. In our analyses, they form, together with several other taxa (Buxaceae, Gunneraceae, Platanaceae, Proteaceae, and Sabiaceae), a paraphyletic group at the base of the eudicots. In comparing vegetative and reproductive morphology, Nast & Bailey (1946) dissociated *Euptelea* from *Trochodendron* and *Tetracentron*, to which they have been frequently allied (Endress, 1986b). Examinations of pollen morphology and leaf architecture corroborated the isolated position of *Euptelea* (Praglowski, 1974; Wolfe, 1989). Nast & Bailey (1946) pointed out that the genus is of general ranalian affinity because it possesses several features of "the syndrome of primitive characters," such as apocarpous gynoecium, incompletely sealed carpels, and numerous stamens originating in centripetal sequence. They suggested that *Euptelea* is obviously not related to the ranalian families with monosulcate pollen and ethereal oil cells, but rather to those with tricolpate pollen and no ethereal oil cells (i.e., Ranunculaceae, Berberidaceae, Lardizabalaceae, Menispermaceae, and Trochodendraceae).

The Sabiaceae were tentatively placed in the Ranunculales by Cronquist (1981). This study shows that the family is not a member of the order, but occupies a basal position in the eudicots.

The exact relationships of Nelumbonaceae have not been certain, although their affinity to the Magnoliidae is generally recognized. Tricolpate pollen, roots with vessels, and production of benzyl-isoquinoline and aporphine alkaloids are among the characters that warrant removal of this family from Nymphaeales. Serological and cytological evidence shows the family does not belong to the Nymphaeales (Simon, 1971; Raven, 1975). These characters plus absence of ethereal oil cells suggest a relationship to basal eudicots rather than the monosulcate magnoliids. Both Donoghue & Doyle's (1989) morphological cladistic study and phytochemical evidence (Gottlieb et al., 1989) support such a position.

## 3. THE BASALMOST LINEAGE OF ANGIOSPERMS

Although the Ranalian Hypothesis that Magnoliidae represent the primitive angiosperms has been generally accepted, which lineage in the subclass is the most primitive remains an extensively debated issue (Friis et al., 1987). Woody Magnoliales with large strobiloid flowers and herbaceous Piperales with diminutive and simple flowers both have their proponents. Reports of chloranthoid and other non-magnolialean reproductive and vegetative structures in the Early and Middle Cretaceous (Couper, 1958; Dilcher, 1979; Krassilov et al., 1983; Upchurch, 1984; Walker & Walker, 1984; Friis et al., 1986; Crane et al., 1986; Crane, 1989; Taylor & Hickey, 1990; Pedersen et al., 1991) challenge the status of Magnoliales as the most primitive angiosperms. Cladistic studies finding that Gnetales and Bennettitales are equally closely related to angiosperms (Crane, 1985; Doyle & Donoghue, 1986) add further controversy to the debate.

Paleobotany has played an instrumental role in

elucidating the early evolution of angiosperms. A large body of fossil evidence of early angiosperms has been gathered in the last several decades, documenting presence of several major lineages of primitive angiosperms in the Early and Middle Cretaceous: Magnoliales, Laurales, Piperales, Nymphaeales, Ranunculales, and "lower" Hamamelidae (Couper, 1958; Doyle, 1969; Muller, 1970, 1981, 1984; Doyle & Hickey, 1976; Doyle et al., 1977, 1990; Hickey & Doyle, 1977; Dilcher, 1979; Hughes et al., 1979; Krassilov et al., 1983; Walker et al., 1983; Dilcher & Crane, 1984; Upchurch, 1984; Walker & Walker, 1984; Crane et al., 1986; Friis et al., 1986; Ward et al., 1989; Drinnan et al., 1990, 1991; Hughes & McDougall, 1990; Taylor & Hickey, 1990; Herendeen, 1991; Pedersen et al., 1991). These studies have greatly expanded our knowledge of early angiosperm evolution but have not answered the question of the origin of angiosperms. Further exploration of sediments of the preceding Early Cretaceous and Late Jurassic ages will be necessary before firm conclusions regarding the origin of the angiosperms are reached (Hughes & McDougall, 1987, 1990).

In a cladistic study of mostly morphological data, Donoghue & Doyle (1989) identified the Magnoliales as the basalmost lineage among angiosperms. However, they found that Nymphaeales are basal in trees only slightly less parsimonious (1 step longer or 0.56% less parsimonious; the length of their shortest trees was 178 steps). Our constraint experiment (Fig. 5) demonstrated a similar small loss of parsimony for this alternate hypothesis (0.32% less parsimonious; see Results). Hamby & Zimmer (1992) reported that Nymphaeales and Piperales are paraphyletic to other angiosperms in their investigation using ribosomal RNA sequences, but many important taxa were absent from their study. Martin & Dowd (1991) found Illiciales to be sister to all other angiosperms in their study of *rbc*S amino acid sequences. In our analyses, we found only weak support for relationships at the base of angiosperms (Fig. 3). Thus, the *rbc*L results, in spite of being resolved in favor of *Ceratophyllum* if outgroups were included, do not strongly support or refute any hypothesis of which group of Magnoliidae is sister to all other angiosperms.

## 4. RELATIONSHIPS OF THE MAGNOLIIDAE TO MONOCOTS AND EUDICOTS

The relationship between Magnoliidae and monocots has been discussed extensively (Dahlgren & Clifford, 1982; Dahlgren et al., 1985). It is widely believed that the two groups are closely related. Hegnauer (1977) reported that the Magnoliidae (including Ranunculales) and monocots exclusively use the tyrosine-pathway for synthesizing cyanogenic compounds, whereas other dicots exploit phenylalanine for the same purpose. In studying the distribution and biosynthesis of shikimate-derived compounds, Kubitzki & Gottlieb (1984) found that angiosperms are essentially composed of two groups, the "magnolialean block" (magnoliids, monocots, and caryophyllids) and the "rosiflorean block" (the rest of the dicots). Previously, different pairs of the magnoliids and monocots have been proposed to account for the origin of the monocots: Ranunculales/Piperales vs. Alismatales (Bessey, 1915), Nymphaeales vs. Alismatales (Takhtajan, 1969; Cronquist, 1968), Piperales vs. Arales (Burger, 1977), and Annonales vs. Dioscoreales (Dahlgren et al., 1985). Considering the heterogeneity of the Magnoliidae and a great number of similarities between the subclass and monocots (Dahlgren & Clifford, 1982; Dahlgren & Bremer, 1985), it is not surprising to see such diverse opinions about their relationship. Most, if not all, of these similarities are based on character states that are potentially symplesiomorphic or due to parallel evolution.

Although resolution of relationships at the base of angiosperms is weak in our study, several groups may be removed from the list of possible close allies to the monocots. The Ranunculales are a member of a well-supported eudicot clade and do not show any relationship to the monocots. The Nymphaeales alone are unlikely to be sister to the monocots because they show a strongly supported relationship to Amborellaceae, Austrobaileyaceae, and Illiciales. Any other major lineage of the Magnoliidae could be placed as a sister group to the monocots with only an insignificant loss of parsimony.

Monophyly and origin(s) of the eudicots have been subject to a remarkable diversity of opinions. Interpretation of traditional phylogenetic diagrams such as those of Takhtajan (1959, 1969, 1980, 1987) would lead to a conclusion that eudicots are polyphyletic and composed of several lineages independently derived from various monosulcate angiosperms with magnoliid features. Under the assumption that eudicots are derived from the monosulcates, Walker & Walker (1984) suggested that the monosulcate magnoliid families Winteraceae, Illiciaceae, Schisandraceae, and Aristolochiaceae have ties with the subclasses Ranunculidae and Caryophyllidae and that the Lactoridaceae,

Piperaceae, Saururaceae, and especially Chloranthaceae are linked to the Hamamelidae and through it to remaining dicots. In a cladistic investigation of basal angiosperms using morphological characters, Donoghue & Doyle (1989) concluded that Ranunculidae, Nelumbonaceae, and paleoherbs (including Lactoridaceae, Aristolochiaceae, Piperaceae, Saururaceae, Nymphaeaceae, Cabombaceae, and monocots) are more closely related to the Hamamelidae and other "higher" dicots than the Magnoliales and Chloranthaceae. Furthermore, they found that in some of their most parsimonious trees ranunculids and hamamelids form a monophyletic group sister to the paleoherbs, whereas in others the ranunculids are dissociated from the hamamelids and united with the paleoherbs. Doyle & Hotton (1991) reported that the oldest tricolpate pollen from the late Barremian–early Aptian of Gabon exhibits two features of typical paleoherb pollen: the sculpture consists of intermixed large and small lumina (heterobrochate) and varies from coarser at the equator to finer at the poles (graded).

The monophyly of eudicots (dicots with tricolpate and derived pollen types, including Nelumbonaceae and Takhtajan's Ranunculidae but excluding Illiciales) is strongly supported by this study. Fossil evidence from the Potomac group in eastern North America shows that all tricolpate pollen and derived types can be traced back to a morphologically generalized complex of tectate-reticulate tricolpate pollen, thus corroborating the hypothesis of single origin of the eudicots (Wolfe et al., 1975). This type of tectate-reticulate tricolpate pollen is found in the extant Rananculales, Platanaceae, and Trochodendrales (Muller, 1984), which is consistent with placement of these taxa at the base of eudicots in the *rbc*L trees (Figs. 1–4; also see Chase et al., 1993).

Many basal eudicots are wind-pollinated, for example, Buxaceae, Eupteleaceae, Menispermaceae, Platanaceae, Tetracentraceae, and possibly Gunneraceae and Trochodendraceae (Crane et al., 1991). Environmental factors such as the increasing aridity in a period immediately after the Barremian (Doyle et al., 1977; Hickey & Doyle, 1977), when tricolpate pollen first appeared (Hughes & McDougall, 1990; Doyle & Hotton, 1991), might have played a critical role in the rise of eudicots (Walker & Walker, 1984). The preponderance of wind-pollination in basal eudicots suggests that the group could be primitively wind-pollinated. Further investigation of other wind-pollinated members of the Ranunculales and "lower" Hamamelidae is needed before we have adequate information to address this question.

## Conclusions

This study of nucleotide sequences of the plastid protein-coding gene *rbc*L has identified the same major lineages as have many classification systems and previous cladistic studies of the Magnoliidae: (i) Magnoliales, (ii) Laurales, (iii) Piperales, (iv) Nymphaeales, and (v) Ranunculales. The exact familial composition of some of these clades is significantly different from any previous hypothesis. The most conspicuous difference is that Amborellaceae, Austrobaileyaceae, and Illiciales are strongly supported as members of the Nymphaeales clade. The relationship of these anomalous woody taxa to the Nymphaeales has only weak corroboration of shared absent features. Another novel feature of our results is that angiosperms fall into two monophyletic groups corresponding to the general pollen types of monosulcate and tricolpate, and they show a sister-group relationship. Our finding of the monophyletic eudicots lends strong support to pollen characters as major synapomorphies for these angiosperms. In contrast, we cannot identify any nonmolecular character to define the weakly supported monosulcate clade. Resolution of relationships at the base of angiosperms is low. The position of Ceratophyllaceae as a sister group to all other angiosperms is likewise controversial, but it is supported, though not unequivocally, by the fossil evidence and the distinctive morphology of these aquatic plants.

We conclude that our molecular survey of putatively basal angiosperms gains great support from the congruence of the groups identified in this study with those recognized in classification systems and recent cladistic analyses of nonmolecular data. Our analyses of the *rbc*L sequence data were conducted merely under the criterion of parsimony, and did not rely on any previous hypothesis of evolution of morphological characters or relationships among basal angiosperms. We take this to be an indication that the molecular character systems contain historically relevant information. The general relationships among basal angiosperms, as well as composition of certain clades (e.g., Nymphaeales) identified in our *rbc*L trees, are novel and intriguing, and we suggest that they be considered as alternatives to the traditional ideas about the phylogeny of the early angiosperms. Ironically, this molecular investigation adds more controversy instead of providing solutions to the questions surrounding early angiosperm evolution. A complete understanding of the origin of angiosperms certainly requires multidisciplinary studies of both fossil and extant plants with morphological and molecular approaches.

# PHYLOGENETIC HYPOTHESES FOR THE MONOCOTYLEDONS CONSTRUCTED FROM *rbc*L SEQUENCE DATA[1]

*Melvin R. Duvall,[2] Michael T. Clegg,[2] Mark W. Chase,[3,4] W. Dennis Clark,[5] W. John Kress,[6] Harold G. Hills,[3] Luis E. Eguiarte,[7] James F. Smith,[8,9] Brandon S. Gaut,[2] Elizabeth A. Zimmer,[8] and Gerald H. Learn, Jr.[2]*

## Abstract

DNA sequences for the plastid locus that encodes the large subunit of ribulose 1,5-bisphosphate carboxylase oxygenase (*rbc*L) were determined for 18 species of monocotyledons in 15 families. These data were analyzed together with sequences for 60 other monocot species in a total of 52 families by the maximum likelihood method producing one, presumably optimal, topology. An additional 26 species were added (104 total monocot species) and analyzed by the parsimony method with an outgroup of 18 dicot species producing 109 trees of 3,932 steps. The *rbc*L data show at least moderate support for seven lineages corresponding to the following orders, superorders, or combinations: Arecanae; Asparagales (excluding Hypoxidaceae) plus Iridaceae; Cyclanthanae plus Pandananae; Dioscoreales; Orchidales; Typhales; and Zingiberanae. Six clades corresponding to families or genera are well supported, including: Agavaceae, Asphodelaceae, Bromeliaceae, Hypoxidaceae, Poaceae, and *Tradescantia*. The two, earliest diverging multispecies clades in our *rbc*L phylogenies, Alismatanae and Aranae, are only weakly supported, and Bromelianae, Commelinanae, and Lilianae are paraphyletic. In all analyses *Acorus calamus* is phylogenetically isolated as the sister species to the remaining species of monocotyledons.

Innovations for the manipulation of nucleic acids and advances in computer technology now permit phylogenetic analysis of homologous sequences of DNA from large numbers of organisms. These base-to-base comparisons of nucleotides afford the highest possible resolution of inherited mutations in DNA molecules and can be applied to questions of higher-order plant systematics. A locus that has been selected for such studies by molecular systematists is the plastid gene that encodes the large subunit of ribulose 1,5-bisphosphate carboxylase/oxygenase (*rbc*L). Phylogenetic reconstructions for lineages of monocotyledons based on *rbc*L sequence data have been attempted previously for: (1) Arecaceae (Wilson et al., 1990); (2) Bromeliaceae (Clark et al., in prep.); (3) Poaceae (Doebley et al., 1990); and (4) Zingiberales (Smith et al., 1993). These initial attempts met with a disappointing lack of resolution, in some cases because of the low substitution rate of *rbc*L, but strongly suggested that these data would have greater phylogenetic utility when applied to more divergent lineages. Our goal here was to reconstruct higher-order phylogenetic relationships among the mono-

For computer analyses we thank G. J. Olsen (University of Illinois, Urbana), R. Overbeek (Mathematics and Computer Science, Argonne National Laboratory, Argonne, Illlinois), the Concurrent Supercomputing Consortium, R. Whitkus, P. Lowe (both, University of California, Riverside) and M. Berres (University of Minnesota, St. Paul). We also thank D. Jarrell (University of California, Riverside), R. Olmstead (University of Colorado, Boulder), and others for unpublished *rbc*L sequences; J. French (Rutgers University, Piscataway, New Jersey) who provided DNA extracts for Araceae; and W. Armstrong (Palomar College, San Marcos, California) for identification of one species. This work was supported by grants from National Science Foundation to M. Duvall (BSR-9002321), M. Chase (BSR-8906496), and W. D. Clark (BSR-8904637); National Institutes of Health (GM45144) to M. Clegg; Scholarly Studies Program, Smithsonian Institution to W. J. Kress and E. Zimmer; and American Orchid Society to M. W. Chase.

cotyledons using DNA sequence data from the *rbc*L locus for a set of species that represented the breadth of taxonomic diversity in the group.

## Materials and Methods

DNA sequences of *rbc*L from 104 species in 52 of 104 monocot families were analyzed (see Appendix in this issue for species, locations of vouchers, sequencing methods, extent of sequences, and authors). Eighteen of those sequences (Table 1) were produced specifically for this study by the following methods. Total DNA was extracted from fresh leaf tissue by the method of Doyle & Doyle (1987) for 16 species, the method of Palmer (1986) for *Cyperus alternifolius*, and the method of Jarrell et al. (1992) for *Lemna minuscula*. Approximately 1 μg of each DNA preparation was used to provide template for *Taq*-mediated amplification of the *rbc*L gene using the protocol provided with *Taq* DNA polymerase by the supplier (Promega Corp.). The primers for the reaction were two highly conserved sequences from the *rbc*L coding region of *Spinacia oleracea*. The 5′ primer consisted of the first 30 base pairs of that sequence and the 3′ (reverse) primer corresponded to positions 1351 to 1380 on the complementary strand. Amplifications utilizing these primers produced 1,320 base pairs of the coding sequence of *rbc*L. Primers that are external to the coding sequence occasionally resulted in successful amplifications of more of the *rbc*L coding sequence. For *Sparganium americanum*, a 27 base pair sequence at the promoter region for *rbc*L derived from positions 53742–53768 in the plastid genome of *Oryza sativa* was used as the 5′ primer. For *Gymnostachys anceps*, *Tradescantia* aff. *pallida*, and *Typha latifolia*, a 24 base pair sequence at a ribosome control site downstream of the coding sequence derived from positions 59146–59123 (complement) in the plastid genome of *Nicotiana tabacum* was used as the 3′ primer. Up to 1,428 base pairs of *rbc*L were produced, depending on the primers that were used in the amplification reactions. For the *rbc*L sequences from the monocotyledons analyzed here, 5.7% of the sequence data was missing largely because of the use of internal primers in the amplification reactions.

Single-stranded DNA was produced in a second round of amplification using the double-stranded product as template and the two primers individually. These single-stranded products were precipitated (7.5% polyethylene glycol-8000, 0.94 M NaCl), the DNA pellets were washed twice with ethanol, and sequencing was accomplished by the dideoxynucleotide chain-termination method using a set of conserved, synthetic, internal *rbc*L primers (obtained from G. Zurawski, DNAX Corp.). Both the *rbc*L coding strand and the complementary strand were sequenced for all species. The 18 *rbc*L sequences produced for this study were entered into "GenBank" under the accession numbers listed in Table 1.

The maximum likelihood method of phylogenetic analysis was selected for use here because it is less biased by the heterogeneous nucleotide substitution rates that have been observed for *rbc*L among different lineages of monocotyledons (Gaut et al., 1992) than are other methods (Felsenstein, 1981). Furthermore, under this method, likelihood scores may be calculated for alternate topologies and subjected to comparative tests of statistical significance. However, only a subset of the entire *rbc*L database could be analyzed since the method is computer-intensive. [To establish an estimate of the computer burden, a maximum likelihood analysis of 79 *rbc*L sequences using the program, DNAML in PHYLIP 3.42 (Felsenstein, 1991), was executed on a CRAY "Y-MP8/864" supercomputer. The analysis spanned 11 days with a run time of about 51 CPU hr. At this speed, ten executions of the program with different input orders (typically recommended) of the 79 *rbc*L sequences would have required over three months of real time utilizing more than 20 CPU *days* on this machine.] Consequently, 78 of the original 104 monocot species were selected for maximum likelihood analysis with *Saururus cernuus* as the outgroup (79 species total). Each of the following taxa, Agavaceae, Arecaceae, Bromeliaceae, Nolinaceae, Poaceae, and Zingiberales, invariably constituted a monophyletic lineage in preliminary phylogenetic analyses that included multiple species in each. The subset was thus selected to contain representatives from each of the 52 families while excluding some of the multiple species in these six taxa, preserving the potential for investigating higher order relationships. The species that were retained in the subset are: Agavaceae—*Manfreda maculosa* and *Yucca recurvifolia*; Arecaceae—*Caryota mitis*, *Phoenix reclinata*, and *Serenoa repens*; Bromeliaceae—*Aechmea chantinii* and *Tillandsia elizabethae*; Nolinaceae—*Nolina* (*Beaucarnea*) *recurvata*; Poaceae—*Oryza sativa* and *Zea mays*; and Zingiberales—*Calathea loeseneri*, *Costus barbatus*, *Globba curtisii*, *Hedychium gardnerianum*, *Heliconia latispatha*, *Maranta leuconeura*, *Musa cavendishii*, *Orchidantha fimbriata*, *Phenakospermum guyannense*, *Ravenala madagascariensis*, and *Tapeinocheilos ananassae*.

TABLE 1. Eighteen species for which *rbc*L was sequenced for this study. Vouchers (herbaria), accession numbers for the *rbc*L sequences submitted to GenBank, superordinal, ordinal, and familial alignments are given. Identities for the remaining 104 species that were analyzed may be found in the Appendix for this issue.

The analysis was executed on the fastest existing computer, the Touchstone Delta Parallel Processing Supercomputer, using "fastDNAml version 1.0.3" (Olsen et al., 1992). Thirty-three replications of the analysis were performed with different randomly determined orders of input. The "categories option," which permits specification of different substitution rates by codon position, was invoked using relative rates of 1.00, 0.85, and 5.80 for first, second, and third codon positions, respectively. These values are based on reported substitution rates at each codon position (Clegg et al., 1986; Ritland & Clegg, 1987). Regional and local branch swapping were employed. This portion of the analysis, which included data from 74 of the 79 species, consumed 125 hours of computer time.

After the initial analysis was performed, the remaining five species (*Aletris farinosa*, *Burmannia biflora*, *Sparganium americanum*, *Stegolepis allenii*, and *Typha latifolia*; total species: 79) with equivocal phylogenetic positions in preliminary analyses were added to the optimal topology from the previous step with 50 (of 120 possible) random

TABLE 2. Distribution of polymorphic sites, constant sites, and sites shared by two or more species (i.e., informative sites), among codon positions of *rbc*L. Sites are calculated for 1,428 base pairs and 79 species. Base substitutions were optimized on the topology of Figures 4 and 5.

| | Codon position | | | Total sites |
|---|---|---|---|---|
| | First | Second | Third | |
| Polymorphic sites | 221 | 210 | 430 | 861 |
| Constant sites | 255 | 266 | 46 | 567 |
| Informative sites | 137 | 124 | 394 | 655 |

input orders. Rearrangements of the optimal topology from this step were performed to arrive at a final result. Kishino & Hasegawa (1989) tests of the likelihood scores associated with topologies produced by each step of the analysis (available from M. Duvall on request) were performed.

Bootstrap and decay analyses were implemented with PAUP Version 3.0s (Swofford, 1991) on a Macintosh IIfx for the *rbc*L data set from 78 species of monocots. A set of 18 trees of length 3,117 was determined with more than ten replications of the input order. Trees one step longer (486 trees) and two steps longer (6,237 trees) were also determined. (An attempt to determine all trees up to four steps longer using a Macintosh Quadra 700 was aborted after 13.8 days of continuous execution. The analysis produced 14,873 trees occupying over 6 Megabytes of memory and was estimated to be 10% complete. Available computer memory was the limiting factor so that the time to perform read-write operations of treefiles from external memory became prohibitive.) Bootstrap analysis with 200 subsamples of the original data matrix was performed with local (i.e., "nearest neighbor interchange" or "NNI") branch swapping.

Three tests to ascertain the effect of constraining topologies so that selected species occupied monophyletic clades were conducted. The selected species groups were: (1) Commelinanae (13 spp.); (2) Alismatanae (4 spp.), and Aranae (4 spp.), together with *Acorus calamus*; and (3) each of nine superorders sensu Dahlgren et al. (1985). These constraints were imposed on parsimony analyses with 10 replications of the input order and NNI branch swapping.

For pragmatic reasons the parsimony method was selected for larger-scale analysis of *rbc*L sequences (104 monocot species). Eighteen dicot species were selected as an outgroup as suggested by a more inclusive analysis of angiosperms (Chase et al., 1993). Ten replications of the input order were executed with the "steepest descent" option invoked and global ("tree-bisection and reconnection" or "TBR") branch swapping employed. All equally most-parsimonious trees were saved.

## RESULTS

Of the 1,428 bases analyzed for 79 species, 861 were polymorphic and 50% of these were at third codon positions (Table 2). Of the 861 polymorphic sites, 655 were shared by two or more species and of these, 60% were at third codon positions.

The results of our phylogenetic analyses show greater congruence with the taxonomic system of Dahlgren et al. (1985) than with other contemporary systems (reviewed in Goldberg, 1989). References to taxa in this report thus follow that system.

The topology resulting from maximum likelihood analysis (Fig. 1) had an associated likelihood score of −18,878.21. Note that other topologies exist which have likelihood scores that are not significantly different from that of Figure 1. Bootstrap values and decay indices for analyses of 79 species are given (Fig. 2, Table 3). Recall that only trees up to two steps longer than the shortest trees were determined so that clades supported with decay indices of two may also be supported at higher,

FIGURE 1. Topology for 78 monocotyledons and the outgroup dicotyledon *Saururus cernuus* (79 spp. total) produced by the maximum likelihood method with a log likelihood of −18,878.21. The analysis was executed using the computer program fastDNAml 1.0.3 (Olsen et al., 1992), on the Touchstone Delta Parallel Processing Supercomputer, the fastest existing computer. The initial phase of the analysis included 74 of these species, employed regional and local branch swapping, specified substitution rates of 1.00, 0.85, and 5.80 for first, second, and third codon position substitutions, respectively, under the "categories" option, was performed with 33 replications of the input order, and consumed more than 125 hours of supercomputer time. Five additional species, *Aletris farinosa*, *Burmannia biflora*, *Sparganium americanum*, *Stegolepis allenii*, and *Typha latifolia*, were added more than 50 times to the initial topology with the largest log likelihood score. Additional rearrangements of the tree with the largest likelihood score produced the tree shown here. Scale bar indicates 1.0% maximum likelihood distance units as calculated under the assumptions specified above. Species are indicated by genera only. For complete binomials see Appendix in this issue.

TABLE 3. Support for clades corresponding to taxa sensu Dahlgren et al. (1985) by *rbc*L data for 78 species of monocotyledons. Parenthetical numbers immediately following taxa indicate the number of species analyzed. Bootstrap values (200 replicates) and decay indices (up to two steps longer than the most parsimonious topologies) are given. Clades supported with decay indices of two may also be supported at a higher, undetermined, decay index. Also given are the numbers of substitution events supporting each lineage and the number of nonhomoplastic synapomorphies (appearing parenthetically following branch lengths) in the maximum likelihood topology (Fig. 1).

| Taxa (number of species) | Bootstrap values (%) | Decay indices | Lengths |
|---|---|---|---|
| Alismatanae (4) | 67 | ≥ 2 | 37 (3) |
| Aranae (4) | 53 | ≥ 2 | 14 (1) |
| Arecanae (3) | 100 | ≥ 2 | 31 (4) |
| Bromelianae (8) | < 50 | 0 | — |
| Bromeliaceae (2) | 100 | ≥ 2 | 14 (0) |
| Typhales (2) | 78 | ≥ 2 | 21 (11) |
| Commelinanae (13) | < 50 | 0 | — |

| Zingiberanae (11) | 93 | ≥ 2 | 20 (1) |
| Costaceae (2) | 72 | ≥ 2 | — |
| Zingiberaceae (2) | 65 | ≥ 2 | — |
| Monocotyledons excluding *Acorus calamus* (77 spp.) | 73 | ≥ 2 | 13 (1) |

undetermined, values. Seven lineages found in the maximum likelihood tree that have associated bootstrap values at or above 78% and decay indices greater than or equal to two correspond to orders, superorders, or combinations of these. These are: (1) Arecanae (3 spp.); (2) Asparagales (excluding Hypoxidaceae: 14 spp.) plus Iridaceae (2 spp.); (3) Cyclanthanae plus Pandananae (1 spp. each); (4) Dioscoreales (2 of 3 spp.); (5) Orchidales (2 spp.); (6) Typhales (2 spp.); and (7) Zingiberanae (11 spp.). Six clades of confamilial or congeneric species are supported by the *rbc*L data at a bootstrap value of at least 90% and a decay index of at least two including: Agavaceae, Asphodelaceae, Bromeliaceae, Hypoxidaceae, Poaceae, and *Tradescantia*.

Parsimony analysis of 122 species produced a set of 109 equally parsimonious trees of 3,932 steps over the 1,428 characters (see overview of strict consensus tree, Fig. 3). These trees have consistency indices (excluding uninformative characters) of 0.267 (the low value reflecting the large number of species) and retention indices of 0.633. One of these 109 trees was arbitrarily selected and is given in detail (Figs. 4, 5) to enumerate genera and illustrate comparative branch lengths.

←

FIGURE 2. Majority rule (50%) consensus tree for 79 species. The bootstrap analysis was conducted using PAUP 3.0s with 200 bootstrap subsamples of the data matrix. Percentage values for those branches occurring in at least 50% of the bootstrap topologies are shown. Selected taxa are identified. Branch lengths are arbitrary. Decay values up to two steps longer are indicated as vertical bars of varying thickness overlaid on the bootstrap topology. The thickest lines indicate clades supported in trees at least two steps longer. The thinnest lines indicate clades supported only in maximum parsimony trees.

Outgroup:
Dicotyledonous
Paleoherbs.

The maximum likelihood tree (79 spp., Fig. 1) and the resolved portions of the consensus tree produced by parsimony (122 spp., Fig. 3) are largely congruent with respect to the constituent species of the seven lineages listed above and the order of divergence of those lineages. Exceptions are: (1) Dioscoreales (excluding *Smilax glauca*) diverge earlier in the parsimony trees; (2) one species each of Cyclanthanae, Pandananae, and Velloziales make up an isolated clade in the maximum likelihood tree, which is found embedded within a clade of seven species of Lilianae in the parsimony tree; (3) *Burmannia biflora* is found in Asparagales in the maximum likelihood tree but with two species of Dioscoreales in the parsimony trees; and (4) *Aletris farinosa* occupies an isolated clade near the base of the maximum likelihood tree but is embedded within the clade of Asparagales in the parsimony trees. In both the maximum likelihood and parsimony trees, two species of Hypoxidaceae are included in Asparagales consistent with Dahlgren et al. (1985).

## Discussion

The order of divergence of the seven major lineages in our phylogenetic analyses is in general agreement with widely accepted views on the evolution of the monocotyledons. Recognition of the early divergences of Alismatanae (Cronquist, 1981; Dahlgren et al., 1985) and Dioscoreales (Dahlgren et al., 1985), and the affinities between the Alismatanae and the Aranae (Dahlgren et al., 1985; Grayum, 1991) correlate with the position of species from these superorders near the base of our molecular phylogenies. Postulated later divergences of Arecanae (Doyle, 1973), Bromelianae, Commelinanae, and Zingiberanae (Cronquist, 1981) are also consistent with our analyses.

In general, deep branches in the tree (Figs. 1, 4, and 5) are shorter than the terminal branches, indicating fewer nucleotide changes along the former. This relationship suggests either that the substitution rate during evolutionary radiations of the monocotyledons was unusually slow, that sampling bias occurred in part because of extinction events, or that the original radiations occurred rapidly. The fossil record, and especially that of fossil pollen, for angiosperms in general (Doyle & Hickey, 1976) and probably for the monocotyledons as well (Doyle, 1973) is certainly consistent with the hypothesis of rapid radiation.

*Acorus calamus* occupies a unique, basal position in all the trees generated for this study. Although *Acorus* was traditionally classified in Araceae because of superficial morphological similarities with the Australian aroid *Gymnostachys anceps*, aroid authorities have recently acknowledged long-recognized difficulties with this classification and, based on a substantial body of evidence (reviewed in Grayum, 1987), proposed removal of *Acorus* to a monogeneric family. A tree (not shown) constrained to include *Acorus* and four species of Arales as monophyletic that was analyzed over the subset of 79 species is 25 steps longer than the shortest trees. Our analysis thus indicates that removal of *Acorus* from the Araceae is consistent with a more parsimonious phylogenetic hypothesis and further offers an explanation for the failure to identify synapomorphies of this genus with other monocot species, if, as we suggest, *Acorus* is distinguished as the most basal extant lineage of monocotyledons.

Several other aspects of the tree of Figure 1, not already considered in the accompanying reports in this issue, are of interest. We have included *rbc*L sequences from 21 species in 12 of 30 families in the large order Asparagales (estimated 5,000 spp. or 10% of monocotyledons) sensu Dahlgren et al. (1985). These species are all found in a single monophyletic clade in both maximum likelihood and parsimony trees, together with only six other species: (1) *Aletris farinosa*, (Melanthiaceae); (2 and 3) two species of Iridaceae: *Anomatheca laxa* and *Iris* × *germanicum*; (4 and 5) two species of Orchidales: *Neuwiedia veratrifolia* (Apostasiaceae) and *Oncidium excavatum* (Orchidaceae); and (6) *Burmannia biflora*. Further, the clade of Asparagales (excluding Hypoxidaceae) is at least moderately supported by boot-

←

Figure 3. Overview of the strict consensus of 109 equally parsimonious trees for 104 monocots and 18 dicots. These trees are of length 3,932, have consistency indices excluding uninformative characters of 0.267, and retention indices of 0.633. Note that the unresolved portions of this topology are within the terminal clades corresponding to: (1) Bromeliaceae; (2) that containing Commelinaceae and three species of Bromelianae; (3) Zingiberanae; (4) Asparagales; and (5) that consisting of Alismatanae, Arecanae, and one species of Melanthiales. The terminal species are identified in the Appendix in this issue and as genera in Figures 4 and 5. The number of species analyzed from each taxon is given parenthetically.

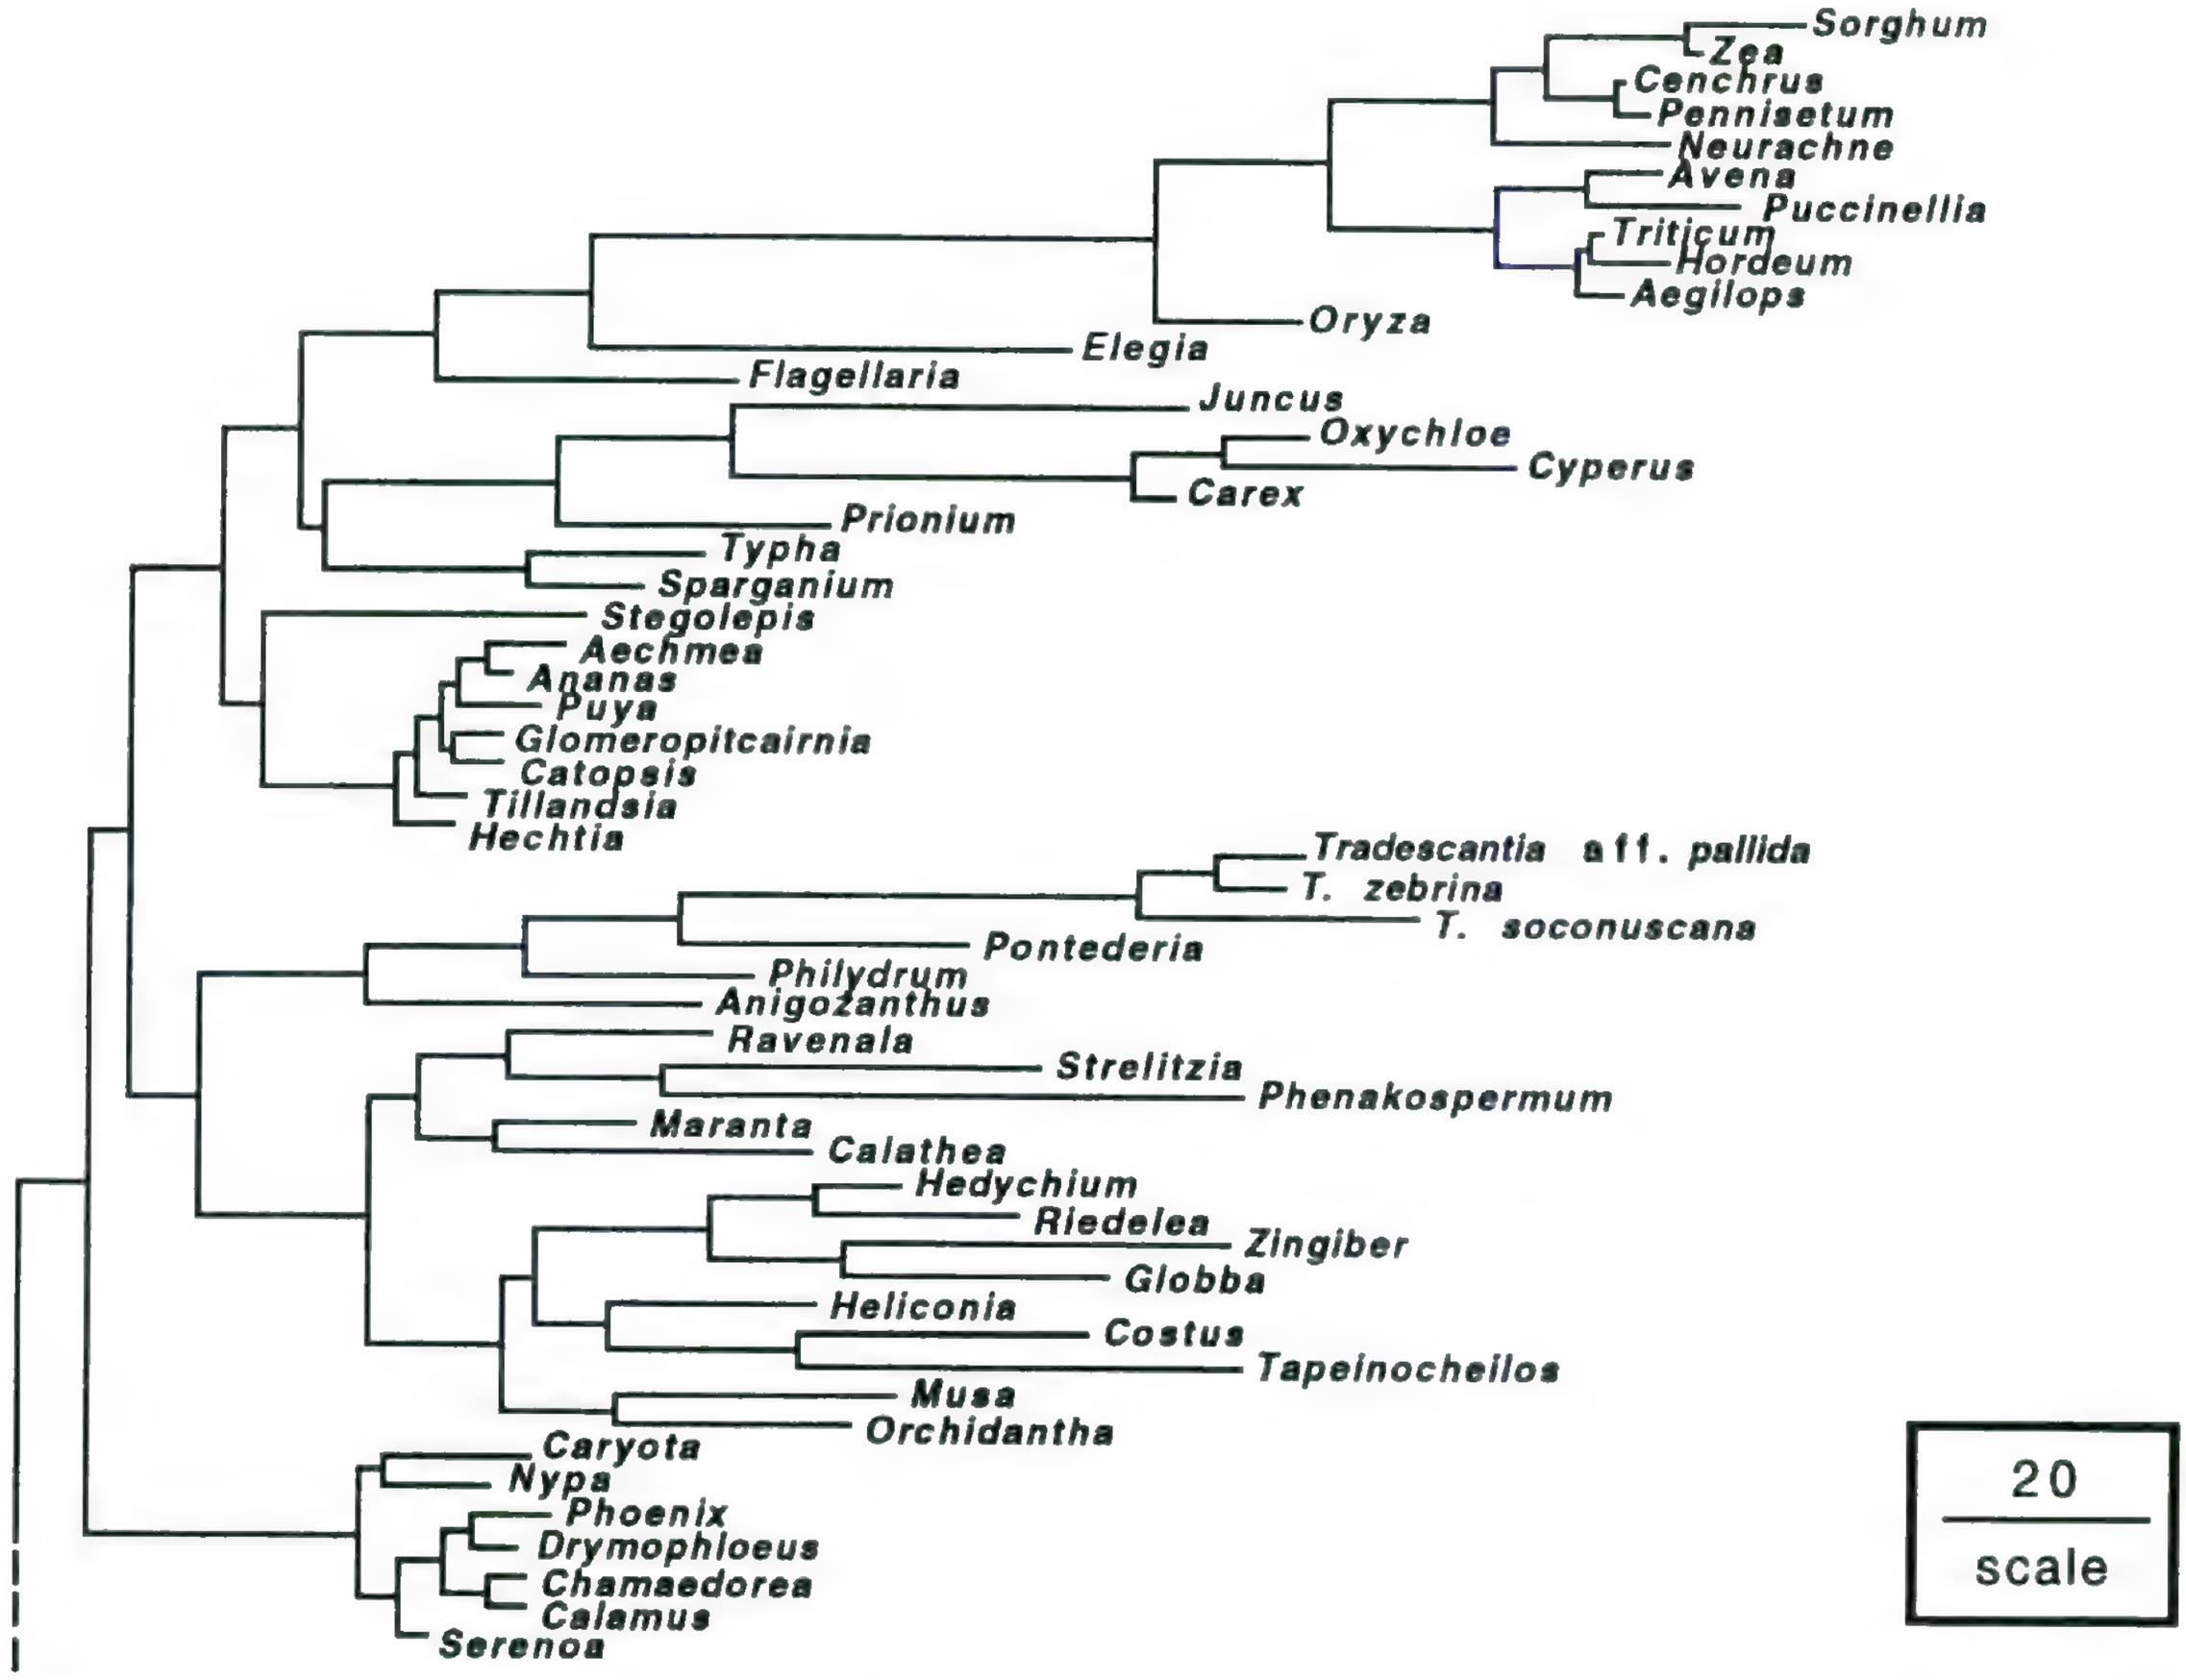

FIGURE 4. Terminal portion of one arbitrarily selected tree from the set of 109 trees (see consensus tree, Fig. 3) of length 3,932, consistency index of 0.267, and retention index of 0.633. This portion of the tree includes species of Commelinanae, Bromelianae, Zingiberanae, and Arecanae (see Fig. 5 for the remainder of the tree). Branch lengths correspond to the number of substitutions optimized along the branches. The scale bar is proportional to a branch length of 20 steps.

strap (84%) and decay (at least two steps longer) analyses. Duvall et al. (in review) have analyzed *rbc*L sequence data from four more species in three additional families of Asparagales that further support the common ancestry of this large order, and they note that the alliance between Iridaceae and Asparagales has morphological and anatomical support.

The historical treatment of Arecanae, Cyclanthanae, and Pandananae as at least marginally related taxa has been contradicted by subsequent taxonomic schemes that treat each as an unrelated superorder (Thorne, 1983) or as separate superorders with a loose alliance between Arecanae and Cyclanthanae (Dahlgren et al., 1985). Phylogenetic hypotheses based on the *rbc*L data support *Freycinetia* (Pandananae) and *Sphaeradenia* (Cyclanthanae) as sister species only distantly related to seven species of Arecanae. This arrangement suggests that Pandananae and Cyclanthanae are more ancient groups than Arecanae. Inclusion of *rbc*L data for a second species of Pandananae, *Pandanus veitchii* does not alter this result (Duvall et al., in review).

The *rbc*L trees suggest that *Smilax glauca* is allied with species of Liliales and isolated from the two other species of Dioscoreales (*Dioscorea polygonoides* and *Tacca integrifolia*). Among the three species a closer relationship has been proposed between the latter two, and *Smilax* has been placed outside of Dioscoreales because of a lack of similarities in secondary chemistry (Dahlgren et al., 1981). The more recent decision to place *Smilax* in Dioscoreales was based on "leaf morphology and floral appearance," although *Smilax* is hypothesized to form a "bridge" between Dioscoreales and species of Lilianae (Dahlgren et al., 1985).

Included in our analyses are 11 species of Poales and five species of the related Cyperales. Phylogenetic analyses of *rbc*L sequences of Poaceae

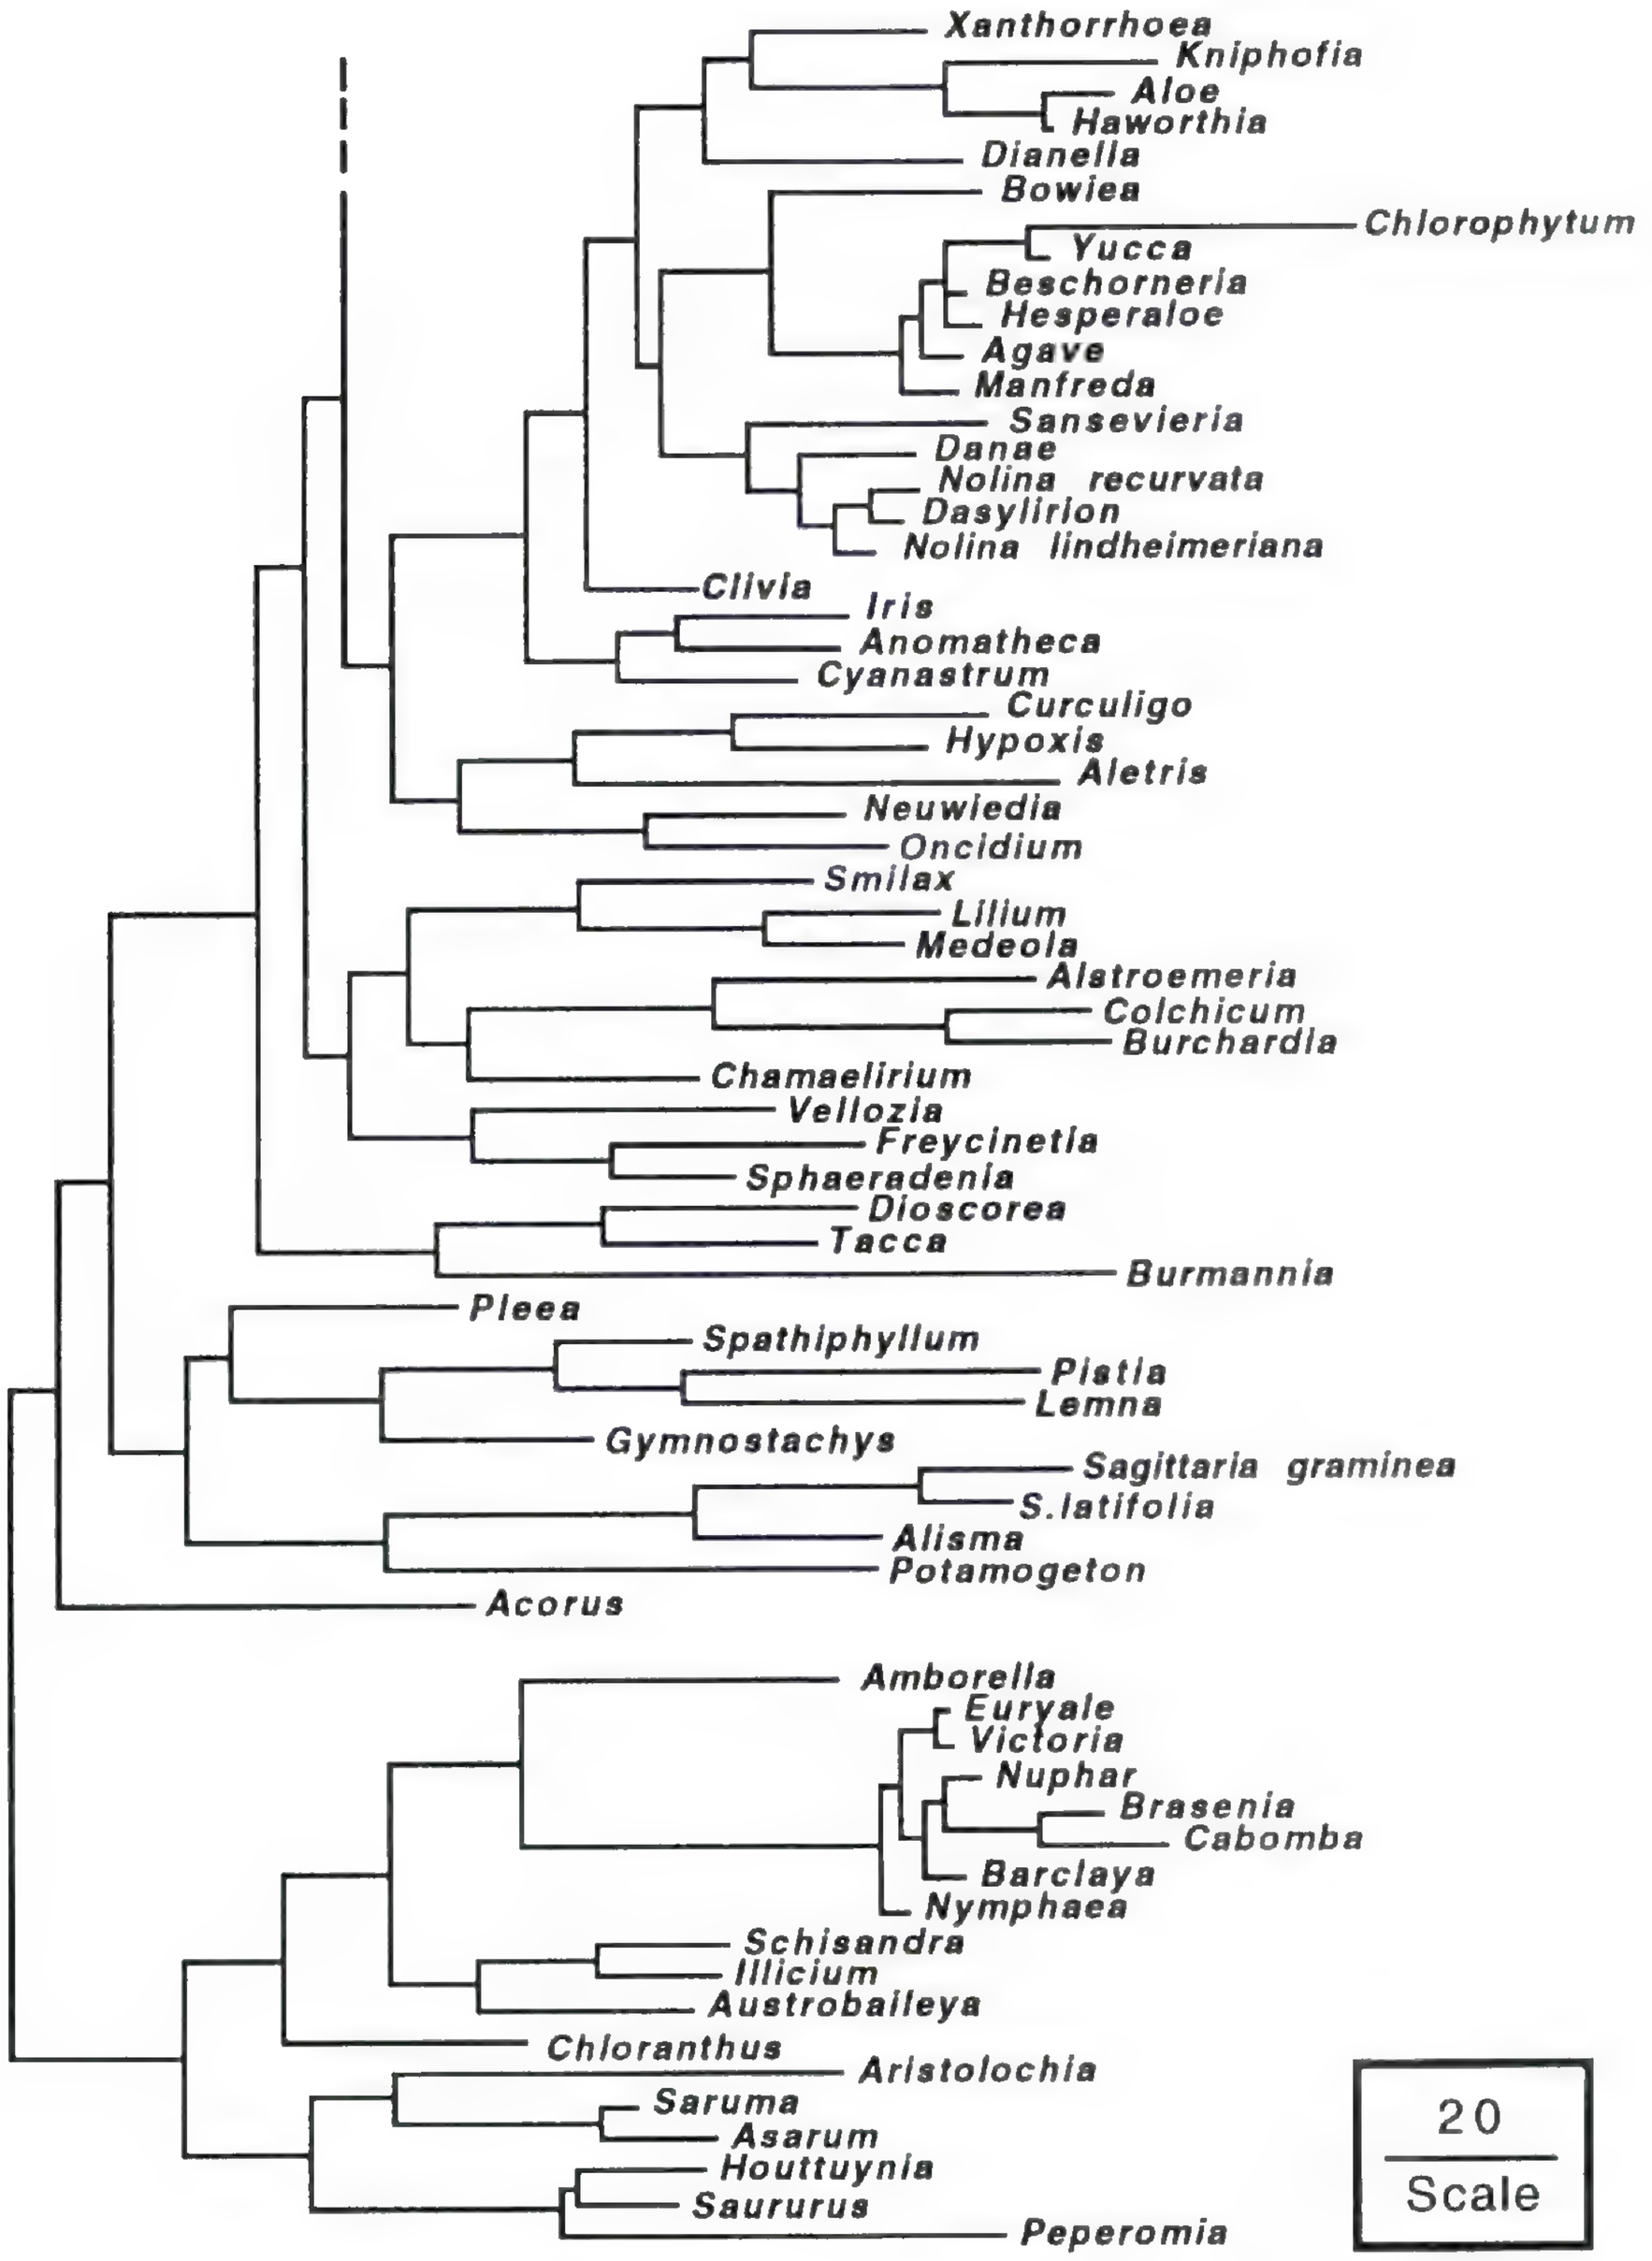

FIGURE 5. Remainder of the tree partially shown in Figure 4. This portion of the tree includes species of Aranae, Alismatanae, Lilianae, outgroup dicotyledons, and *Acorus calamus* (see Fig. 4 for the remainder of the tree). Branch lengths correspond to the number of substitutions optimized along the branches. The scale bar is proportional to a branch length of 20 steps.

have been thoroughly discussed (Doebley et al., 1990). We here note that pooid and panicoid grasses are segregated into sister clades in Figure 2, and that *Oryza sativa* occupies the most basal position of Poaceae. In the clade consisting of Poales (Fig. 3), a species of Restionaceae is most closely related to Poaceae, and Cyperales are found as a component of a sister clade which also contains Typhales contra Dahlgren et al. (1985). This topology is in agreement with the distribution of three inversions in the plastid genomes of these taxa (Doyle et al., 1992) that further predicts that Joinvilleaceae are immediately basal to Poaceae. This prediction has been confirmed by analysis of *rbc*L data as well (Duvall et al., in review).

In our analyses Commelinaceae (three species) cluster with three species of Bromelianae: *Pontederia sagittaria*, *Philydrum lanuginosum*, and *Anigozanthus flavidus* in a clade that is sister to Zingiberanae and separated from 18 other species

of Commelinanae (Fig. 4). A parsimony tree over the 79 species subset constrained to include 13 spp. of Commelinanae as monophyletic (not shown) is 15 steps longer than the tree without constraints. Parsimony analysis of *rbc*L thus does not support the recognition of a monophyletic Commelinanae.

*Pistia* has been tentatively aligned with *Lemna* based on similarities of seedling structure (Grayum, 1991). Analysis of *rbc*L sequences supports this alignment at a bootstrap value of 69% and a decay index value of at least two.

Three species of Melanthiaceae are found in three different primary lineages. These species exhibit a great deal of variation and when combined into a single family are considered a "difficult" treatment (Dahlgren et al., 1985). Our results support the suggestion (Dahlgren et al., 1985) that the Melanthiaceae should be divided into several families, and we further suggest that those families may not be closely related to each other.

The phylogenetic analysis presented here offers support for the recognition of seven primary lineages of monocotyledons that diverged over a relatively short period of geologic time. As noted, this result is in agreement with the taxonomic treatment of Dahlgren et al. (1985). However, a parsimony tree for the 79 species subset constrained to include nine of ten superorders sensu Dahlgren et al. (1985) as monophyletic groups (not shown) was considerably less parsimonious (52 steps longer). (Note that the tenth superorder, Triuridanae, is composed exclusively of achlorophyllous species unlikely to possess a phylogenetically meaningful copy of the *rbc*L sequence.) With regard to the paraphyletic arrangements of Bromelianae, Commelinanae, and Lilianae, the phylogenetic hypotheses presented here are at odds with those based on morphological, anatomical, chemical, and other characters. These discrepancies may reflect a new understanding of the affinities among these taxa. However, insufficient sampling of the *rbc*L data for these groups of species may also be a factor. For example, we have here included *rbc*L data from only half of the 52 families of Lilianae. Additional sampling of molecular characters may resolve these discrepancies or offer further insight into the phylogenetics of the monocotyledons.

The focus of this project was the phylogenetic framework supported by the *rbc*L data set for the monocotyledons. Another valuable feature of the data set, now generally available in GenBank, will be to further develop our understanding of the mechanisms and underlying probabilities of nucleotide substitution, particularly as influenced by structural and functional constraints of the molecules. These further studies will undoubtedly refine methods of the phylogenetic analysis of molecular data.

# PHYLOGENETIC ANALYSIS OF THE ZINGIBERALES BASED ON *rbc*L SEQUENCES[1]

*James F. Smith,*[2,3,4] *W. John Kress,*[3] *and Elizabeth A. Zimmer*[2,3]

## Abstract

Morphological data have been used previously to construct phylogenies of the eight families of the Zingiberales, one of the most widely accepted monophyletic groups of flowering plants. To provide additional support for phylogenetic relationships within the order, and placement of the order among monocots, we present a parsimony analysis of DNA sequences from the chloroplast-encoded gene, *rbc*L, for 21 species of Zingiberales and proposed relatives. Five analyses with equal, and differential weights were performed. All analyses resulted in the same most parsimonious tree for taxa within the Zingiberales and the immediate outgroup. The closest sister group to the Zingiberales based on these data is a clade containing Commelinaceae/Haemodoraceae/Pontederiaceae. The tree topology within the order based on *rbc*L sequence data is different from previous morphological analyses. The order can be divided into two sister groups, one containing the Costaceae and Marantaceae, and the other, the remaining six families. All recognized families are monophyletic with the exception of the Musaceae, which is paraphyletic with the Cannaceae. With trees one and two steps longer than the most parsimonious trees, phylogenetic resolution is rapidly lost, suggesting that the phylogenetic utility of *rbc*L sequence data for the Zingiberales is limited to interordinal and intrafamilial relationships.

The Zingiberales, a morphologically distinctive order of monocots, are one of the most widely accepted monophyletic groups of plants (Bentham & Hooker, 1883; Petersen, 1889; Schumann, 1900, 1902, 1904; Hutchinson, 1934, 1959, 1973; Nakai, 1941; Tomlinson, 1962, 1969; Stebbins, 1974; Cronquist, 1978, 1981; Dahlgren & Rasmussen, 1983; Dahlgren et al., 1985; Kress, 1990). Dahlgren et al. (1985) listed six apomorphies for the Zingiberales: root hair cells shorter than other epidermal cells, sieve tube plastids containing starch, presence of silica bodies, epigynous flowers, lack of distinctive apertures on the pollen grains, and the occurrence of arillate seeds. In addition, the herbaceous arborescent stem, distichous phyllotaxy, large petiolate leaves with blades possessing transverse venation, conspicuous colorful bracteate inflorescences, and the substitution of one to five staminodia for the fertile stamens are characters easily used to identify members of the Zingiberales (Kress, 1990).

As currently classified, the order consists of eight families (Kress, 1990): Musaceae, Lowiaceae, Heliconiaceae, Strelitziaceae, Zingiberaceae, Costaceae, Marantaceae, and Cannaceae. Subordinal classification, including delimitation and rank of these families, has been subject to many changes (reviewed in Kress, 1990). Cladistic analyses of morphological characters have greatly improved the understanding of phylogenetic relationships of the families (Dahlgren & Rasmussen, 1983; Kress, 1990). Dahlgren & Rasmussen (1983) performed the first cladistic analysis of the Zingiberales using the eight families listed above and polarized characters using their Commeliniflorae. This analysis resulted in a single tree (Fig. 1) composed of three main clades that included the ginger group (Zingiberaceae/Costaceae and Marantaceae/Cannaceae), the banana group (Musaceae/Heliconiaceae), and the bird-of-paradise group (Strelitziaceae/Lowiaceae). The relationships among the three groups remained equivocal.

Kress (1990) re-analyzed the data of Dahlgren & Rasmussen (1983) and performed a separate analysis that included other characters which were rooted with the Bromeliales. This second analysis resulted in a different cladogram (Fig. 2) from that of Dahlgren & Rasmussen (1983). Although the ginger group relationship was retained in both, the families of the banana and bird-of-paradise groups

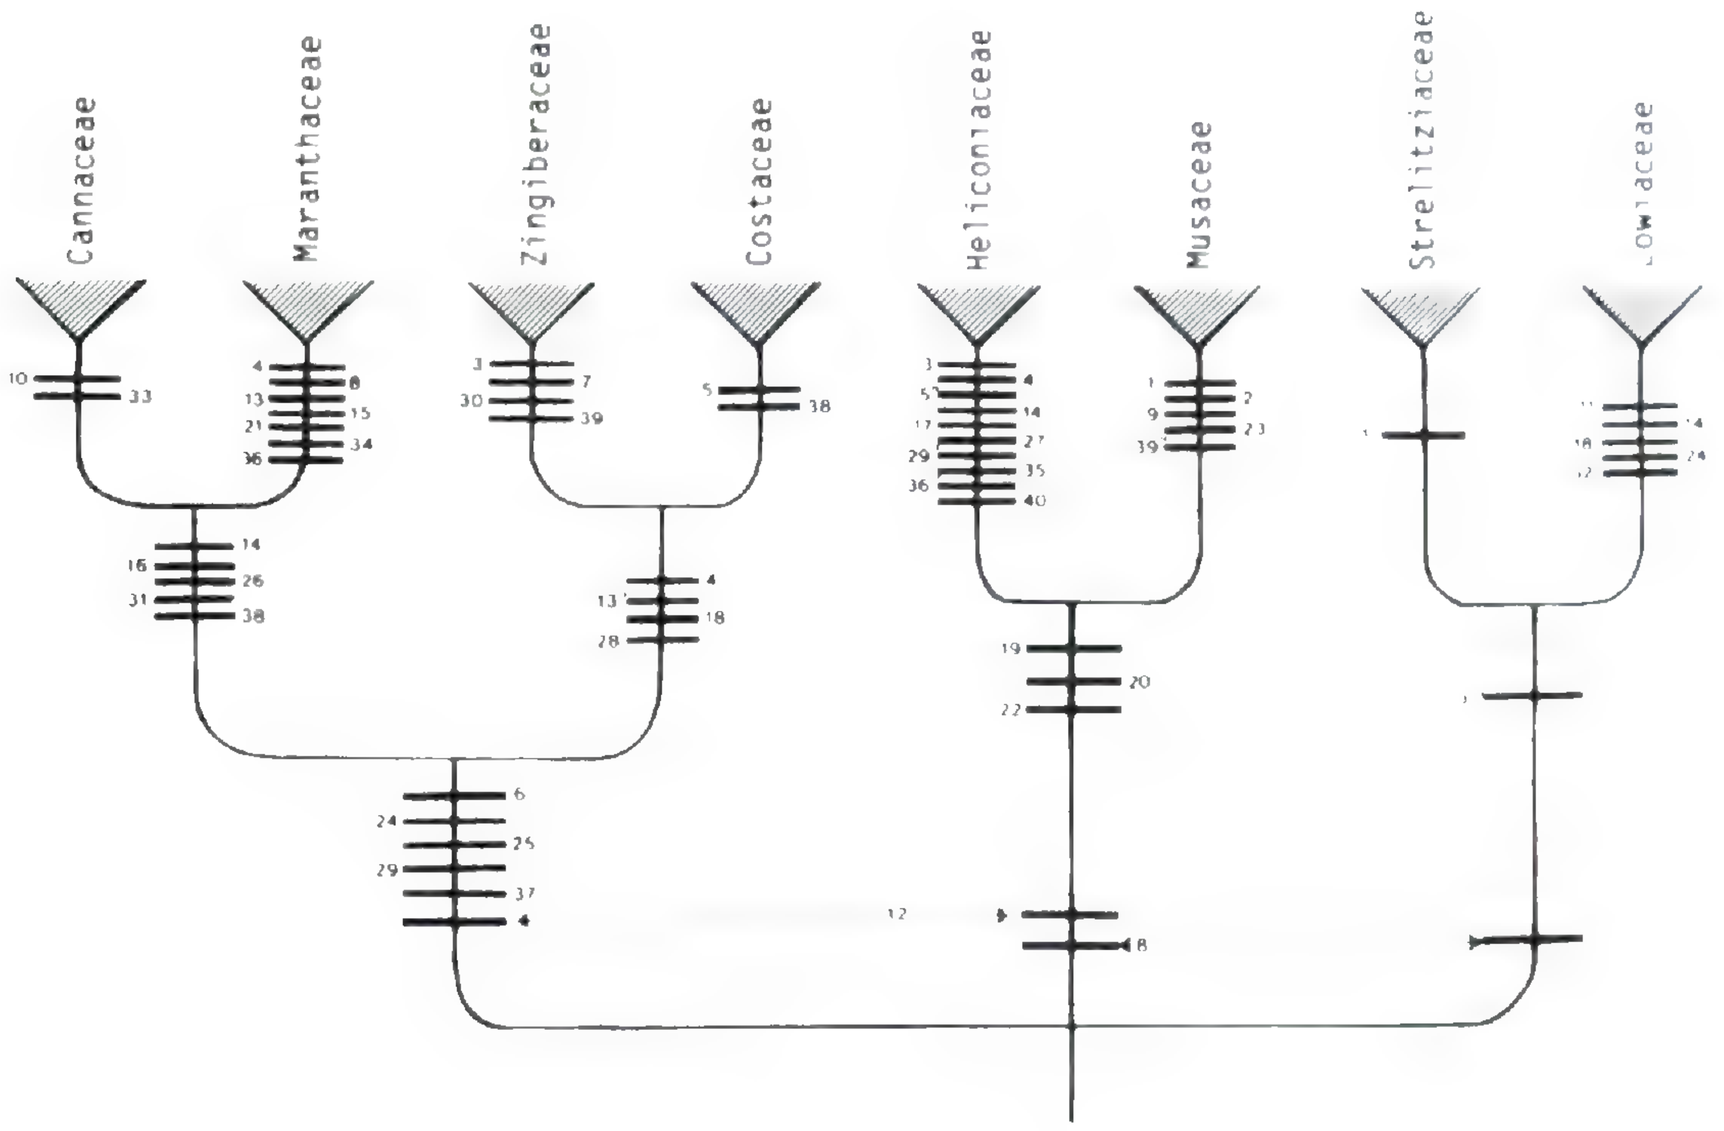

FIGURE 1. Cladogram of the Zingiberales from Dahlgren & Rasmussen (1983, their figure 9).

were shown to be paraphyletic (Kress, 1990). These analyses have been highly informative in terms of familial relationships, yet the utility of many of the morphological characters at this level is questionable. The eight families of the Zingiberales are highly distinctive with many unique and highly modified morphological structures. Interpretation of homology between families has posed difficult problems without detailed developmental analysis for many of the structures (Kirchoff, 1991).

The numerous autapomorphies of the Zingiberales have also made difficult the determination of the evolutionary relationship of the order to other monocots. The Zingiberales have generally been allied with the Bromeliales and/or Commelinales (Hutchinson, 1973; Dahlgren et al., 1985; Thorne, 1992). The presence of starchy endosperm, epicuticular wax of the *Strelitzia* type, UV-fluorescent organic acids in the cell walls, and two or four subsidiary cells in the stomatal complex are all specialized characters that unite the Zingiberiflorae with the Bromeliiflorae and Commeliniflorae (Dahlgren et al., 1985). Most modern classifications have placed the Zingiberales near the Bromeliales (containing the single family Bromeliaceae) (Hutchinson, 1973; Stebbins, 1974; Takhtajan, 1980; Cronquist, 1978, 1981) based on the similarity of inflorescence and flower structures (primarily the large, conspicuous bracts and petaloid perianth parts). Although these morphological homologies are potentially equivocal, the presence of several chemical constituents (myricetin and/or quercetin glycosides) also has suggested a common ancestor for the Zingiberales and Bromeliales (Williams & Harborne, 1977). Thorne (1992), however, recognized three separate orders in his superorder Commelinanae: Bromeliales, Commelinales, and Zingiberales.

Alternatively, Walker (1987) derived his Zingiberidae (excluding the Bromeliales) and his Pontederiidae (Haemodoraceae, Pontederiaceae, and Philydraceae) directly from a liliid lineage. Sepal nectaries, vessels primarily in the roots, and several chemical characters (e.g., chelidonic acid) found in the Zingiberales support their placement with a lilialean lineage (Takhtajan, 1980).

The use of molecular characters in cladistic analyses has been highly successful in plants (Palmer et al., 1988; Crawford, 1990), particularly in taxonomically difficult groups in which it is hard to interpret morphological homology (e.g., Chase & Palmer, 1989; Smith, 1991). Recently, sequence data derived from the chloroplast gene *rbc*L, which encodes the large subunit of ribulose bisphosphate carboxylase, has provided resolution at higher taxonomic levels in plants (e.g., Doebley et al., 1990; Donoghue et al., 1992; Olmstead et al., 1992; other papers this issue). The relatively slow rate of mutation of the *rbc*L gene has made this gene useful for taxonomic investigations at and above the generic level. However, the limits and taxonomic range for which *rbc*L can adequately resolve phylogenetic relationships have not been examined widely.

To compare phylogenies based on morphological analyses in the Zingiberales, we initiated a cladistic analysis of *rbc*L sequence data. Our goals in this research were: (1) to examine the monophyly of

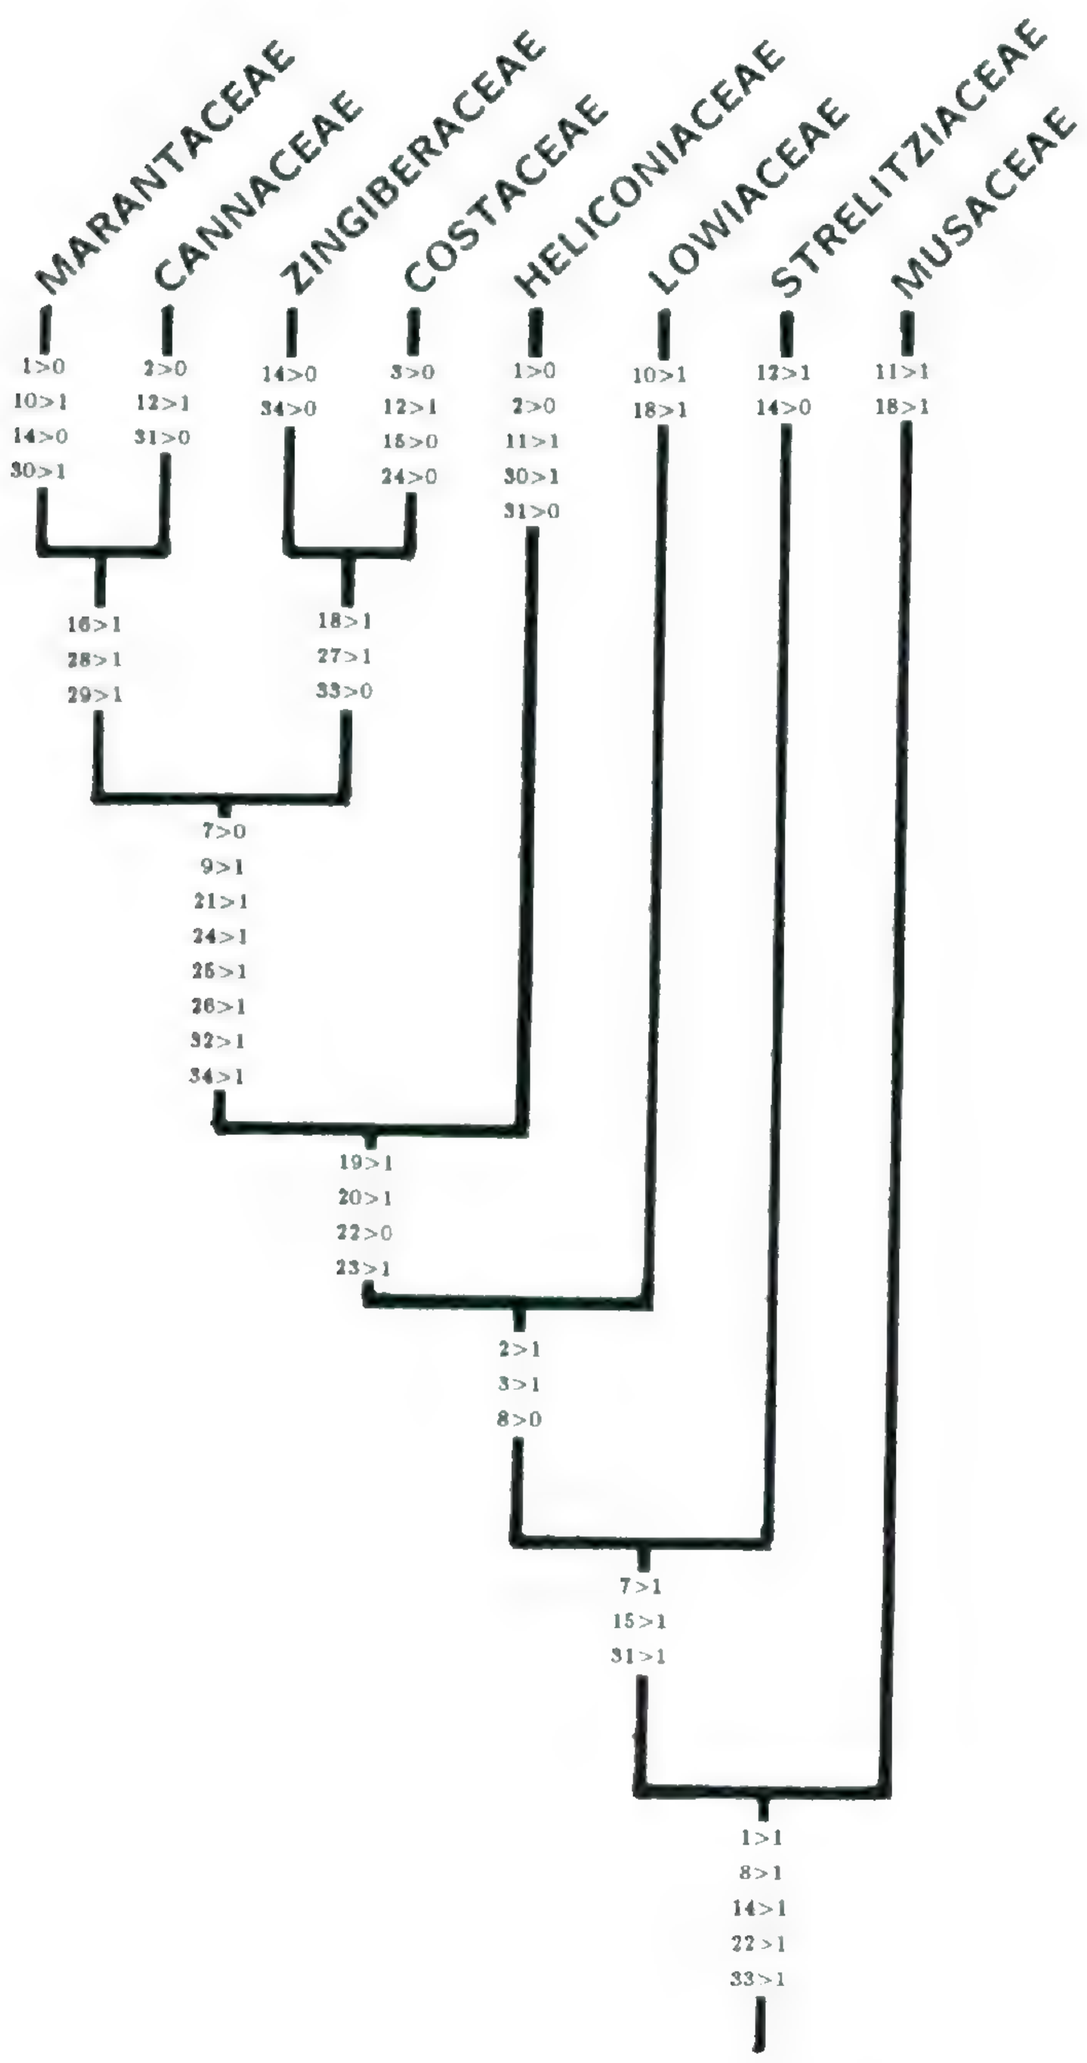

FIGURE 2. Most parsimonious tree of the Zingiberales from Kress (1990, his figure 7).

the eight recognized families; (2) to construct the phylogenetic relationships of the families within the order based on *rbc*L sequence data; and (3) to determine the sister group relationship of the Zingiberales.

## MATERIALS AND METHODS

Species were selected in an attempt to represent the most divergent members of each family. For example, in the large family Zingiberaceae, the species selected represent each of the four tribes. Different genera were represented wherever possible, depending on availability and number of genera in each family. A minimum of two taxa per family was chosen to reduce potential long branch effects (Felsenstein, 1978), which result when a single taxon with no close affinities is included in an analysis. Species, collection localities, and voucher information are listed in Table 1.

Total genomic DNA was extracted from fresh or frozen leaf tissue by a modified CTAB method (Smith et al., 1991 [1992]). An approximately 1,401 bp segment of double-stranded DNA containing the sequence for the *rbc*L gene was amplified via the Polymerase Chain Reaction (Cetus Corporation) (PCR). Two synthetic oligonucleotides were used as amplification primers. The 5′ primer is the Z-1 *rbc*L primer based on the first 30 bp of the *rbc*L sequence of maize, and the 3′ primer is the corresponding Z-1375R primer, which is a 26 bp primer derived from position 1375–1401 of the maize sequence (Zurawski, DNAX). Initial attempts were made to amplify DNA from zingiberalean taxa using the primers of Olmstead et al. (1992); however, an apparent substitution unique to the Zingiberales in this region of the gene prevented amplification with these primers. This substitution is currently under investigation (Smith et al., unpublished).

Sequences were obtained by cloning the PCR product into BlueScript SK$^+$ (Stratagene, Inc.) using either the *Hinc II* or *EcoR V* site. The ligation was facilitated by first incubating the PCR products with DNA polymerase to assure blunt ends. The products of the ligation reactions were used to transform competent cells of *Eschericia coli* (XL-1 Blues; Stratagene, Inc.). Actively growing liquid cultures of transformed bacteria were inoculated with the helper phage VCS-M13 (Stratagene, Inc.) and single-stranded DNA was harvested that contained the inserted *rbc*L gene. This single-stranded DNA was then sequenced using Sequenase version 2.0 (US Biochemicals), and fragments were separated on 4% polyacrylamide gels. Internal sequencing primers were derived from sequences distributed by G. Zurawski (DNAX).

Additional sequences for *Lilium*, *Magnolia*, *Vellozia*, *Puya*, *Tillandsia*, *Stegolepis*, *Pontederia*, *Lachnanthes*, *Tradescantia*, and *Maranta* were graciously provided by colleagues (see Chase et al., 1993).

Sequences were read directly from the autoradiographs and entered into a NEXUS file. This file was read into PAUP version 3.0s (Swofford, 1991) for cladistic analysis. Characters were directly scored for each nucleotide and not modified in any way. Missing data or ambiguous regions were scored as missing. Initial analyses used HEURISTIC SEARCH and STEPWISE ADDITION of 500 RANDOM ADDITION SEQUENCE replicates, TBR branch swapping, saving ALL MINIMAL

TREES, and COLLAPSING ZERO LENGTH BRANCHES. These options were chosen as an initial analysis due to the sensitivity of PAUP (and all other programs) to taxon order in the data matrix (Maddison, 1991). The order of taxa in the data set was then altered to produce the same most parsimonious tree with the GENERAL HEURISTIC OPTION and default options for further weighting analyses. Neighborhood trees of 1 and 2 steps longer were also examined using the same default options with the exception that trees of a specified length and shorter were saved.

Several separate analyses were performed using the above options to determine if choice of outgroup had an effect on the arrangement of taxa within the Zingiberales. These analyses used: (1) *Magnolia* as the outgroup, with all other monocots included as ingroup; (2) *Lilium* as the outgroup with all other monocots included as ingroup, and *Magnolia* excluded; (3) *Tradescantia Pontederia–Lachnanthes* as outgroup, with only the zingiberalean taxa included as ingroup.

Character state changes were plotted onto trees using the ACCTRAN option. Because the DELTRAN option can sometimes drastically alter the distribution when equally parsimonious options are available, character state changes also were plotted with this option, and the two distributions compared.

## Results

### SEQUENCE DATA

Sequences of 1,345 bp or more were obtained for 33 species including 10 sequences graciously provided by other workers (see Chase et al., 1993) (Table 1). For the 32 species used in the majority of analyses (excluding *Magnolia*, which was used to determine outgroup relationships), 464 positions (~34%) were variable. Of these 464 characters, 183 (~39% of the variable characters) were autapomorphic. Therefore, 281 of the original 1,345 bp (~21%) were shared by two or more taxa. Of the 464 variable characters, 105 (~23%) were first codon positions, 92 (~20%) were second positions, and 267 (~57%) were third positions (Table 2).

### ANALYSES

The equally weighted analysis from the RANDOM ADDITION SEQUENCE search resulted in two most parsimonious trees of 1,163 steps (CI of 0.41; RI of 0.49). The two trees differed only in the relationships of *Stegolepis* and the Bromeliaceae. The strict consensus of these most parsimonious trees is presented in Figure 3. The topology was unaltered whether *Magnolia*, *Lilium*, or *Tradescantia/Lachnanthes/Pontederia* were used to root the tree.

Character state change distributions differed only slightly between the ACCTRAN and DELTRAN option. At only four nodes did the distributions differ in more than two character state changes and in none of these did a strongly supported node become weakly supported or vice versa. Based on the character state distribution of the most parsimonious trees, 709 (~61%) of the 1,163 character state changes were transitions, and 454 (~39%) were transversions (Table 3).

The strict consensus of the 62 trees of 1,164 steps or fewer loses most of the resolution found in the most parsimonious trees (Figs. 3, 4). A search for trees two steps longer than the most parsimonious trees produced 1,541 trees of 1,165 steps or fewer. A strict consensus of these 1,541 trees lost nearly all resolution with the exception of monophyly of the five major clades in the Zingiberales, Strelitziaceae, Zingiberaceae, Cannaceae, Lowiaceae, and *Calathea/Marantochloa*, as well as outgroup clades (Fig. 4).

## Discussion

A cladistic analysis of the *rbc*L sequence data produced a single most parsimonious tree for the families of the Zingiberales (Fig. 3) that differs from any previous phylogenetic analysis of morphological data (Figs. 1, 2) (Kress, 1990). The Lowiaceae and Strelitziaceae lineage is the only between-family clade shared by both the molecular analysis and one of the cladistic analyses of morphological characters (Dahlgren & Rasmussen, 1985) (Fig. 1).

The conflicts between the trees based on morphological characters and molecular data are many. One conspicuous example pertains to floral morphology. In all traditional classifications of the order (see Kress, 1990, for summary), the reduction in the number of pollen-bearing stamens from 6 or 5 (Musaceae, Strelitziaceae, Lowiaceae, and Heliconiaceae) to 1 or $\frac{1}{2}$ (Zingiberaceae, Costaceae, Cannaceae, and Marantaceae), and the associated modification of these stamens into petaloid staminodes, are characters that have served as the basis for dividing the families into two basic groups, the banana group and the ginger group, respectively. The homology of these specialized floral features

is supported by ontogenetic studies in the Zingiberales as well (Kirchoff, 1983, 1988, 1991). Although the four families of the banana group may be variously related, the ginger group, defined by these highly derived staminal features, has always been considered monophyletic (Dahlgren & Rasmussen, 1985; Kress, 1990; Kirchoff, 1991).

The topology based on the molecular data places the four families of the ginger group into three separate lineages (Marantaceae and Costaceae; Cannaceae and Musaceae; and Zingiberaceae and Heliconiaceae; see Fig. 3), which would require at the minimum three independent reductions (if 5–6 stamens is plesiomorphic) or one increase and two reversals to reduction (if $1-\frac{1}{2}$ stamens is plesiomorphic) in stamen number. Although we should certainly reconsider the possible nonhomology of these traditionally recognized morphological features, the molecular characters must be examined critically (through increased sampling of taxa, or examination of other molecular characters) before concluding that the morphological features are homoplastic.

The rapid "decay" of the various clades in the most parsimonious tree found from the *rbc*L data suggests that the interfamilial phylogenetic signal of this plastid gene is low for the Zingiberales (Fig. 4). There are 62 different topologies that are one step or fewer longer than the most parsimonious; 1,541 topologies can be found searching for trees two or fewer steps longer.

In contrast to interfamilial relationships, the *rbc*L data strongly support both the monophyly of the order within the monocots as well as the monophyly of most of the families. Although the position of the *Lachnanthes/Pontederia/Tradescantia* clade as the sister group to the Zingiberales collapses in the consensus of trees one step longer (Fig. 3), the coherence of the order itself remains robust. In a larger analysis of the phylogeny of the monocots

TABLE 2. Variable characters according to codon position. Homoplastic character states are based on the ACCTRAN character state distributions for the most parsimonious trees (Fig. 3). The first values are the numbers of characters, the second are the percentages of total states. Synapomorphic character states include only non-homoplastic character states.

| Position | Variable | | Homoplastic | | Synapomorphic | | Autapomorphic | |
|---|---|---|---|---|---|---|---|---|
| First | 105 | ~ 22% | 30 | ~ 15% | 23 | ~ 28% | 52 | ~ 28% |
| Second | 92 | ~ 20% | 30 | ~ 15% | 19 | ~ 23% | 43 | ~ 23% |
| Third | 267 | ~ 58% | 139 | ~ 70% | 40 | ~ 49% | 88 | ~ 49% |
| Total | 464 | 100% | 199 | 100% | 82 | 100% | 183 | 100% |

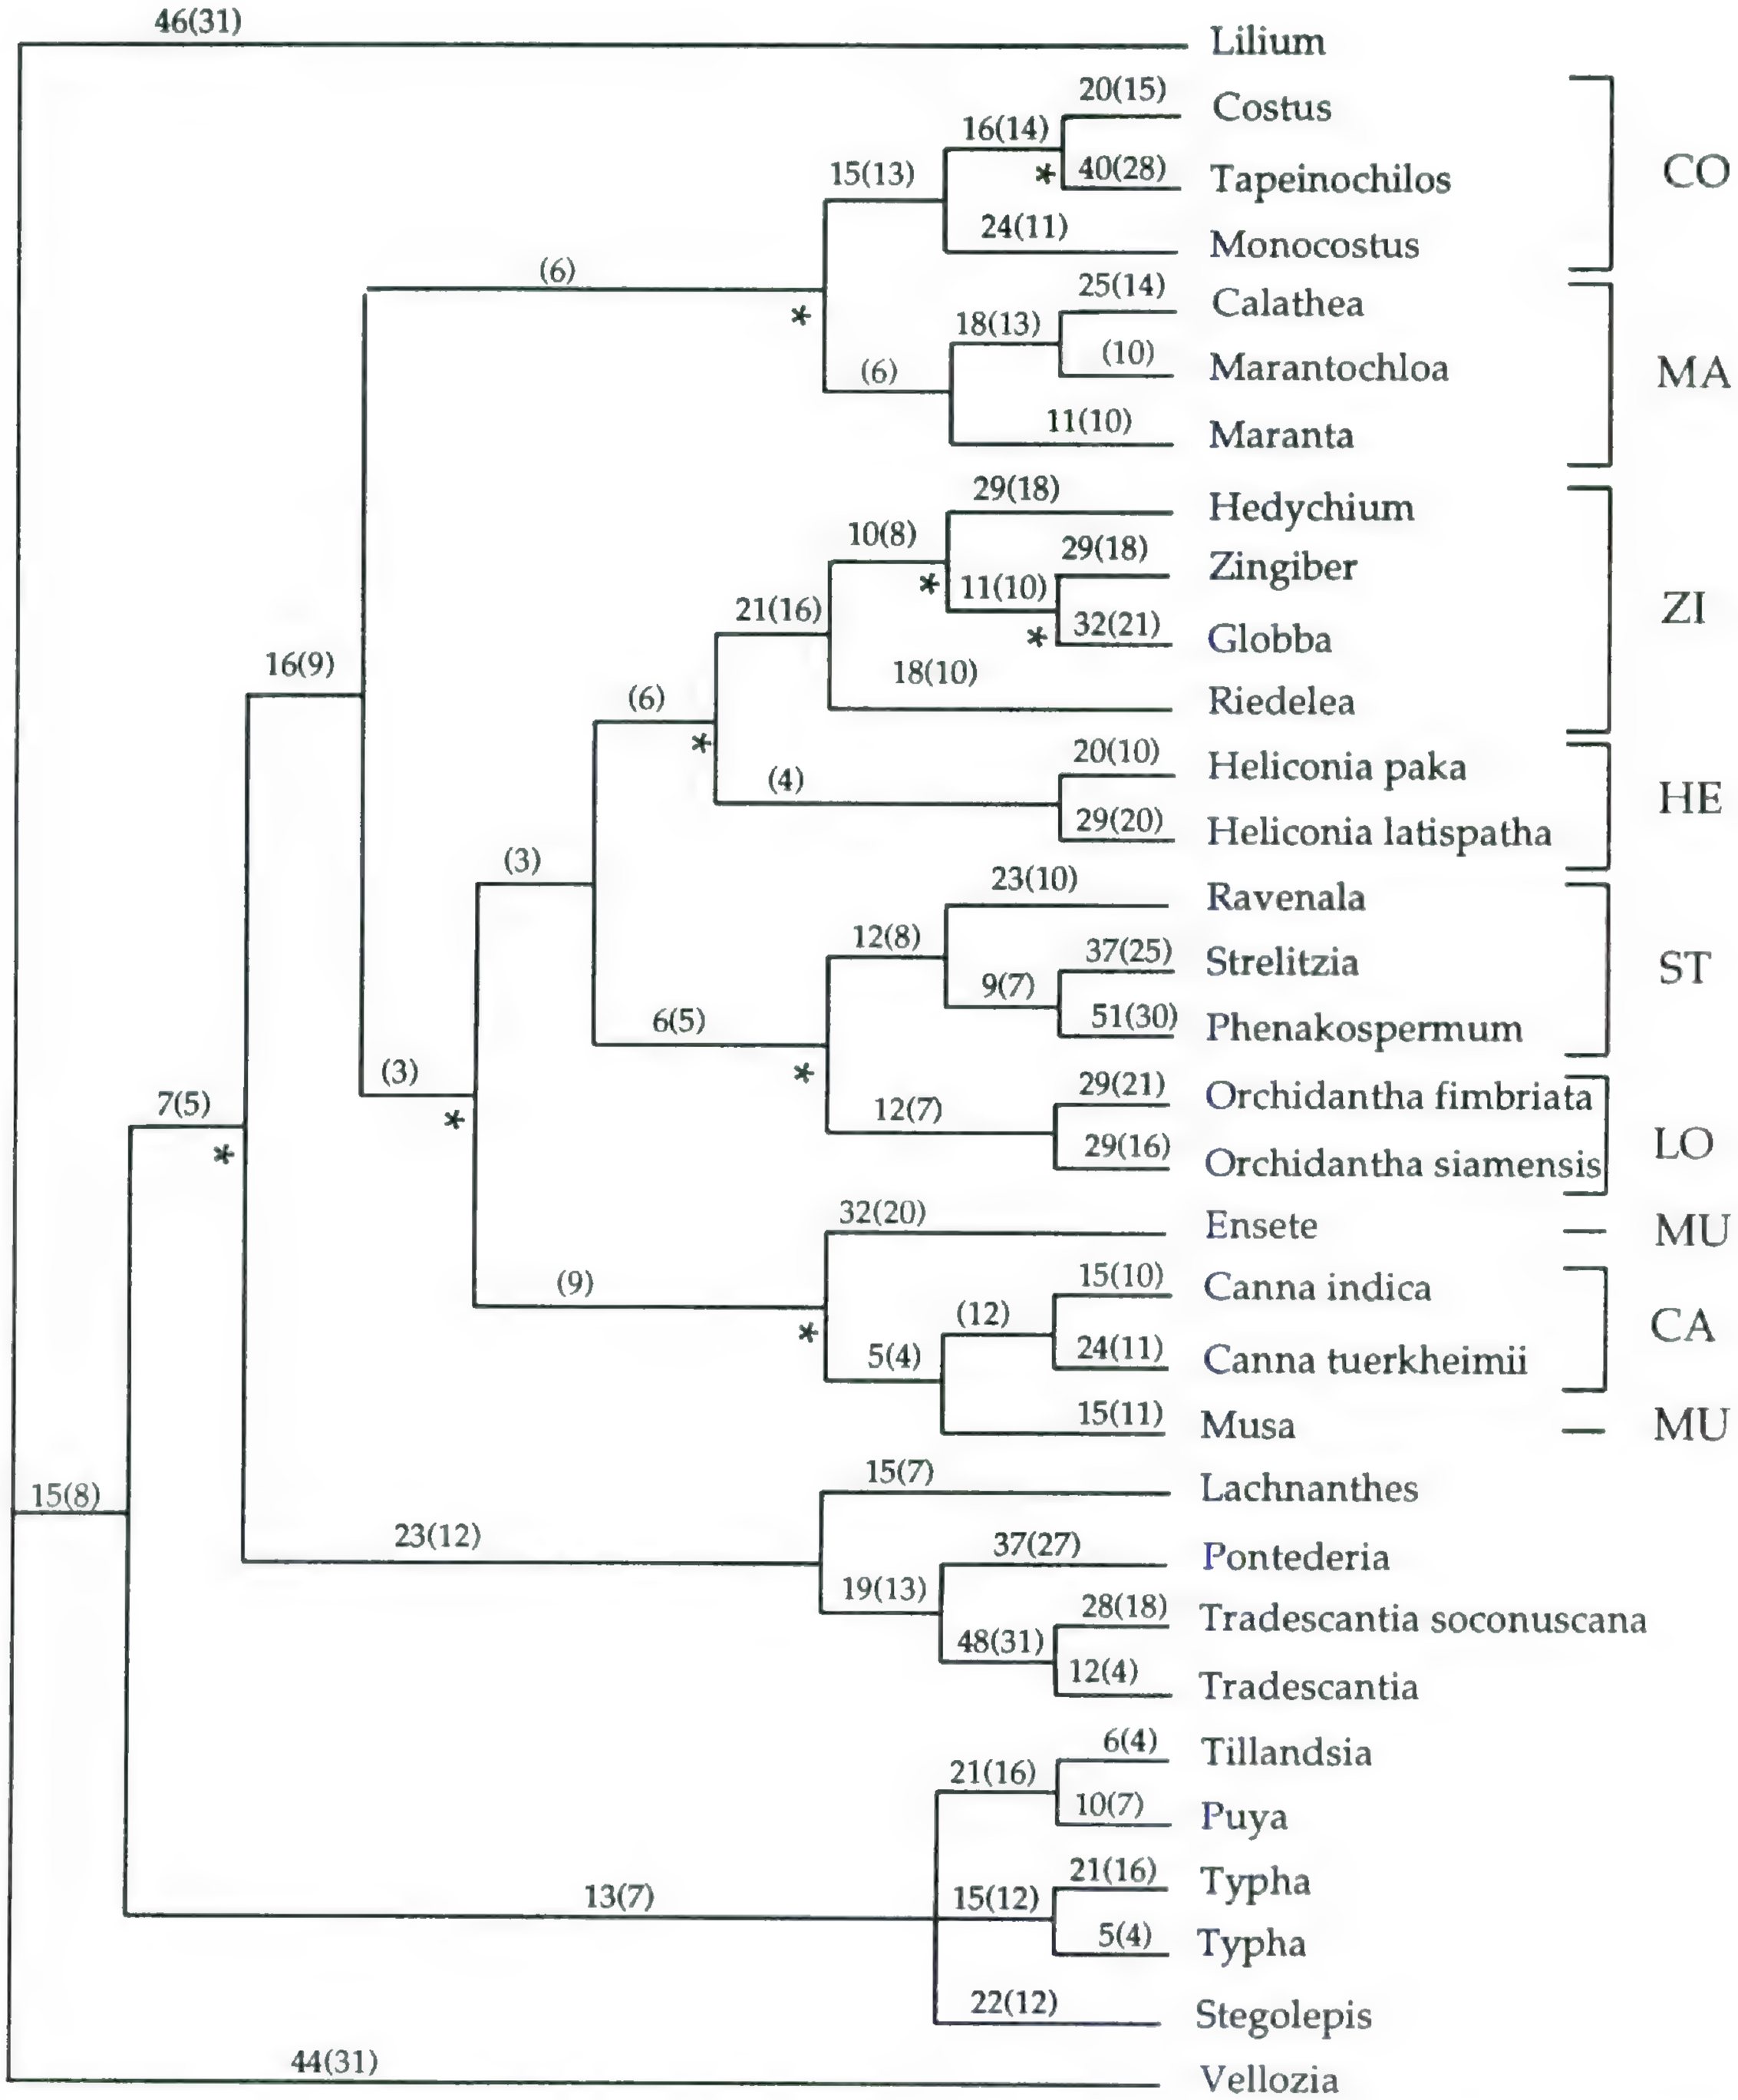

FIGURE 3. Strict consensus of the two most parsimonious trees from the equally weighted analysis. The two trees differ only in the relationships of *Stegolepis*/*Typha*/Bromeliaceae. Numbers along branches indicate substitutions supporting that clade, numbers in parentheses are the portion of substitutions that are homoplastic. Character state change distributions are based on tree 1 of the two most parsimonious trees (*Typha* as sister group to Bromeliaceae), and the ACCTRAN option. Asterisks denote clades that are lost in the consensus of the 62 trees one step longer than the most parsimonious trees (see Fig. 4). Families of the Zingiberales are denoted as follows: CO = Costaceae, MA = Marantaceae, ZI = Zingiberaceae, HE = Heliconiaceae, ST = Strelitziaceae, LO = Lowiaceae, MU = Musaceae, CA = Cannaceae.

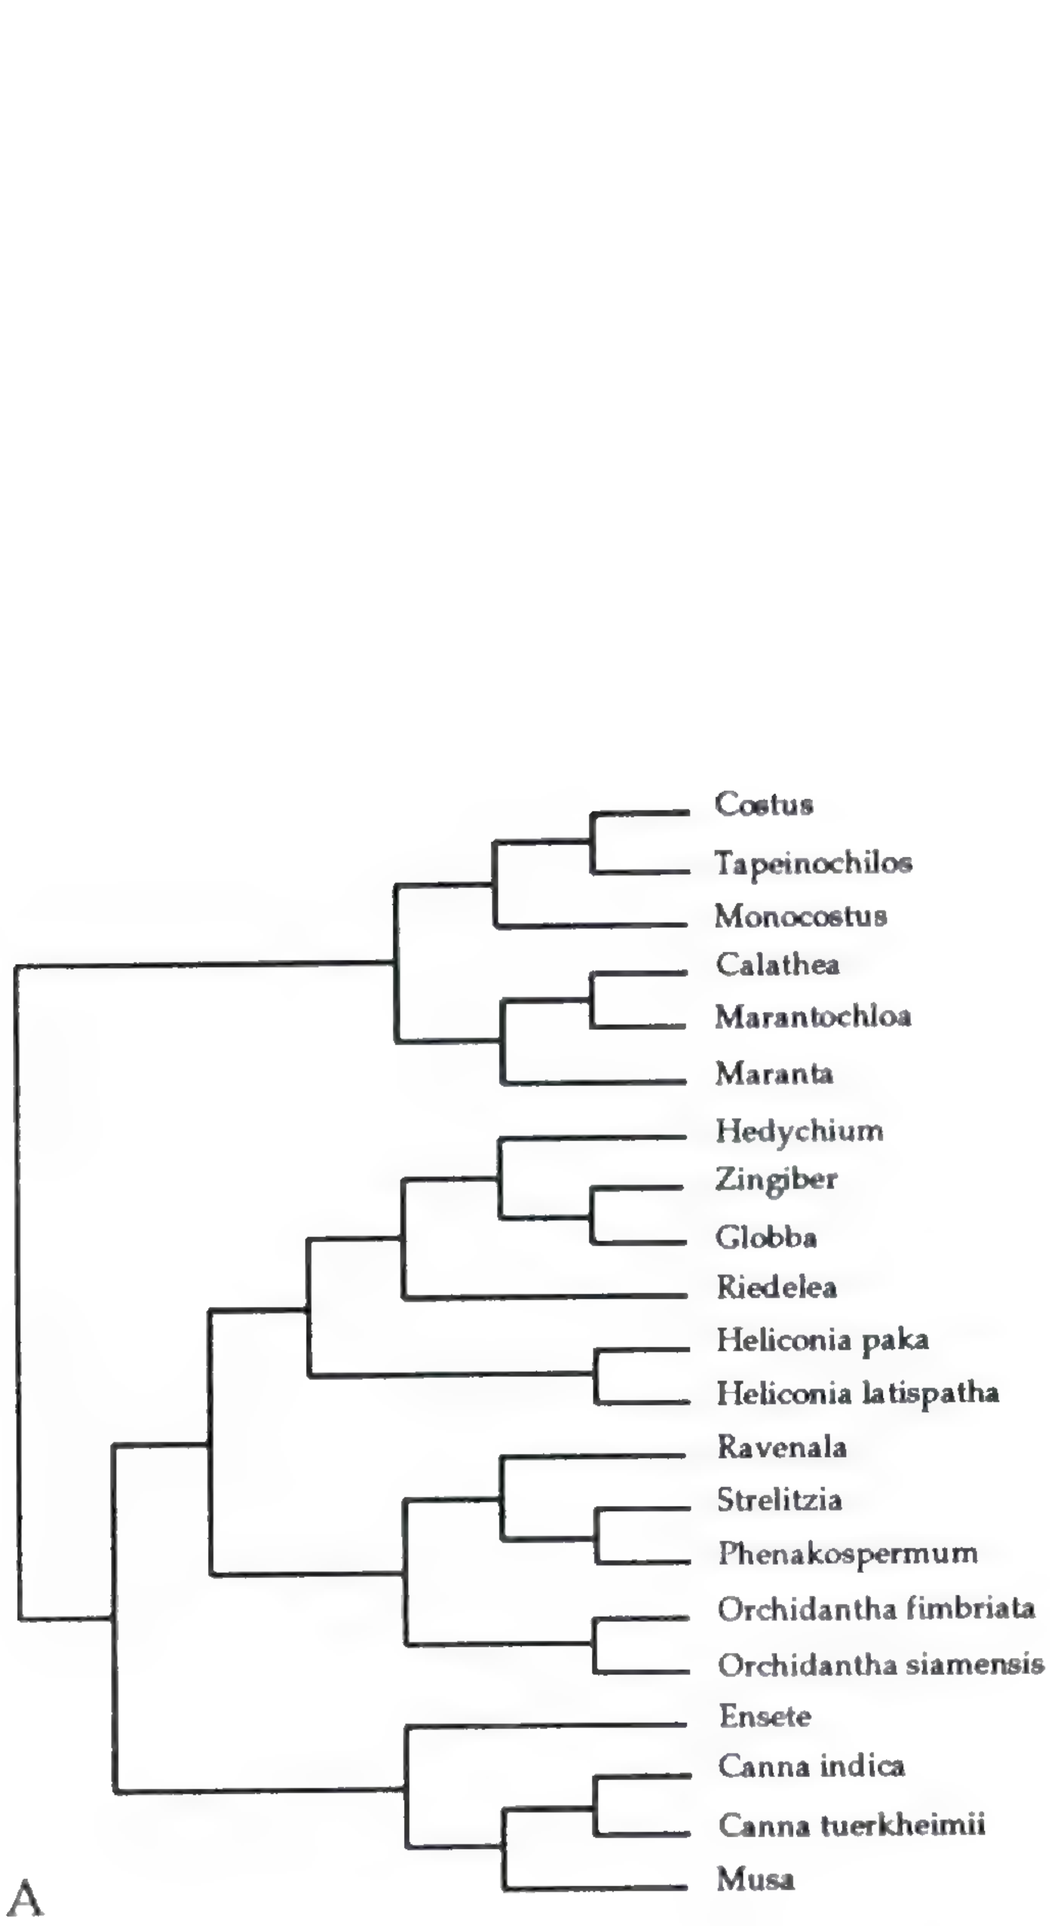

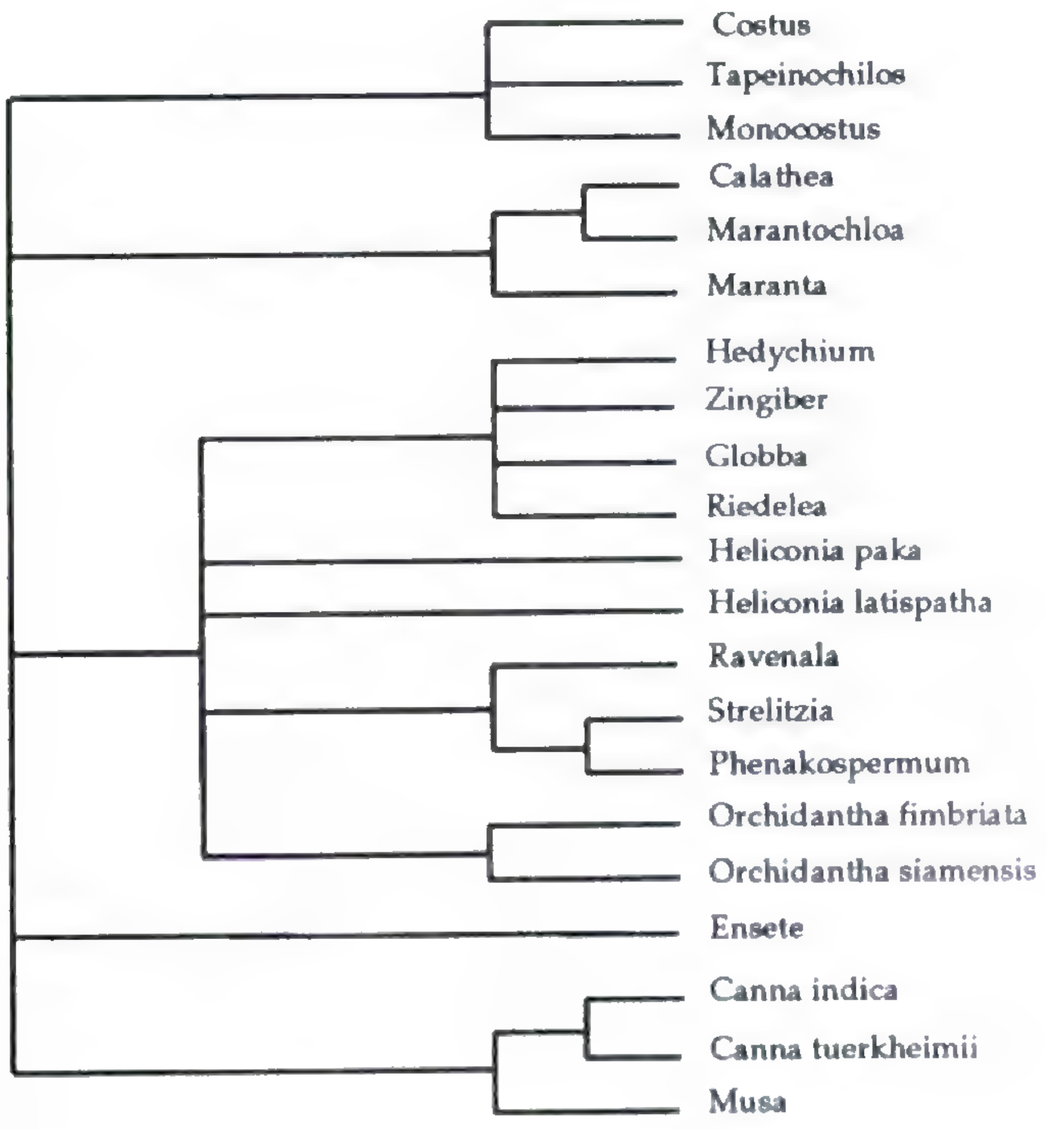

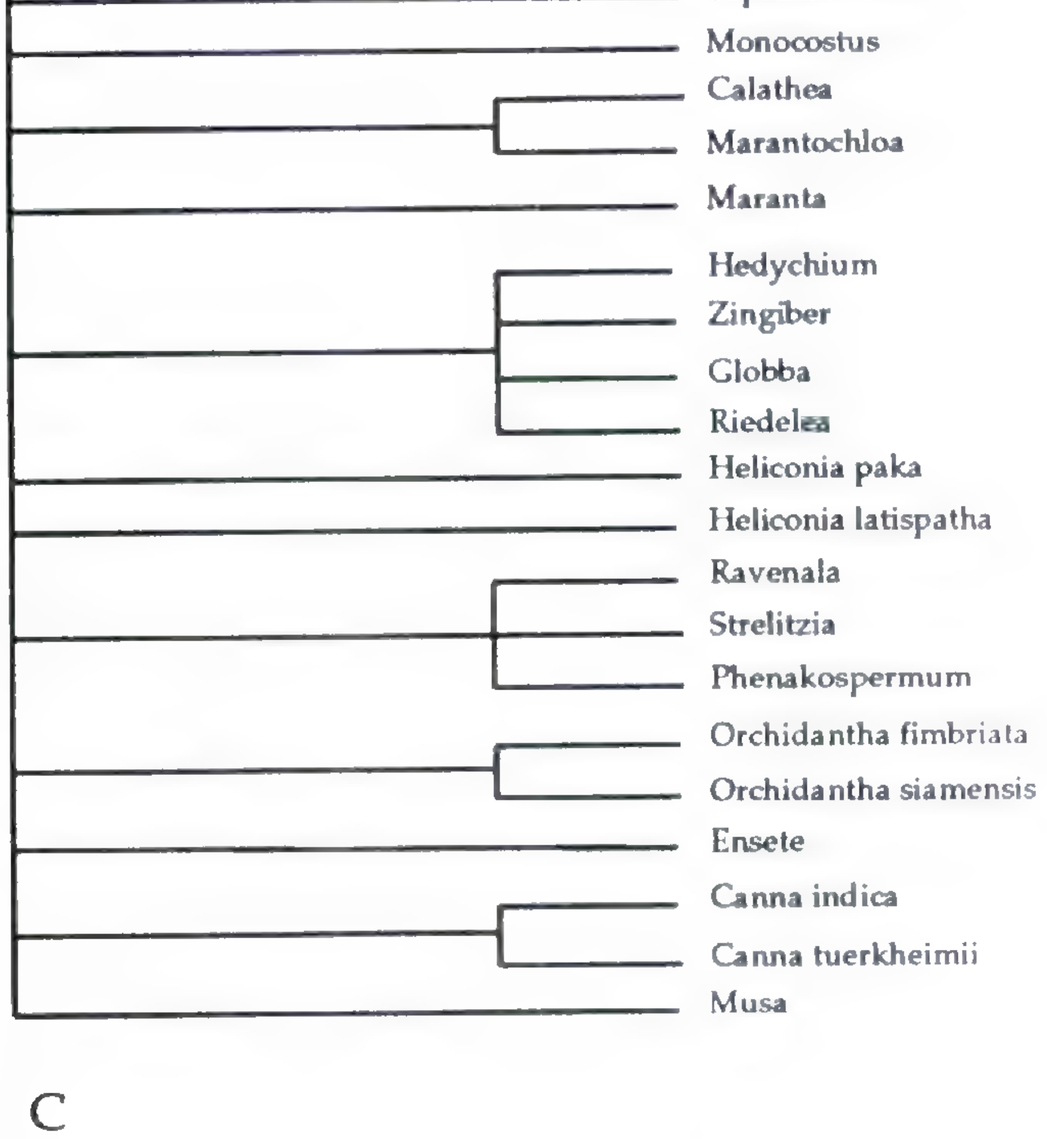

FIGURE 4. Strict consensus trees of the topologies based on A: two trees of 1,163 steps each, B: 62 trees of 1,164 steps each, and C: 1,541 trees of 1,165 steps each. Only taxa of the Zingiberales are illustrated in these figures.

based on *rbc*L sequence data (Duvall et al., 1993), the sister group relationships of the Zingiberales and the Haemodoraceae/Pontederiaceae/Commelinaceae is supported.

The Musaceae (paraphyletic with the Cannaceae) are the only family in the Zingiberales that is not monophyletic in the most parsimonious tree. The monophyly of the Heliconiaceae is also lost in

TABLE 3. Type of character state changes based on tree 1 of the most parsimonious trees (*Typha* and Bromeliaceae as sister groups) in the equally weighted analysis (Fig. 3). Transversions are indicated in bold.

| | A | C | G | T |
|---|---|---|---|---|
| A | — | **103** | 276 | **110** |
| C | — | — | **137** | 433 |
| G | — | — | — | **104** |

the consensus of trees one step longer. These discrepancies may be the result of limited sampling. Sequences for additional *Heliconia* and *Canna* species, as well as other representatives of the Musaceae, may stabilize these portions of the tree. The other six families are well supported as monophyletic groups by the molecular data even in the less parsimonious trees.

A clear weakness in this analysis is the unbalanced sampling for some of the families, e.g., Heliconiaceae and Musaceae. The addition of two to three more taxa for these families may result in a more robust analysis and provide a better overall estimate of phylogeny for the Zingiberales. In particular, the monophyly of these families would probably be more strongly supported by the addition of taxa to the analysis.

Regardless of the problem of uneven taxon sampling, the limitations of the data set are most apparent when the distribution of character state changes are mapped onto the tree (Fig. 3). Of the 281 phylogenetically informative characters used in the analysis, there are only 90 (32%) synapomorphic character state changes that are not homoplastic (based on Fig. 3). Within the Zingiberales, there is only one character state change that is synapomorphic between families and not homoplastic (Strelitziaceae and Lowiaceae lineage). In contrast, seven nonhomoplastic character state changes support the monophyly of the order, and 29 nonhomoplastic character state changes support monophyly of, or are synapomorphic within, the families of the Zingiberales. Likewise, the monophyly of the outgroup clades (Haemodoraceae/Pontederiaceae/Commelinaceae and Bromeliaceae/Typhaceae/Rapateaceae) is supported by nonhomoplastic character states (Fig. 3).

The weakness of the signal is also apparent when codon position is examined. Third position codons account for 58% of the variation in the data set and 70% of the homoplasy (Table 2). This is not a surprising result as the redundancy of the genetic code permits a higher rate of substitution at third position codons without altering the amino acid sequence of the resulting protein. However, the high percentage of homoplastic third position codons (139 of the 464 variable positions) and the presence of 3–4 different nucleotides at 64 of these sites indicate that the substitution rate within the Zingiberales may be close to saturation, thereby reducing the interpretable phylogenetic signal of the *rbc*L sequence data.

Our results suggest that although phylogenetic signal is present in the data, there is a "window" in which *rbc*L sequence data does not strongly resolve phylogenetic relationships. For the Zingiberales this window is at the between-family level. At the ordinal and family levels, the molecular data are much more robust in defining and resolving phylogenetic relationships.

An explanation for this window may be related to the age of the Zingiberales and the time since divergence of the families within the order. Olmstead et al. (1992) explained the lack of phylogenetic resolution of the higher dicot lineages as a result of rapid divergence of these clades during the late Cretaceous. In contrast, phylogenetic resolution of lineages within the Asteridae sensu lato is resolved adequately with *rbc*L sequence data (Olmstead et al., 1992).

Extant Zingiberales possess numerous derived morphological features, and five of the eight families are known from the fossil record (Kress, 1990). Although most of the fossil material has been collected in Eocene deposits, the oldest specimens are leaves of the Zingiberaceae from the late Cretaceous (Hickey & Peterson, 1978). The common ancestor of the lineages leading to the banana group is therefore hypothesized to have diverged from the remainder of the Zingiberales by the late Cretaceous (Friedrich, 1987), suggesting that the major lineages within the order had rapidly differentiated by the early Tertiary. These times of lineage splitting and divergence in the Zingiberales are similar to those described by Olmstead et al. (1992) for the higher dicots. The lack of phylogenetic resolution using *rbc*L data in these unrelated flowering plant taxa may be due to their common age of origin and diversification.

To further clarify phylogenetic relationships within the Zingiberales, data from other sources will be necessary. The morphological data will necessarily be re-examined to accommodate new interpretations of homology and to include taxa such that the molecular and morphological data sets will be directly comparable. Sequence data from the nuclear encoded 18S and 26S ribosomal genes are currently being collected for the Zingiberales (Kress et al., unpublished results), which have been suc-

cessful in resolving some ancient phylogenetic events in other seed plants (Hamby & Zimmer, 1992). Additional data may also be obtained by restriction site comparison of the highly conserved inverted repeat regions of the chloroplast genome (Downie & Palmer, 1992; Smith et al., unpublished results).

# PHYLOGENETIC RELATIONSHIPS AMONG MEMBERS OF SAXIFRAGACEAE SENSU LATO BASED ON *rbc*L SEQUENCE DATA[1]

*David R. Morgan*[2] *and Douglas E. Soltis*[2]

## ABSTRACT

In an attempt to elucidate relationships among the morphologically diverse members of Saxifragaceae sensu lato, phylogenetic analyses of *rbc*L sequence data were conducted on representative genera of 16 of the 17 subfamilies. Also included were many putatively related families, as well as a diverse array of dicotyledonous flowering plants. Our phylogenetic analyses suggest that taxa of Saxifragaceae sensu lato are allied with at least 10 separate, often distantly related, lineages of several subclasses of flowering plants. Sequence data, in combination with other lines of evidence, suggest that Saxifragaceae sensu stricto should consist only of subfamily Saxifragoideae, a group of about 30 herbaceous genera that form the core of Saxifragaceae sensu lato. These data also suggest that potential close relatives of Saxifragaceae sensu stricto include Iteoideae, Pterostemonoideae, and Ribesoideae and possibly Penthoroideae and Tetracarpaeoideae, all traditional subfamilies of Saxifragaceae sensu lato, as well as Crassulaceae. These members of Saxifragaceae sensu lato, along with Saxifragaceae sensu stricto, Crassulaceae, and several genera from the subclass Hamamelidae, are basal to a large assemblage of taxa, most of which are usually placed in Rosidae. Within this primarily rosid alliance, representatives of four other subfamilies of Saxifragaceae sensu lato (Francooideae, Baueroideae, Parnassioideae, and Lepuropetaloideae) are allied with the rosid families Greyiaceae, Cunoniaceae, and Celastraceae. According to *rbc*L sequence evidence, Hydrangeoideae and Cornaceae are closely related members of a clade that is basal to a large group of taxa primarily from subclass Asteridae. Representative genera of four subfamilies of Saxifragaceae sensu lato (Phyllonomoideae, Escallonioideae, Montinioideae, and Vahlioideae) are in our results allied with taxa usually included in Asteridae. Significantly, relationships of Saxifragaceae sensu lato suggested by *rbc*L sequence data are in very close agreement with those supported by several other lines of evidence, especially embryology, serology, and iridoid chemistry.

Many systematists consider Saxifragaceae to occupy a pivotal position in the evolution of a number of major angiosperm lineages. Takhtajan (1969, 1980), for example, described such diverse groups as Myrtales, Cornales, Celastrales, Gentianales, and Campanulales as all having been derived from an ancestral "Saxifragalean stock." In spite of its potential evolutionary importance, however, Saxifragaceae are one of the least understood families of flowering plants. The family has been thought to consist of a wide array of morphologically diverse taxa, and the heterogeneity among the proposed constituents of Saxifragaceae is so great that the family has been nearly impossible to define. As a result, few families of angiosperms offer the magnitude and diversity of systematic problems posed by Saxifragaceae.

Many different classifications of Saxifragaceae have been proposed; a partial listing includes Cronquist (1981), Dahlgren (1975a, 1980, 1983), Dahlgren et al. (1981), Engler (1890, 1928), Hutchinson (1973), Schulze-Menz (1964), Takhtajan (1969, 1980, 1987), and Thorne (1968, 1976, 1983, 1992). These schemes of classification differ from one another not only in how they define Saxifragaceae, but also in how they ally them with other families. Frequently, the differences among classifications of Saxifragaceae are substantial.

A comparison of six recent classifications of the family is shown in Table 1. Saxifragaceae were broadly defined by Engler (1890, 1928) and Schulze-Menz (1964). The Saxifragaceae of Schulze-Menz (1964) are the most broadly de-

fined, consisting of 17 subfamilies: Saxifragoideae, Penthoroideae, Tetracarpaeoideae, Ribesoideae, Iteoideae, Pterostemonoideae, Baueroideae, Francooideae, Brexioideae, Parnassioideae, Lepuropetaloideae, Hydrangeoideae, Phyllonomoideae, Escallonioideae, Montinioideae, Vahlioideae, and Eremosynoideae (Table 1). In this paper, we will use this classification as a reference and will refer to it as Saxifragaceae sensu lato (Saxifragaceae *s. l.*). Saxifragaceae *s. l.* are a heterogeneous assemblage, including annual, biennial, and perennial herbs, shrubs, trees, and woody vines, and also having considerable chemical, anatomical, palynological, and cytological diversity.

Most recent authors have defined Saxifragaceae more narrowly and treated many members of Saxifragaceae *s. l.* either as separate families or as components of other families. Hutchinson (1973; Table 1) separated the woody and herbaceous constituents of Saxifragaceae *s. l.*, allying the woody taxa with Cunoniaceae. Other authors do not draw as sharp a distinction as did Hutchinson but do tend to separate woody from herbaceous taxa. Some classifications (e.g., Cronquist, 1981; Table 1), while defining Saxifragaceae narrowly, nevertheless included most members of Saxifragaceae *s. l.* in one order (Rosales), suggesting a fairly close relationship among them. Others, in contrast (Dahlgren, 1983; Takhtajan, 1987; Thorne, 1992; Table 1), considered some of the herbaceous and woody members of Saxifragaceae *s. l.* to be only distantly related and allied many of the woody taxa with groups such as Cornales.

The widely divergent views regarding the composition and affinities of Saxifragaceae clearly indicate that the family remains enigmatic. Although some experimental research has provided useful insights (e.g., Bensel & Palser, 1975a, b, c, d; Grund & Jensen, 1981; Hideux & Ferguson, 1976), the actual phylogenetic affinities of the taxa composing Saxifragaceae *s. l.* remain poorly understood. Results from a preliminary study of Saxifragaceae *s. l.* using sequence data from the chloroplast gene *rbc*L (Soltis et al., 1990) suggested strongly that this approach should prove useful in unravelling the taxonomic problems surrounding Saxifragaceae *s. l.* This study revealed that several of the constituent subfamilies are only distantly related to one another. We therefore initiated a broad phylogenetic analysis of *rbc*L sequence data from taxa representing not only Saxifragaceae *s. l.*, but also many putative relatives. We also included sequences representing a diverse array of dicot families, with two major objectives. The first objective was to ascertain how best to define Saxifragaceae. Secondly, we hoped to determine potential close relatives of the members of Saxifragaceae *s. l.* based on *rbc*L sequences currently available.

## Materials and Methods

We generated *rbc*L sequences from at least one representative of 16 of the 17 subfamilies of Saxifragaceae *s. l.* (Table 1). The only subfamily not analyzed was Eremosynoideae. Material of this subfamily could not be obtained (despite repeated attempts) because of its restricted distribution in western Australia. Fourteen of the subfamilies consist of only one or two genera (Table 1); hence, the one *rbc*L sequence obtained from each represents a nearly complete generic sampling. The largest subfamilies are Saxifragoideae and Hydrangeoideae, which consist of approximately 30 and 17 genera, respectively. We sequenced at least five representatives from each of these two subfamilies.

The many proposed classifications of Saxifragaceae have resulted in a long list of possible allies of Saxifragaceae *s. l.* We therefore generated one or more *rbc*L sequences from each of several families that have been considered closely related to members of Saxifragaceae *s. l.* in most taxonomic schemes (Crassulaceae, Cephalotaceae, Droseraceae, Greyiaceae, Cunoniaceae and its allies, Gunneraceae, and Rosaceae). Sequences were also generated for many other potentially related families (Pittosporaceae, Roridulaceae, Garryaceae, and Cornaceae and its relatives). Additional *rbc*L sequences representing a diverse array of dicots were also used in our phylogenetic analyses. These sequences were obtained from many other investigators (listed in the Appendix at the end of this issue). Plant material for sequencing was obtained from field collections, plants grown from seed, silica gel-dried leaf material, or, in a few cases, herbarium specimens (information on sources of plant material is also given in the Appendix at the end of this issue). Total DNA was extracted using a CTAB buffer method (Doyle & Doyle, 1987) as modified by Soltis et al. (1991).

### Amplification and Sequencing

With the exception of the eight sequences originally reported from Saxifragaceae *s. l.* (Soltis et al., 1990), *rbc*L was amplified using thermostable DNA polymerase. We performed amplifications using either *Taq* I polymerase (Promega) or Replitherm (Epicentre Technologies) following the directions of the manufacturers. Synthetic oligonucleotides were used as primers. The forward

primer (Z1) represents bases 1–30 of *rbc*L from *Zea mays* L. The reverse primer typically employed (3′ *rbc*L) is external to the 3′ end of the *rbc*L gene. This primer is 34 nucleotides long, corresponds to the sequence of *Nicotiana*, and begins 103 base pairs outside the coding sequence termination of the gene in *Nicotiana* (Olmstead et al., 1992). In several instances we were unable to amplify *rbc*L using this Z1-3′ *rbc*L primer combination. In these taxa, *rbc*L was successfully amplified using an internal reverse primer (Z1351R) in place of the 3′ *rbc*L primer. The Z1351R primer represents bases 1351–1380 of *rbc*L from *Zea mays*.

Two amplifications were performed. A double stranded reaction with both forward and reverse primers was first performed. The double stranded product was subsequently used as a template in an amplification using only one primer to produce single-stranded DNA for sequencing. Single-stranded DNA was then purified by precipitation with a 20% PEG/2.5 M NaCl solution, washes in 70% and 95% ethanol, and resuspension in 1 × TE.

Purified single-stranded products were sequenced directly. Both forward and reverse strands were sequenced using 30-mer primers corresponding to the *rbc*L sequence of *Zea mays*. These primers were kindly provided by G. Zurawski; six sequencing primers were used for each strand. Dideoxy sequencing reactions were performed using the Sequenase version 3.1 kit (United States Biochemicals) and $^{35}$S dATP. Fragments were separated at 2,000 volts/70 watts in 6% polyacrylamide gels (0.4 mm thick), using 1 × TBE buffer. Gels were fixed with 10% acetic acid, washed with distilled water, dried, and used to expose Kodak X-Omat AR film for 16–24 hours.

A total of 1,377 base pairs of *rbc*L (bases 31–1407) was standardly used for analysis. Several of our sequences from Saxifragaceae *s. l.* were amplified by cloning (Soltis et al., 1990). Because the cloning site was just inside the 3′ end of the gene, our sequence data for these taxa do not extend past base pair 1407. Therefore, our comparisons herein involve *rbc*L sequence data up to base pair 1407. The first 30 base pairs were also not used because, after amplification, this portion of the gene is identical to the Z1 forward amplification primer. Most taxa were amplified with the external reverse primer (3′ *rbc*L), but *Chrysobalanus*, *Licania*, *Kalanchoe*, *Crassula*, *Sedum*, *Dudleya*, and *Eucryphia* could only be amplified with the internal reverse primer (Z1351R), and for these seven taxa 1,320 base pairs of sequence data (bases 31–1350) were used.

PHYLOGENETIC ANALYSIS

Sequence data were analyzed using PAUP version 3.0s (Swofford, 1991). Because the various *rbc*L-supported lineages of Saxifragaceae *s. l.* are allied with so many distantly related taxa, several phylogenetic analyses were necessary to best determine potential relatives of all the component subfamilies. These analyses were carried out using the results of a previous broad analysis as an initial framework (Chase et al., 1993).

According to Maddison (1991), multiple "islands," or separate clusters, of most parsimonious trees are likely to be present for a given data set, especially if it includes a large number of taxa. To maximize our chances of finding as many shortest trees as possible, we performed as part of each analysis a series of searches aimed specifically at finding multiple islands of trees.

Two primary tree search methods were employed. In the first method, 200 consecutive searches were performed without MULPARS using random taxon addition and nearest-neighbor-interchange (NNI) branch-swapping. This search normally resulted in one to three relatively short trees. Each of the shortest trees resulting from this search was used as the starting tree for a subsequent search with MULPARS using tree-bisection-reconnection (TBR) branch-swapping. This set of analyses was repeated several times (each time a different random number seed for the NNI search was used) with the TBR tree searches each beginning with a different starting tree, the expectation being that several analyses with different starting trees would find multiple islands of shortest trees if they exist.

In the second tree search method employed, 50 consecutive searches were performed with MULPARS using random taxon addition and TBR branch-swapping. To reduce the amount of time involved, the program was allowed to save no more than ten trees of any length longer than that of the shortest trees found by using the first method, above. This second search strategy was recommended by Swofford (1991). We compared the results of these two search methods with those obtained using a widely employed method of analysis: a single search using simple taxon addition and TBR branch-swapping. The results of these comparisons will be discussed below.

Our initial broad analysis included all of our representatives of Saxifragaceae *s. l.* and putative relatives plus a broad sampling of non-magnoliid dicots. This analysis included 100 taxa and was performed to: (1) obtain a rough approximation of

likely alliances of the members of Saxifragaceae *s. l.* and (2) help focus subsequent, more detailed analyses of smaller groups that include members of Saxifragaceae *s. l.* The initial broad analysis made use of the first search method described above and involved three separate tree searches, each with a different starting tree. The resulting trees were rooted with an outgroup consisting of *Tetracentron*, *Trochodendron*, *Sabia*, and *Platanus* because in the broad analysis of Chase et al. (1993) these genera were identified as sister taxa to the group that we analyzed.

With the results of our initial broad analysis as a guide, four subsequent, more detailed analyses were conducted using subsets of the larger data set to identify more accurately potential relatives of taxa of Saxifragaceae *s. l.* For each of these four subsequent analyses portions of the *rbc*L-based phylogeny resulting from our initial broad analysis were selected, with particular attention given to groups that occurred in the results of both our initial analysis and that of Chase et al. (1993). Additional sequences were added to the four groups based on the results of the analysis of Chase et al. (1993) so that each group would contain greater taxon density. For each of these four analyses, an outgroup was specified consisting of five taxa that were closely related to and basal to the group being analyzed. Tree searches for these four analyses employed both primary search methods described above. Seven separate TBR searches were conducted using the first method. Because some of these analyses resulted in very few shortest trees, we decided to perform further analyses using the second search method, hoping to find additional shortest trees. Three of the four groups were also subjected to bootstrap analyses, which were performed using 100 replicates, simple taxon addition, TBR branch-swapping, and MULPARS.

## Results

We have chosen to show for our initial broad analysis, as well as our four subsequent smaller analyses, the 50% majority-rule consensus tree because it effectively summarizes the major features present among all shortest trees. Additionally, we have constructed each majority-rule consensus tree so that it includes compatible groupings of less than 50% occurrence. For our broad analysis and our four smaller analyses we obtained in each case a consensus tree identical to one of the shortest trees; thus we can place nucleotide substitutions on these trees (Figs. 1–5).

Our initial broad analysis of 100 sequences included three separate tree searches, each of which found a different island of trees. The first search found 351 trees, 3,811 steps long, the second found 27 trees, 3,811 steps long, and the third found nonminimal trees (3,812 steps long). The majority-rule consensus tree was constructed from the 378 trees that were 3,811 steps long (Fig. 1). Two portions of this tree were selected for further analysis (see Fig. 1). For convenience we will refer to them as the "rosid clade" and the "asterid clade," although both include many taxa normally included in other subclasses.

Analysis of the rosid clade resulted in 16 shortest trees, 3,060 steps long, in two islands of eight trees each (Fig. 2). The second search method found both islands, but one of the two islands was not found by the first search method or by the single analysis using simple taxon addition. One of the objectives of our analysis was to obtain information on the amount of support for alliances involving members of Saxifragaceae *s. l.* using bootstrap analysis. Because of the size of the rosid clade (86 taxa) it was necessary to conduct further analyses of the group by dividing it into two smaller parts, which we will refer to as rosid groups A and B. Group B consists of an alliance of 61 taxa taken from within the rosid clade, a group supported by 10 nucleotide substitutions (see Fig. 2). A second group (group A) was formed to accomplish further analysis of the remaining taxa of the rosid clade (i.e., those outside of group B). For this analysis, the number of taxa in the rosid clade was reduced by deleting 31 sequences from among those included in group B. Group A, therefore, included the same taxa as did the rosid clade, except that group B was represented in the analysis by 30 taxa rather than 61 (see Fig. 2).

Analysis of rosid group A resulted in 12 shortest trees, 2,000 steps long, in only one island (Fig. 3). These 12 trees were found by both primary search methods and by the single analysis using simple taxon addition. The taxa that we will emphasize as part of group A include representatives of "core" Saxifragaceae (i.e., subfamily Saxifragoideae) as well as genera representing five other subfamilies: *Itea* (Iteoideae), *Pterostemon* (Pterostemonoideae), *Ribes* (Ribesoideae), *Penthorum* (Penthoroideae), and *Tetracarpaea* (Tetracarpaeoideae).

Analysis of rosid group B resulted in 40 shortest trees, 2,584 steps long, in four islands of 2, 4, 14, and 20 trees (Fig. 4). All four islands of shortest trees were found by both primary search methods, but the single analysis using simple taxon addition found only the island consisting of two trees. Representatives of several subfamilies of Saxifragaceae

*s. l.* are included in group B: *Francoa* (Francooideae), *Bauera* (Baueroideae), *Brexia* (Brexioideae), *Parnassia* (Parnassioideae), and *Lepuropetalon* (Lepuropetaloideae).

Analysis of the asterid clade resulted in 36 shortest trees, 1,496 steps long, in one island (Fig. 5). These 36 trees were found by both primary search methods and by the single analysis using simple taxon addition. The asterid clade includes, in addition to many taxa usually included in subclass Asteridae (sensu Cronquist, 1981), representatives of five subfamilies of Saxifragaceae *s. l.*: *Escallonia* (Escallonioideae), *Phyllonoma* (Phyllonomoideae), *Vahlia* (Vahlioideae), *Montinia* (Montinioideae), and five genera of Hydrangeoideae. According to our *rbc*L sequence data, all of these taxa are distantly related to core members of Saxifragaceae (Olmstead et al., 1993, have conducted more detailed analyses of taxa in Asteridae).

## Discussion

Our phylogenetic analysis of *rbc*L sequences indicates that the taxa traditionally included in Saxifragaceae *s. l.* are not a monophyletic assemblage. Rather, they are allied with at least ten different, often very distantly related, lineages representing most of the traditionally recognized subclasses of dicots (Fig. 1). The results of this analysis do not correspond closely with any proposed classification of Saxifragaceae; in many cases *rbc*L sequence data suggest relationships that differ substantially from traditional classifications. For ease of presentation, we will discuss the systematic implications of this study by examining the relationships of each of the subfamilies of Saxifragaceae *s. l.* individually. Our discussion will be divided into five parts corresponding to more inclusive alliances involving the subfamilies of Saxifragaceae *s. l.*: I. Saxifragoideae and associated subfamilies (Saxifragoideae, Iteoideae, Pterostemonoideae, Ribesoideae); II. Subfamilies associated with Crassulaceae (Penthoroideae, Tetracarpaeoideae); III. Subfamilies associated with other families of Rosidae (Baueroideae, Francooideae, Brexioideae, Parnassioideae, Lepuropetaloideae); IV. Subfamilies associated with Cornaceae (Hydrangeoideae); V. Subfamilies associated with Asteridae (Phyllonomoideae, Escallonioideae, Montinioideae, Vahlioideae).

### I. Saxifragoideae and associated subfamilies

*Saxifragoideae.* It is generally agreed that approximately 30 genera placed in Saxifragoideae (Table 1) comprise a natural group. These taxa share many morphological, anatomical, and chemical features, and most classifications maintain these genera as a distinct group at the familial, subfamilial, or tribal level. Saxifragoideae are the core of the original Saxifragaceae *s. l.* and some classifications define Saxifragaceae so narrowly that the family consists only of this subfamily or perhaps a few additional taxa. For example, the Saxifragaceae of Takhtajan (1987) and Thorne (1992) are basically equivalent to Schulze-Menz's subfamily Saxifragoideae. Saxifragaceae as defined by Hutchinson (1973) and Dahlgren (1983) consist only of Saxifragoideae and a few genera from other subfamilies of Saxifragaceae *s. l.*. Other classifications (e.g., Cronquist, 1981) include still additional genera in the family.

The results of our analyses support the monophyly of Saxifragoideae by defining a monophyletic group composed of six genera of the subfamily (Figs. 2, 3). These data also suggest that many subfamilies that have been combined with Saxifragoideae to form broader versions of Saxifragaceae (e.g., Parnassioideae, Lepuropetaloideae, Penthoroideae, Francooideae, Vahlioideae; Fig. 1) are distantly related to Saxifragoideae.

The distinctiveness of Saxifragoideae and the distant relationships between them and other subfamilies are confirmed by other molecular data. Downie et al. (1991) have determined that some angiosperms lack the intron of the chloroplast gene *rpl2*. Significantly, this intron is absent in all tested species of Saxifragoideae but present in genera from all other subfamilies of Saxifragaceae *s. l.* examined (Iteoideae, Ribesoideae, Francooideae, Penthoroideae, Brexioideae, Escallonioideae, Par-

Figure 2. Majority-rule consensus tree (including compatible groupings) constructed from 16 most parsimonious trees resulting from phylogenetic analysis of *rbc*L sequences of the rosid clade. This tree is identical to one of the 16 shortest trees and has a consistency index of 0.293 and a retention index of 0.496. Arrows point to nodes that did not occur in all shortest trees; all other nodes were present in all 16 most parsimonious trees. Numbers above each branch indicate the number of base substitutions. Names of taxa of Saxifragaceae sensu lato are shown in capital letters and boldface type. Rosid group B, selected for further analysis, is indicated by a bracket and labeled. Taxa not included in the rosid group A analysis are indicated by asterisks.

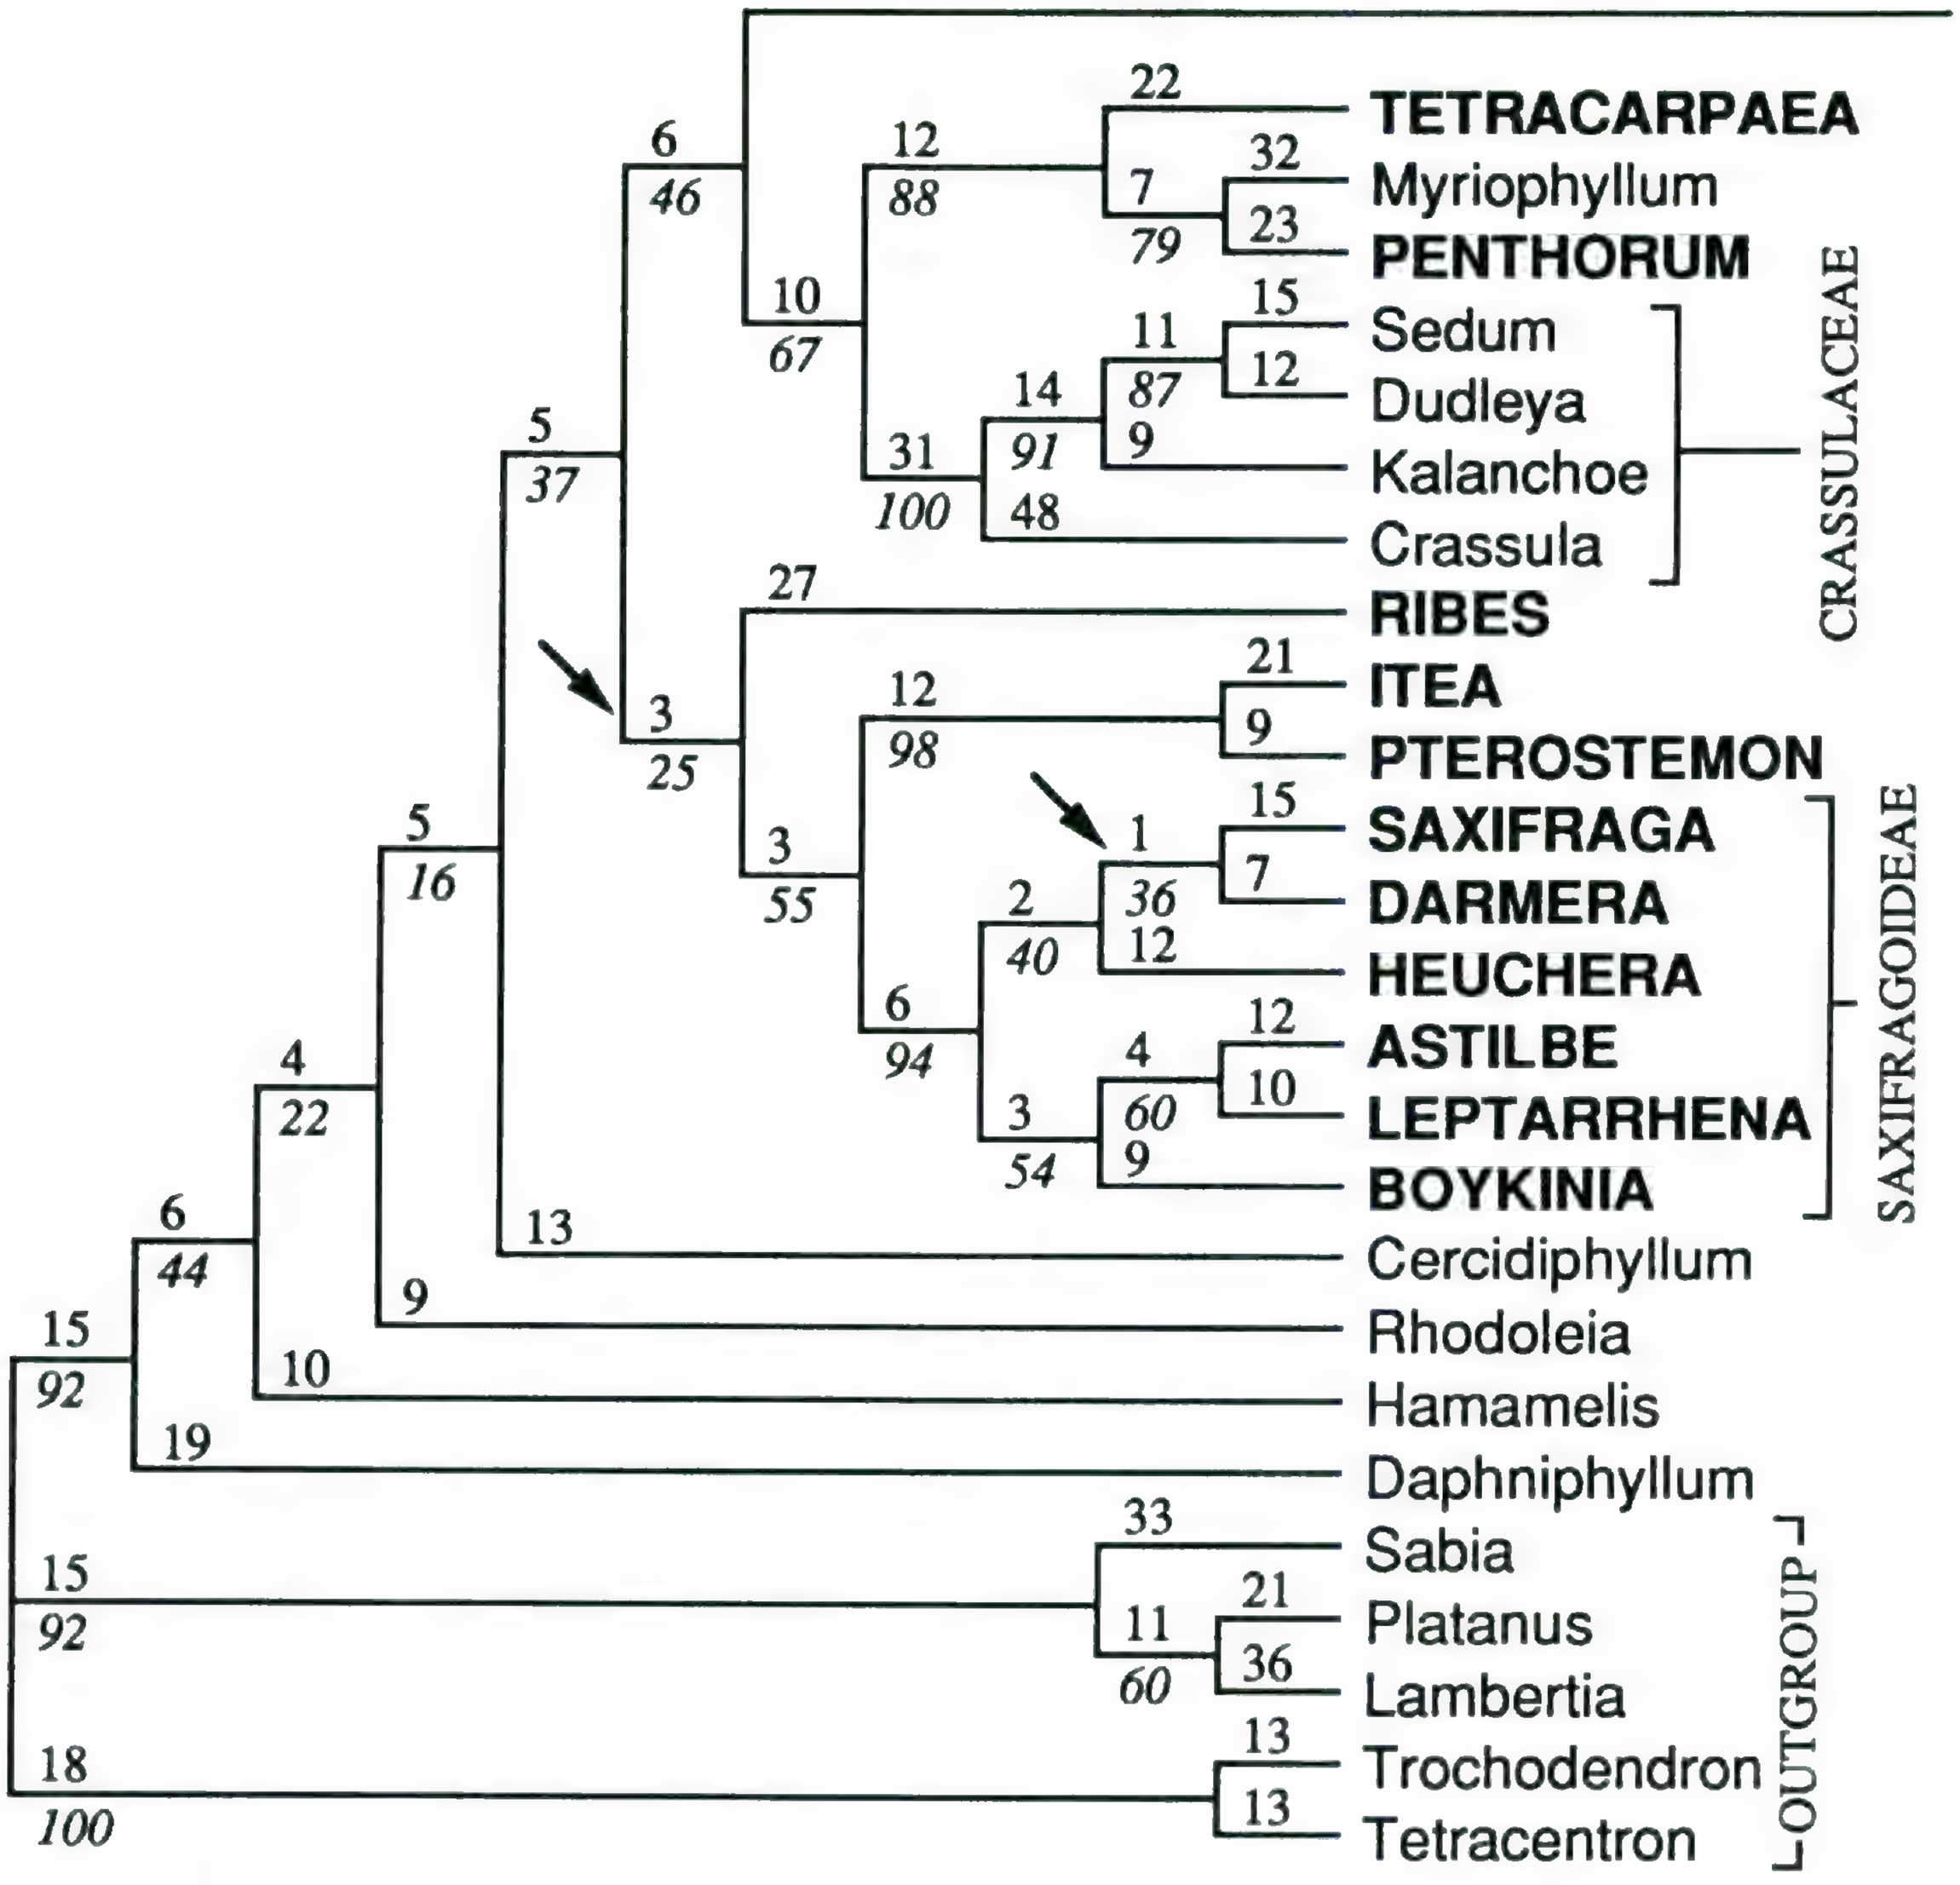

FIGURE 3. Majority-rule consensus tree (including compatible groupings) constructed from 12 most parsimonious trees resulting from phylogenetic analysis of *rbc*L sequences of rosid group A. This tree is identical to one of the 12 shortest trees and has a consistency index of 0.374 and a retention index of 0.473. Arrows point to nodes that did not occur in all shortest trees; all other nodes were present in all 12 most parsimonious trees. Numbers above each branch indicate the number of base substitutions; numbers in italics below each branch indicate the percentage occurrence of each monophyletic group in the results of 100 bootstrap replicates. Names of taxa of Saxifragaceae sensu lato are shown in capital letters and boldface type.

nassioideae, Hydrangeoideae). Downie et al. (1991) suggested that the *rpl*2 intron has been lost in six separate angiosperm lineages, one of them being Saxifragoideae. Chloroplast DNA restriction site data (Soltis et al., 1993) likewise support Saxifragoideae being a distinct group. According to cpDNA restriction site data, Saxifragoideae are a well-supported monophyletic group separate from *Ribes* and *Francoa*, two taxa that have very often been associated with it. These three lines of evidence suggest that the family Saxifragaceae would be best defined as comprising only subfamily Saxifragoideae (sensu Schulze-Menz, 1964) and that other subfamilies of Saxifragaceae *s. l.* should be treated either as separate families or as members of other families. This narrow definition of Saxifragaceae is identical to the concept of the family proposed by Takhtajan (1987) and Thorne (1992).

In addition to helping resolve a long-standing taxonomic problem (the composition of Saxifragaceae), *rbc*L sequence data are of value in identifying potential close relatives of this narrowly defined group and in determining the possible affinities of the other subfamilies of Saxifragaceae *s.*

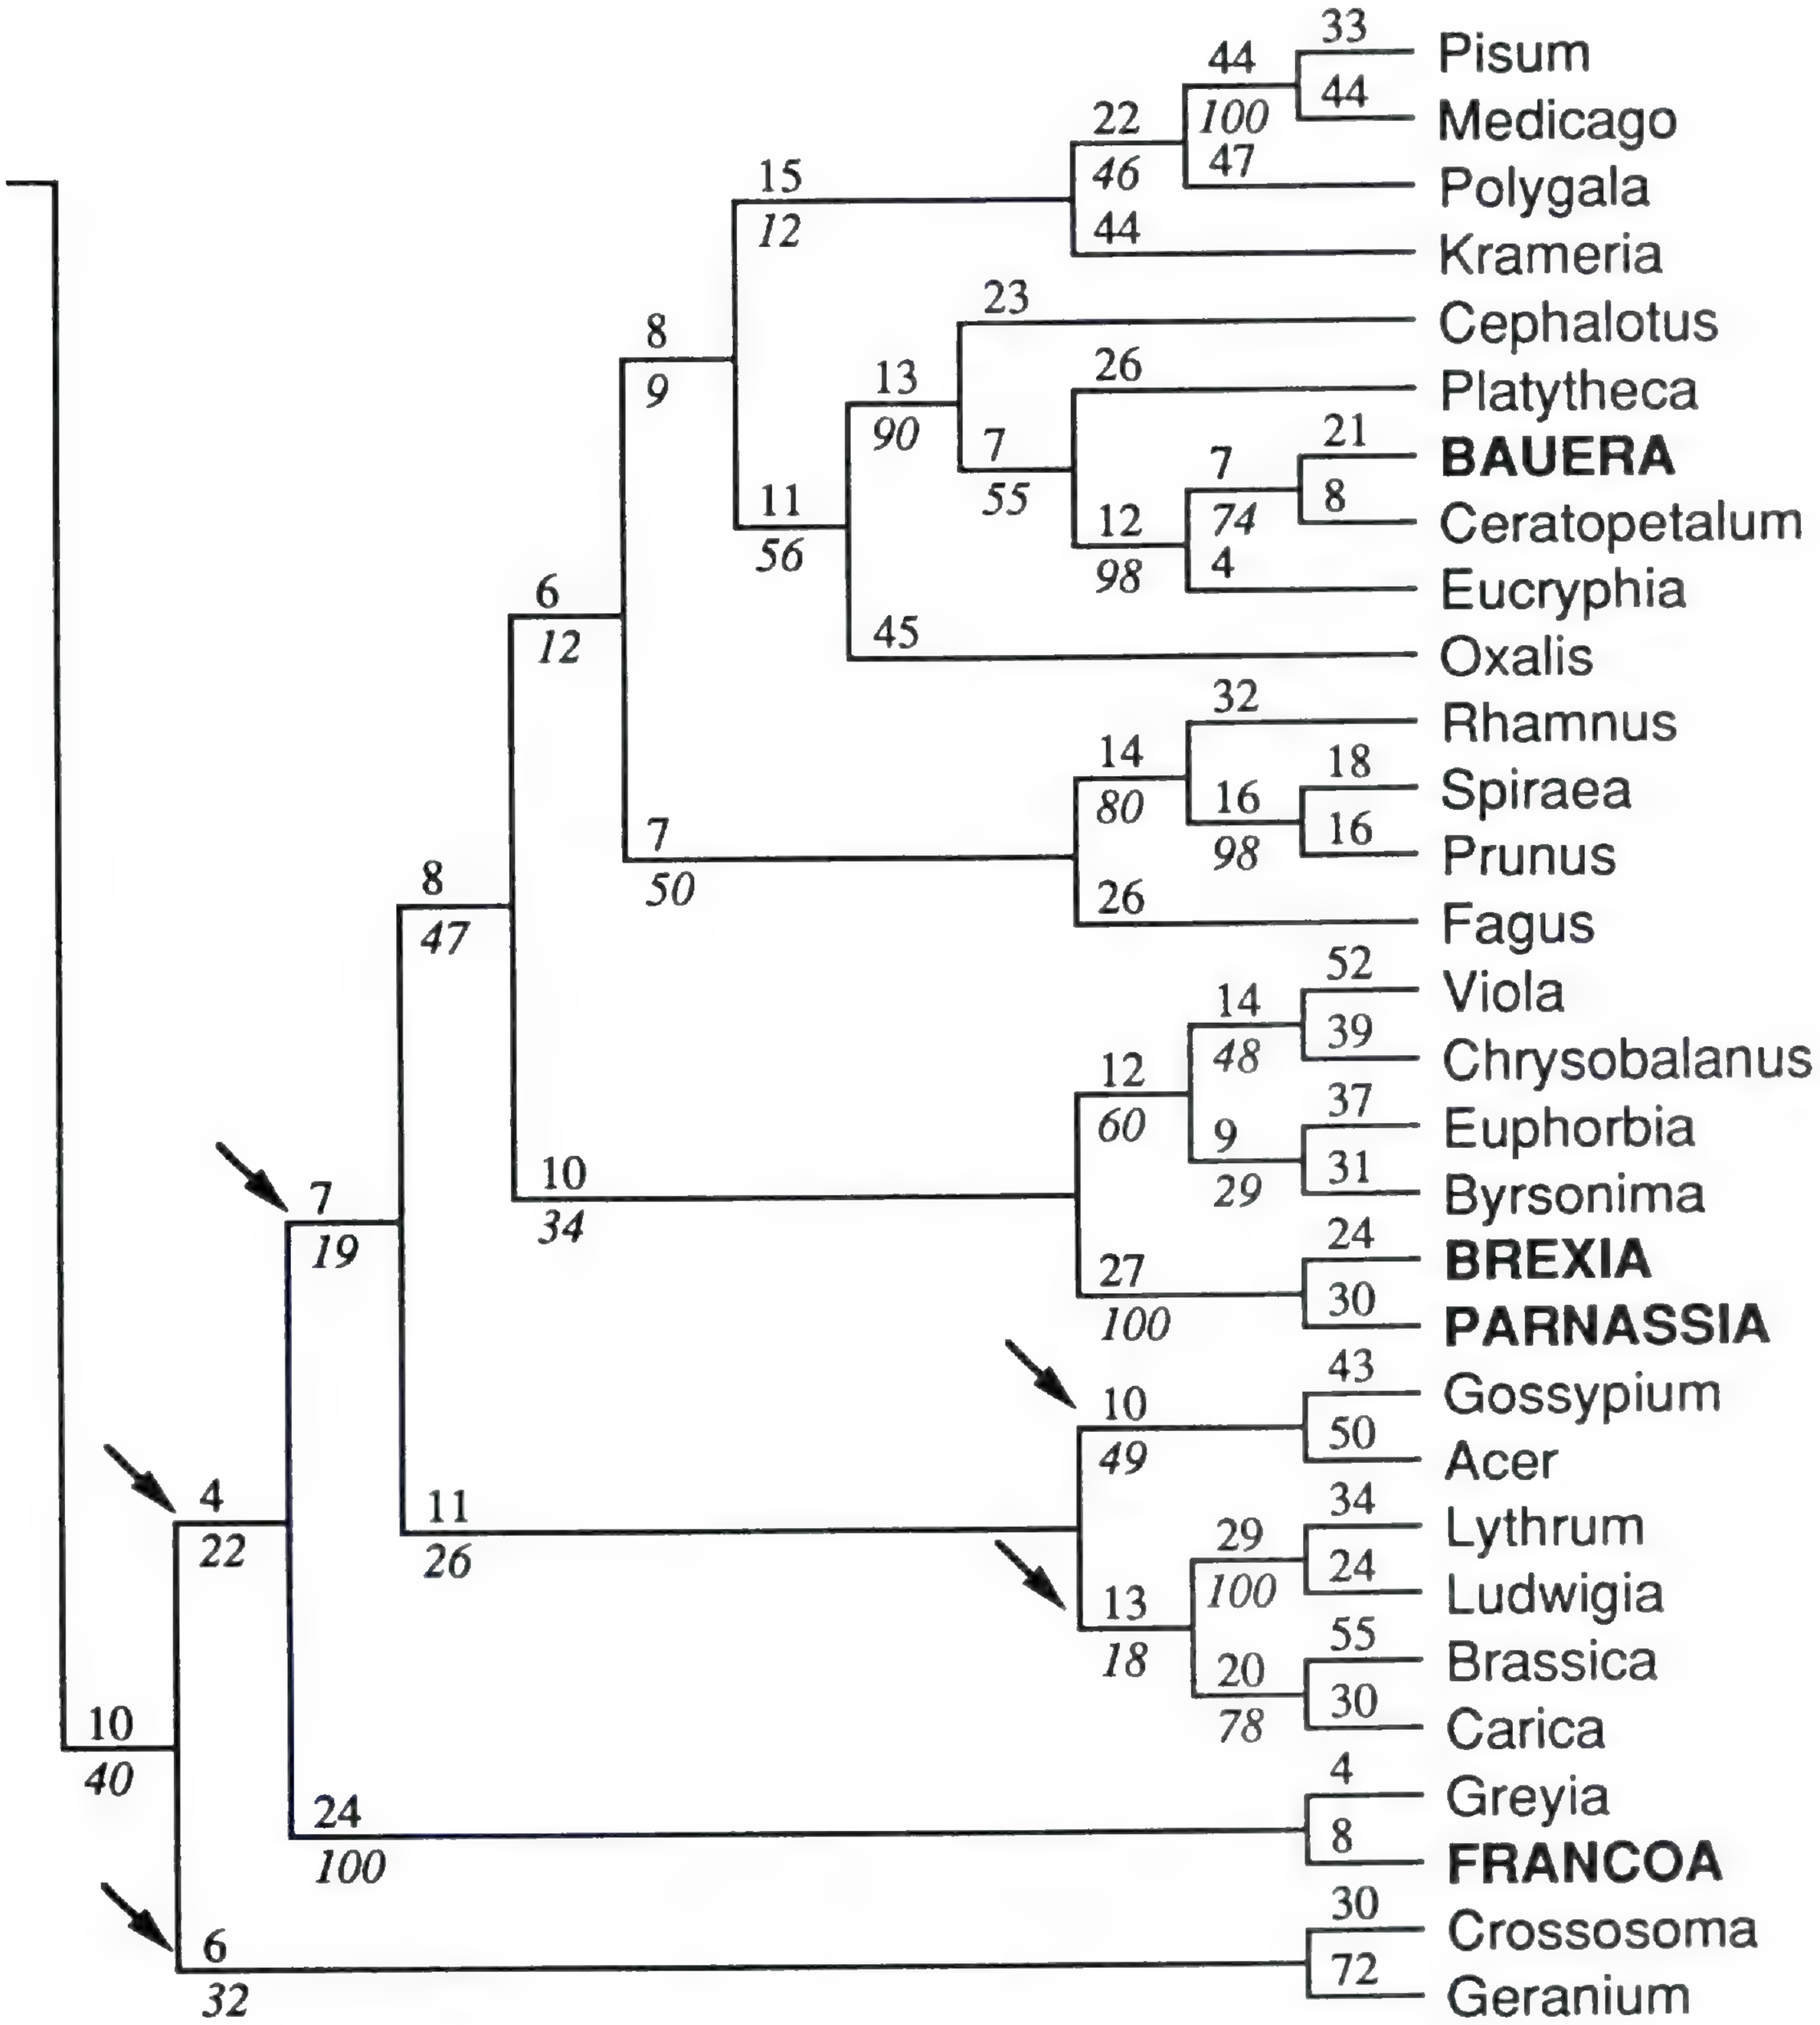

FIGURE 3. Continued.

*l.* In the following sections we will discuss the systematic implications of *rbc*L sequence data for the remaining subfamilies of Saxifragaceae *s. l.*

*Iteoideae.* Our *rbc*L sequence evidence suggests that *Itea*, the only genus in Iteoideae, is closely related to Saxifragoideae (Figs. 2, 3). *Itea* has at times been associated with herbaceous rather than with woody Saxifragaceae *s. l.* (Dahlgren, 1983; Takhtajan, 1987), but has also been placed nearer the woody subfamilies by some (Cronquist, 1981; Hutchinson, 1973; Thorne, 1992). Sequence data, however, suggest that *Itea* is clearly separated from most other woody subfamilies (Figs. 1–3).

Previous investigations have provided conflicting results regarding the alliances of *Itea*. According to Spongberg (1972), chambered pith and stipulate leaves distinguish *Itea* from Escallonioideae. Embryologically, *Itea*, which has bitegmic and crassinucellate ovules, is identical to Saxifragoideae, as well as Ribesoideae, and distinct from Hydrangeoideae, Escallonioideae, and Montinioideae, which have unitegmic tenuinucellate ovules (Table 2).

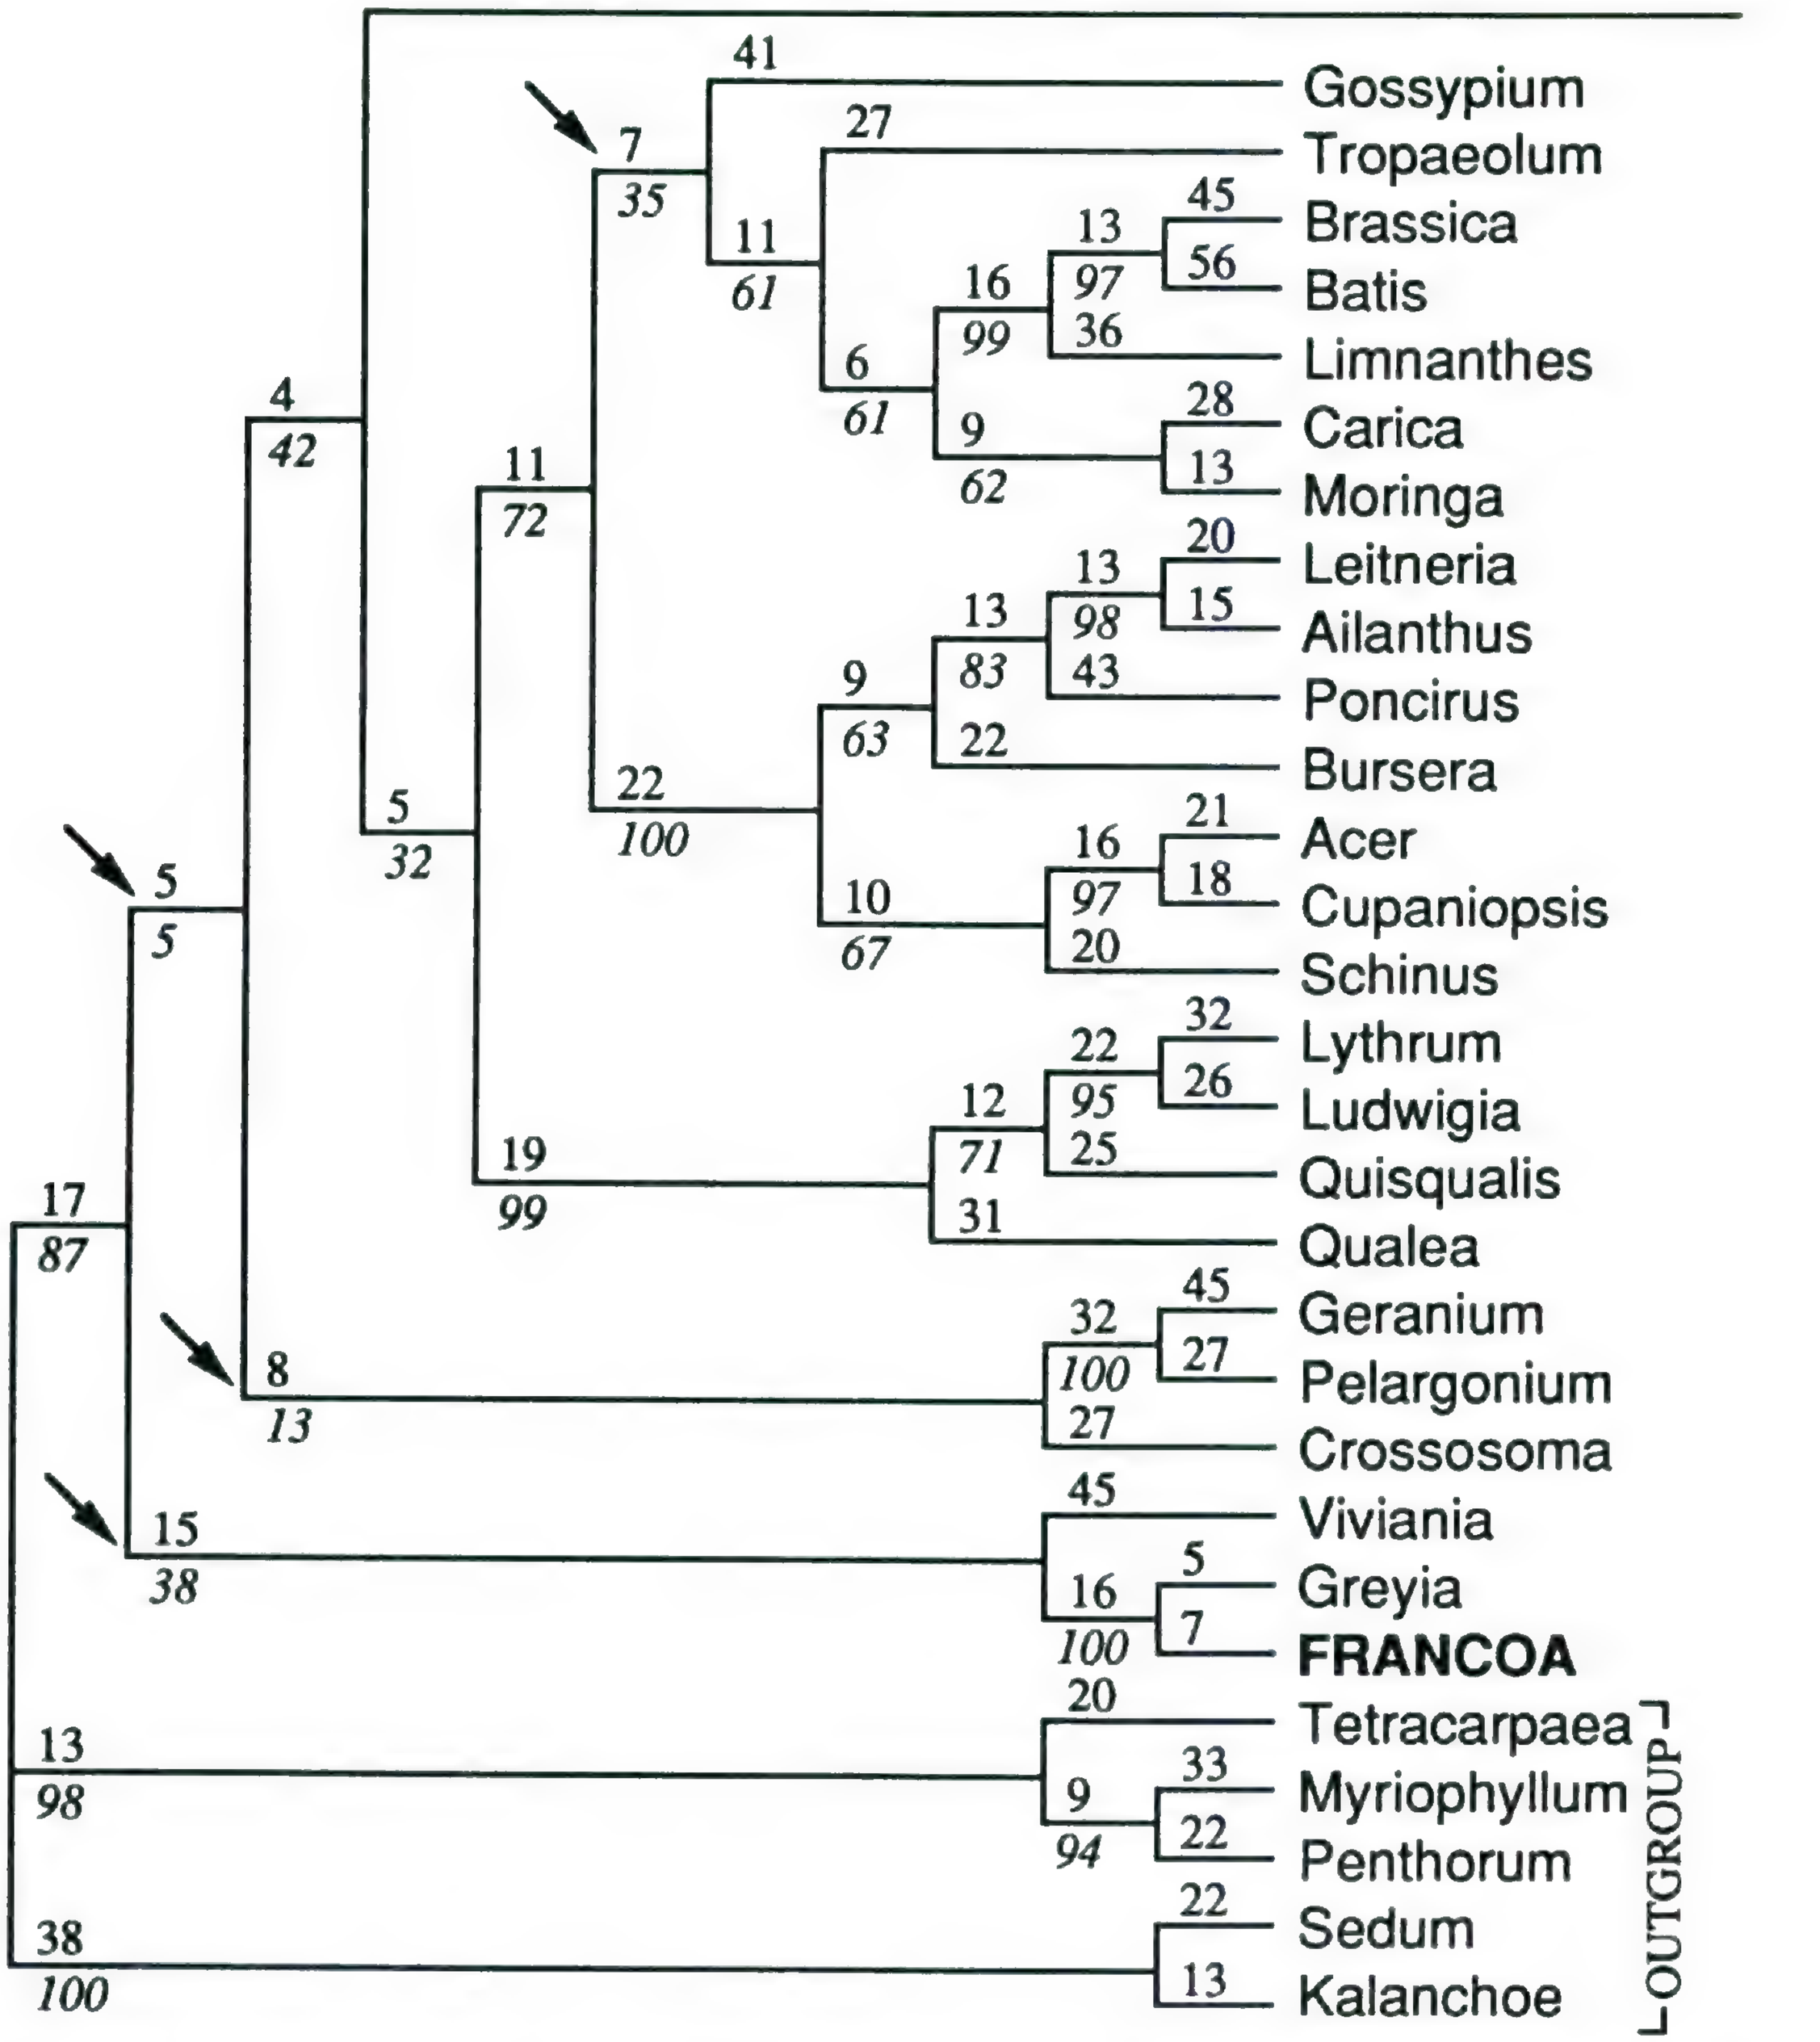

FIGURE 4. Majority-rule consensus tree (including compatible groupings) constructed from 40 most parsimonious trees resulting from phylogenetic analysis of *rbc*L sequences of rosid group B. This tree is identical to one of the 40 shortest trees and has a consistency index of 0.326 and a retention index of 0.476. Arrows point to nodes that did not occur in all shortest trees; all other nodes were present in all 40 most parsimonious trees. Numbers above each branch indicate the number of base substitutions; numbers in italics below each branch indicate the percentage occurrence of each monophyletic group in the results of 100 bootstrap replicates. Names of taxa of Saxifragaceae sensu lato are shown in capital letters and boldface type.

Also, Bensel & Palser (1975b, d) found morphological and anatomical characteristics of the flowers of *Itea* to be virtually identical to those of Saxifragoideae, and noted that it was essentially impossible to differentiate between flowers of *Itea* and Saxifragoideae, externally or internally.

In contrast, other lines of evidence suggest that *Itea* is more closely related to other woody subfamilies. Hamel (1953) concluded, on the basis of karyological data, that *Itea* was most closely allied with *Escallonia*. The pollen of *Itea* is bilateral and two-porate (Hideux & Ferguson, 1976; Spongberg,

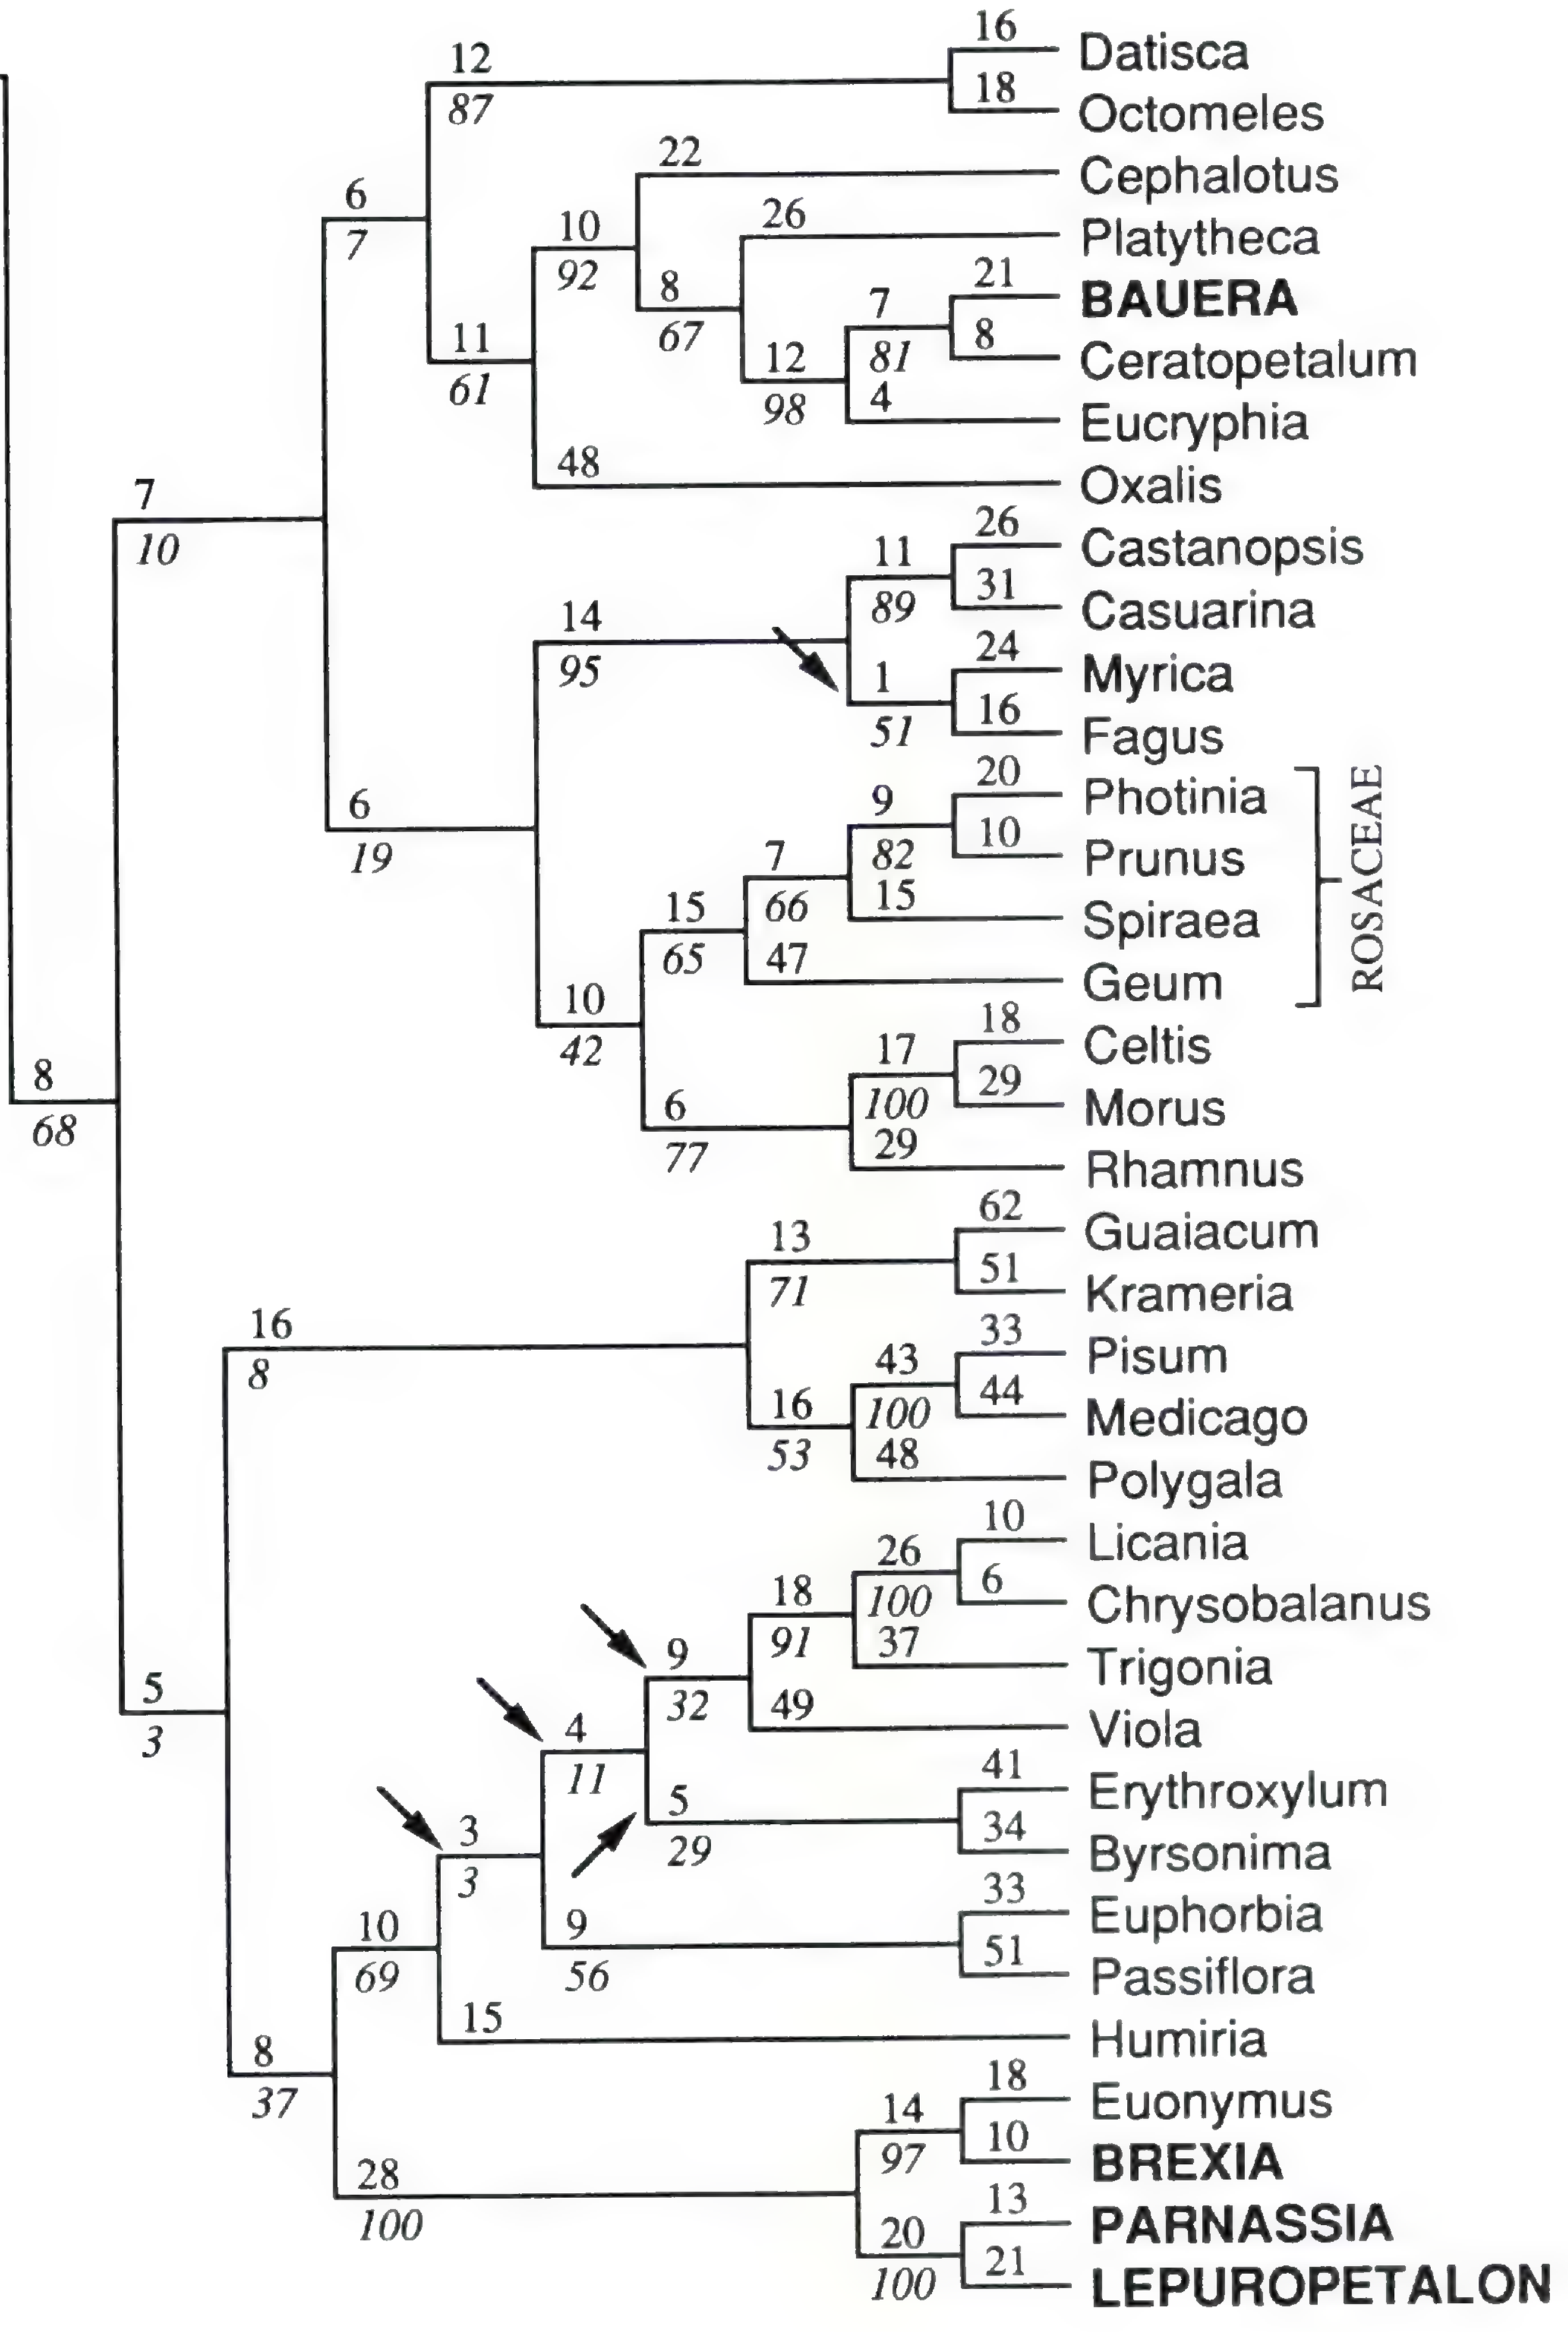

FIGURE 4. Continued.

| Haloragaceae | 2 | crassinucellate | C |

1972). This is an extremely uncommon pollen type, apparently found elsewhere only in *Choristylis*, which is usually included in Escallonioideae. In other pollen characteristics, *Itea* is very much like several genera in Escallonioideae, and the complete tectum and reduced ectoaperture of its pollen further distinguish *Itea* from Saxifragoideae.

Chemical evidence generally suggests that *Itea* is distinct from Saxifragoideae and more closely allied with other woody taxa. Plouvier (1965) found allitol in *Itea* and dulcitol in *Brexia*. He proposed a close alliance between the two because allitol and dulcitol are isomers, and allitol was not found in genera of Saxifragoideae. Plouvier furthermore suggested that both *Itea* and *Brexia* were related to Celastraceae, members of which also accumulate dulcitol. Jay (1970) reported that *Itea* and *Brexia* were essentially identical in flavonoid characteristics, having equal amounts of leucodelphinidine and leucocyanidine and lacking flavonols. Jay advocated a close relationship between *Itea* and *Brexia* and an alliance between them and *Escallonia*. Bohm et al. (1988) confirmed the absence of flavonols in *Itea* and remarked that, while many members of Saxifragaceae *s. l.* (both herbaceous and woody taxa from several subfamilies) produce flavonols,

←

36 shortest trees and has a consistency index of 0.428 and a retention index of 0.486. Arrows point to nodes that did not occur in all shortest trees; all other nodes were present in all 36 most parsimonious trees. Numbers above each branch indicate the number of base substitutions; numbers in italics below each branch indicate the percentage occurrence of each monophyletic group in the results of 100 bootstrap replicates. Names of taxa of Saxifragaceae sensu lato are shown in capital letters and boldface type. Occurrence of iridoids is indicated for all taxa: "++" = genera known to produce iridoids, "+" = genera that have not been studied but are members of families known to have iridoids, "−" = genera and members of families that are known not to produce iridoids, "?" = unknown for iridoid occurrence. Sources of data on iridoid occurrence: Dahlgren et al. (1977, 1981); Jensen et al. (1975); Kaplan & Gottlieb (1982).

*Itea* is virtually alone in that it accumulates only flavones.

Our data provide no support for a close alliance between *Itea* and Cornales (Dahlgren, 1983; Takhtajan, 1987) or for the contentions of Plouvier (1965) and Jay (1970) that *Itea* is closely related to *Brexia*. According to *rbc*L sequence data, *Itea* is only distantly related to woody subfamilies such as Hydrangeoideae, Escallonioideae, and Montinioideae. Sequence results of *rbc*L suggesting a close relationship between *Itea* and Saxifragoideae are intriguing and parallel embryological characters and the floral data of Bensel & Palser (1975b, d). The closest relative of *Itea* may be the subfamily discussed below, Pterostemonoideae.

*Pterostemonoideae.* Evidence from *rbc*L sequences suggests that there is a close alliance between *Pterostemon* and *Itea* (Figs. 2, 3). The monogeneric subfamily Pterostemonoideae consists of shrubs native to Mexico and has traditionally been classified with the woody subfamilies Hydrangeoideae, Escallonioideae, and Montinioideae. However, the position of *Pterostemon* is usually described as uncertain (Cronquist, 1981; Dahlgren, 1983; Hutchinson, 1973; Takhtajan, 1987). As with the woody genus *Itea*, *Pterostemon* is more closely allied in our results with Saxifragoideae than with Hydrangeoideae, Escallonioideae, and Montinioideae.

Embryological characteristics corroborate the placement of *Pterostemon* suggested by *rbc*L sequence data. As with Saxifragoideae and *Itea*, *Pterostemon* is crassinucellate and bitegmic (Table 2), thus the genus is distinct from the tenuinucellate and unitegmic Hydrangeoideae, Escallonioideae, and Montinioideae. Saxifragoideae and *Itea* also have cellular endosperm formation. The type of endosperm present in *Pterostemon* is, however, not known. The presence of cellular endosperm formation in *Pterostemon* might add to the support for its alliance with Saxifragoideae and *Itea*.

In contrast to embryological characters, some morphological and palynological features do not seem to support a close alliance among *Pterostemon*, Saxifragoideae, and *Itea*. *Pterostemon* has, in addition to five fertile stamens, five staminodes. It also has five carpels and little endosperm. *Itea* and Saxifragoideae usually have two carpels, copious endosperm, and no staminodes.

Hideux & Ferguson (1976) described the pollen of *Pterostemon* as having a complete tectum, long ectoaperture, and a complex endoaperture, characteristics most similar to certain escallonioid genera. The tectum surface of *Pterostemon* is much like that of *Itea*, although the short ectoaperture of *Itea* differs from the condition in *Pterostemon*. Hideux & Ferguson (1976) did not, however, include *Pterostemon* in their numerical analysis that included many more pollen characters. They also provided no further description of its pollen, and they had little to say about its possible relationships. According to the description of Erdtman (1966), the pollen of *Pterostemon* may not be similar to that of *Itea*, but with the incomplete descriptions of *Pterostemon* pollen given by both Erdtman (1966) and Hideux & Ferguson (1976), a more detailed palynological study is warranted.

*Pterostemon* has not been studied in great detail; little is known about its wood anatomy, floral anatomy, detailed embryological features, or secondary chemistry. Chemical, anatomical, and additional molecular evidence for *Pterostemon* might help resolve the relationships of this poorly understood genus. For example, given the unique flavonoid profile of *Itea*, secondary chemical data for *Pterostemon* should prove useful.

*Ribesoideae.* The results of *rbc*L sequence analysis indicate that the monogeneric, woody subfamily Ribesoideae is more closely related to Saxifragoideae than to such woody groups as Hydrangeoideae, Escallonioideae, and Montinioideae (Figs. 1–3). Like *Itea*, *Ribes* has been placed close to Saxifragoideae and other herbaceous members of Saxifragaceae *s. l.* (Dahlgren, 1983; Engler, 1928; Takhtajan, 1987; Thorne, 1992), although some (Cronquist, 1981; Hutchinson, 1973) place it closer to other woody members of Saxifragaceae *s. l.*

Many studies have pointed to a close relationship between *Ribes* and Saxifragoideae, and a distant relationship between *Ribes* and other woody taxa. Hamel (1953) found *Ribes* to be homogeneous cytologically ($n = 8$) and advocated placing it very near to, but distinct from Saxifragoideae. Xylem anatomy and embryological characters (Huber, 1963) also support a close relationship between *Ribes* and Saxifragoideae. Gelius (1967) found the floral morphology of *Ribes* to resemble that of Saxifragoideae much more closely than that of other woody Saxifragaceae *s. l.* Similarly, Bensel & Palser (1975a, d) found numerous features of floral anatomy shared by *Ribes* and Saxifragoideae and concluded that, according to floral features alone, *Ribes* should be included in Saxifragoideae.

Plouvier (1965) found that the absence of certain secondary chemicals in *Ribes* distinguished the genus from Saxifragoideae, but he also noted that there were chemical similarities suggesting a close alliance. Jay (1970) stated that flavonoid data

also support a close relationship between *Ribes* and Saxifragoideae. Serological data (Grund & Jensen, 1981) likewise indicate a close relationship between *Ribes* and Saxifragoideae and a distant relationship between *Ribes* and other woody Saxifragaceae *s. l.* The combination of bitegmic crassinucellate ovules with cellular or helobial endosperm formation (Dahlgren, 1975b; Philipson, 1974, 1977; Table 2) also supports a close relationship between *Ribes* and Saxifragoideae.

The pollen of *Ribes*, however, is distinct from most Saxifragoideae. *Ribes* is distinguished from Saxifragoideae in having pollen that is 8–9-aperturate and spheroidal (Erdtman, 1966) with a complete, smooth tectum (Hideux & Ferguson, 1976). The pollen of *Ribes* is most similar to that of certain genera of Escallonioideae and, according to Hideux & Ferguson (1976), it could be accommodated in a broadly defined Escallonioideae including many other woody genera.

Results of *rbc*L sequence analysis agree with most experimental data in placing *Ribes* distant from such woody groups as Hydrangeoideae, Escallonioideae, and Montinioideae. Our data also suggest a relationship between Ribesoideae and the Saxifragoideae–Iteoideae–Pterostemonoideae group, although support for the alliance is low (Figs. 2, 3).

### II. SUBFAMILIES ASSOCIATED WITH CRASSULACEAE

*Penthoroideae.* Our *rbc*L sequence data suggest that *Penthorum* (the only genus of Penthoroideae) is part of an alliance including Crassulaceae and is most closely related to *Myriophyllum* (Haloragaceae; Figs. 2, 3). There has been considerable debate regarding the placement of *Penthorum*. Some have included this enigmatic genus in Saxifragaceae (Cronquist, 1981; Dahlgren, 1983), others in Crassulaceae (Hutchinson, 1973), and some recognize Penthoraceae (Takhtajan, 1987; Thorne, 1992). *Penthorum* has morphological characteristics of both Saxifragoideae and Crassulaceae and, depending on which features are emphasized, a case could be made for its alliance with either. In having a hypanthium, partially connate carpels, and nonsucculent leaves, *Penthorum* is more like Saxifragoideae. However, *Penthorum* is more similar to Crassulaceae in number of floral parts. Syncarpous gynoecia and shallow hypanthia in two crassulaceous genera (*Diamorpha* and *Triactinia*) also suggest a link between *Penthorum* and Crassulaceae.

*Penthorum* has been the subject of numerous systematic studies, but the results have for the most part been inconclusive. Hamel (1953) found that $n = 8$ and 9 in *Penthorum* and suggested that, since the same numbers were present in Saxifragoideae, it could be included there. Hideux & Ferguson (1976) found the complex, H-shaped endoapertures in the pollen exine of *Penthorum* to be much like those of *Sedum* (Crassulaceae), but in other pollen characteristics *Penthorum* appeared intermediate between Saxifragoideae and Crassulaceae. According to Jay (1970), *Penthorum* has more phenolic constituents in common with Saxifragoideae (notably ellagic acid) than with Crassulaceae. Soltis & Bohm (1982), however, found that *Penthorum* was chemically distinct from Saxifragoideae in containing many unique, unidentified flavonoids. Also, while myricetin and flavones are found in Saxifragoideae, they are absent in *Penthorum*.

Because Crassulaceae are a much more easily defined group without *Penthorum*, the genus is often allied with Saxifragoideae (Spongberg, 1972). The phylogenetic analysis of morphological and chemical data of Hufford (1992) suggests that *Penthorum* is more closely related to Saxifragoideae than to Crassulaceae. Similarly, Haskins & Hayden (1987) remarked that *Penthorum* does not possess the morphological characters that define Crassulaceae. However, in a detailed anatomical study, they found that *Penthorum* also shares no definite synapomorphies with Saxifragoideae; most of its distinguishing features are either plesiomorphic or of uncertain status. Finding no anatomical or morphological characters to place *Penthorum* in either Saxifragoideae or Crassulaceae, Haskins & Hayden suggested that the genus is most easily accommodated in its own family (Penthoraceae).

Our data also suggest that *Penthorum* should not be accommodated in either Saxifragoideae or Crassulaceae, although the genus is more closely related to Crassulaceae than to Saxifragoideae (Figs. 2, 3). The closest relative of *Penthorum* identified by *rbc*L sequence data is *Myriophyllum* (Haloragaceae). A close relationship between Haloragaceae and *Penthorum* or Crassulaceae has apparently never been suggested. Haloragaceae are occasionally placed in the order Haloragales, often with *Gunnera* (Cronquist, 1981; Dahlgren, 1983); the family is also often placed in the Myrtales (Hutchinson, 1973; Melchior, 1964a; Takhtajan, 1987). Haloragaceae are, however, distinguished from most families in Myrtales by several features, such as an aquatic habit, anemophily, reduced unisexual flowers, a partly apocarpous gynoecium, and a persistent, copious endosperm. Some of these fea-

tures (a partly apocarpous gynoecium and copious endosperm) are also found in *Penthorum*, *Tetracarpaea*, and Crassulaceae, the taxa most closely associated with *Myriophyllum* in our analysis. Furthermore, *Myriophyllum*, *Penthorum*, and Crassulaceae have bitegmic crassinucellate ovules and cellular endosperm formation (Table 2). This is a rather uncommon combination of characters, with bitegmic crassinucellate ovules more often being associated with nuclear endosperm development. This latter, more common combination is found in Myrtales (Dahlgren, 1975b; Davis, 1966; Philipson, 1974, 1977).

The *rbc*L-supported alliances are generally in agreement with the suggestion of Haskins & Hayden (1987) that *Penthorum* is perhaps most easily accommodated in its own family separate from both Saxifragaceae and Crassulaceae. The placement of *Penthorum* and *Myriophyllum* as sister taxa by sequence data, however, raises the new possibility of a close relationship between *Penthorum* and Haloragaceae. The embryological similarities between *Penthorum* and *Myriophyllum* are intriguing, and the relationship between these taxa should be investigated further. Sequence data for additional genera of Haloragaceae would be extremely helpful. Another potential avenue of inquiry would be to investigate the flavonoids in *Myriophyllum*. Soltis & Bohm (1982) found the most distinctive feature of *Penthorum* to be the presence of numerous unidentified flavonoids different from anything found in Saxifragaceae. Identification of these compounds in *Penthorum* and determination of whether they are present in Haloragaceae would be useful.

*Tetracarpaeoideae.* Tetracarpaeoideae consist only of the single shrubby species *Tetracarpaea tasmanica* Hook.f. Our *rbc*L results (Figs. 2, 3) indicate that *Tetracarpaea* is most closely allied with the herbaceous genera *Penthorum* and *Myriophyllum*, and only distantly related to most other woody taxa of Saxifragaceae *s. l.* This placement of *Tetracarpaea* does not parallel most classifications of the genus, which usually place it as a close ally of other woody taxa of Saxifragaceae *s. l.* (e.g., Hydrangeoideae, Escallonioideae, Montinioideae). The placement of *Tetracarpaea* suggested by *rbc*L evidence is, however, similar to the classification of Thorne (1992), who considered it to be more closely related to Saxifragoideae and other herbaceous taxa.

Although *Tetracarpaea* has usually been allied with other woody taxa of Saxifragaceae *s. l.*, there have nonetheless been indications that the true alliances of this genus lie elsewhere. Hideux & Ferguson (1976) suggested that, based on overall pollen characteristics, *Tetracarpaea* is most closely related to Cunoniaceae, a woody family of Rosidae. Hils et al. (1988), however, discounted such a relationship because of floral morphology. Furthermore, in exine characteristics alone, the pollen of *Tetracarpaea* is different from that of Cunoniaceae, and also unlike that of most other woody taxa of Saxifragaceae *s. l. Tetracarpaea* appears most similar in pollen exine features to *Tellima* and *Astilboides*, genera of Saxifragoideae (Hideux & Ferguson, 1976).

Hils et al. (1988) revealed that, although the wood anatomy of *Tetracarpaea* was similar to that of other woody Saxifragaceae *s. l.*, the vascular anatomy of the nodes, leaves, and floral parts of *Tetracarpaea* was different from that of woody Saxifragaceae *s. l.* In addition, whereas the ovules in many other woody members of Saxifragaceae *s. l.* are unitegmic and tenuinucellate, in *Tetracarpaea* they are identical to Saxifragoideae and Crassulaceae in being bitegmic and crassinucellate (Table 2). The closer relationship of *Tetracarpaea* to Saxifragoideae than to other woody Saxifragaceae *s. l.* suggested by embryological, anatomical, and morphological studies is corroborated by *rbc*L sequence data (Figs. 1–3).

Some features of *Tetracarpaea* (e.g., hypogynous flowers with completely separate carpels) are distinctly like those of Crassulaceae, and *rbc*L sequence data also provide support for a closer relationship of this genus to Crassulaceae than to Saxifragoideae. *Tetracarpaea* has not, however, been considered most closely related to *Penthorum* or *Myriophyllum*. Further investigation of the entire *rbc*L-supported *Tetracarpaea–Penthorum–Myriophyllum* alliance is in order. One possible course is to extend the identification of the many unknown flavonoids found in *Penthorum* (see above) to *Tetracarpaea* and *Myriophyllum*. Myricetin, which is found in both Saxifragoideae and Crassulaceae, is absent in *Penthorum* (Gornall et al., 1979; Soltis & Bohm, 1982), and its presence or absence should be confirmed in *Tetracarpaea* and Haloragaceae. Flavones are also found in Saxifragoideae and Crassulaceae but are absent in *Penthorum* and are not yet known in Haloragaceae (Gornall et al., 1979; Soltis & Bohm, 1982). In addition, endosperm development, although known for *Penthorum* and Crassulaceae, has apparently not been determined for *Tetracarpaea* and several members of Haloragaceae and Haloragales.

### III. SUBFAMILIES ASSOCIATED WITH OTHER FAMILIES OF ROSIDAE

*Baueroideae.* Except for Engler (1890, 1928), Schulze-Menz (1964), and Hutchinson (1973), most workers have considered *Bauera* to be distinct from all other constituents of Saxifragaceae *s. l.* and more closely related to, or included in, Cunoniaceae. Sequence data of *rbc*L are in complete agreement with a close relationship between *Bauera* and Cunoniaceae and a distant relationship between *Bauera* and all other members of Saxifragaceae *s. l.* (Figs. 2, 4). In supporting the alliance of *Bauera* with *Ceratopetalum* (Cunoniaceae), our data corroborate many other lines of evidence.

Some fairly obvious morphological features shared by *Bauera* and Cunoniaceae that are rare or absent in most other members of Saxifragaceae *s. l.* are compound leaves and numerous stamens. Bensel & Palser (1975d) advocated a close relationship between *Bauera* and Cunoniaceae because of similarities in floral anatomy. Among other features, they found that sepal-plane vascular bundles do not contribute to either androecial or gynoecial vasculature in *Bauera*, whereas they do in many other taxa of Saxifragaceae *s. l.*

The ovules in *Bauera*, Cunoniaceae, Saxifragoideae, and the subfamilies of Saxifragaceae *s. l.* already discussed here are bitegmic and crassinucellate. Whereas endosperm formation in Saxifragoideae and allied subfamilies (e.g., Ribesoideae, Penthoroideae) is cellular or helobial, in *Bauera* and Cunoniaceae it is nuclear (Table 2). In fact, only one other subfamily of Saxifragaceae *s. l.* (Francooideae) is known to have the same three embryological features (Table 2). Also, both *Bauera* and Cunoniaceae have a zigzag micropyle, whereas all other members of Saxifragaceae *s. l.* have more typical straight micropyles (Davis, 1966). Prakash & McAlister (1977) cited many embryological and seed characteristics that were similar in *Bauera* and Cunoniaceae but markedly different in other members of Saxifragaceae *s. l.*

*Bauera* is also palynologically similar to Cunoniaceae. Erdtman (1966) reported the pollen of *Bauera* and Cunoniaceae to be similar in being two-colpate and approximately half as large as the pollen of Saxifragoideae. Hideux & Ferguson (1976) described exine features and results of a numerical analysis of many pollen characters that also indicated a close *Bauera*–Cunoniaceae relationship. Similarities in secondary chemicals also indicate a relationship between *Bauera* and Cunoniaceae (Jay, 1970). Recent phylogenetic analyses of morphological, anatomical, and chemical characters (Hufford, 1992; Hufford & Dickison, 1992) indicate that *Bauera* should be included within Cunoniaceae.

In recent years it has rarely been suggested that *Bauera* is more closely related to other members of Saxifragaceae *s. l.* than to Cunoniaceae. Dickison (1975) described vegetative patterns, anther dehiscence, and flower vestiture features that distinguished *Bauera* from Cunoniaceae and suggested that *Bauera* was closer to Saxifragoideae than to Cunoniaceae. Nearly all other evidence, however, including *rbc*L sequence data, strongly suggests that *Bauera* should be included within or closely allied with Cunoniaceae.

*Eucryphia*, the only genus in Eucryphiaceae, is also a close relative of *Bauera* and Cunoniaceae in our results (Figs. 2, 4). *Eucryphia* is a genus of shrubs and trees that, like Cunoniaceae and *Bauera*, is distributed in the Southern Hemisphere. Focke (1895) and Melchior (1964b) placed *Eucryphia* near Dilleniaceae and Ochnaceae, but most recent workers consider it closely related to or part of Cunoniaceae (Cronquist, 1981; Dahlgren, 1983; Takhtajan, 1987; Thorne, 1992). Evidence from flavonoids (Bate-Smith et al., 1967) and cytology (Hamel, 1959) supports a close relationship between Eucryphiaceae and Cunoniaceae. More recently, investigations of floral, leaf, and wood anatomy (Dickison, 1978) and pollen features (Hideux & Ferguson, 1976) have also supported a close relationship between the two families. Hufford (1992) and Hufford & Dickison (1992) performed phylogenetic analyses of morphological, anatomical, and chemical characters, finding that *Eucryphia* is very closely related to and possibly should be included in Cunoniaceae. Our *rbc*L sequence data, therefore, correlate well with several lines of evidence in supporting a close alliance between *Eucryphia* and Cunoniaceae.

*Francooideae.* Our *rbc*L sequence data suggest that *Francoa* (one of two genera in the subfamily) is distantly related to Saxifragoideae and all other members of Saxifragaceae *s. l.*, and closely related to *Greyia* (Greyiaceae; Figs. 2, 4). In most classifications Francooideae has been closely allied with Saxifragoideae, either as part of a narrowly defined Saxifragaceae (Cronquist, 1981; Dahlgren, 1983) or as a closely related family (Hutchinson, 1973; Takhtajan, 1987; Thorne, 1992).

Some evidence indicates a close relationship between Francooideae and Saxifragoideae. Bensel & Palser (1975b) found the floral anatomy of *Fran-*

*coa* to be very much like that of other genera in Saxifragoideae. Hamel (1953) reported the chromosome number of *Francoa sonchifolia* Cav. to be $n = 26$ and suggested a close relationship between *Francoa* and Saxifragoideae because the same number also occurs in Saxifragoideae, although rarely. Jay (1970) also suggested that *Francoa* and Saxifragoideae were closely related, based on the shared occurrence of ellagic acid.

Other evidence parallels *rbc*L sequence data in suggesting a distant relationship between *Francoa* and Saxifragoideae. Bohm et al. (1986) identified several flavonoids in *Francoa* (e.g., quercetin and kaempferol aglycones) that had not been reported for this genus by Jay (1970). They also found myricetin and rutinosides, compounds commonly found in Saxifragoideae, to be absent in *Francoa*. Bohm et al. (1986) concluded, in contrast to Jay (1970), that *Francoa* was distinct from Saxifragoideae and should be recognized as a separate family. Hideux & Ferguson (1976) found the complex apertures of both genera in Francooideae (*Francoa* and *Tetilla*) to be different from the diffuse and simple endoapertures of Saxifragoideae. Their numerical analysis of 25 pollen characters also separated *Francoa* and *Tetilla* from Saxifragoideae.

Our sequence data indicate that the closest relative of *Francoa* is *Greyia* (Figs. 2, 4). Greyiaceae have been allied with or included in Melianthaceae by some authors (e.g., Scholz, 1964). *Greyia* is, however, distinguished from Melianthaceae by several morphological and chemical features (Bohm & Chan, 1992), and recently the family has been included in the same order or suborder as Saxifragaceae (Cronquist, 1981; Dahlgren, 1983; Takhtajan, 1987; Thorne, 1992). It has, however, never been thought to be closely related to *Francoa*.

Although a close relationship between *Francoa* and *Greyia* may initially seem anomalous, other data do corroborate our *rbc*L results. Myricetin, while common in Saxifragoideae, is absent in both *Francoa* (Bohm et al., 1986) and *Greyia* (Gornall et al., 1979). According to Erdtman (1966), the pollen of *Francoa* is quite different from Saxifragoideae, having an equatorial constriction. Hideux & Ferguson (1976) revealed that the pollen of both genera of Francooideae is very similar to that of *Greyia*. There are also floral characters that distinguish *Francoa* from Saxifragoideae and support its relationship with *Greyia*. Whereas most Saxifragoideae have two carpels, *Francoa* has four (*Greyia* has five). Staminodes are not known in Saxifragoideae, but *Francoa* and *Greyia* both possess staminodes equal in number to fertile stamens. Finally, in both *Francoa* and *Greyia* endosperm formation is initially nuclear, whereas Saxifragoideae (as well as Crassulaceae and other taxa related to Saxifragoideae) have cellular (or sometimes helobial) endosperm formation (Table 2).

The results of *rbc*L sequence analysis also suggest that there is an alliance between the *Francoa–Greyia* group and *Viviania*, although support for this relationship is low (Figs. 2, 4). *Viviania*, which has been either included in Geraniaceae or recognized as a separate, monogeneric family, is poorly known chemically and embryologically. At this time we cannot, therefore, provide useful comparisons between this *rbc*L-supported alliance and other lines of evidence; the possible relationship between *Viviania* and *Greyia–Francoa* must be investigated further.

*Brexioideae.* The *rbc*L sequence data suggest a close alliance between *Brexia* (one of three genera of Brexioideae) and *Euonymus* (Celastraceae), separating *Brexia* from Saxifragoideae and most other members of Saxifragaceae *s. l.* (Figs. 2, 4). *Brexia* has typically been associated with Escallonioideae and other woody subfamilies of Saxifragaceae *s. l.* (Cronquist, 1981; Engler, 1890, 1928; Hutchinson, 1973; Thorne, 1992). Dahlgren (1983), however, allied *Brexia* more closely with a narrowly defined Saxifragaceae than with Escallonioideae. Takhtajan (1987) placed Brexiaceae with Celastraceae (in Celastrales).

The relationships of *Brexia* have been difficult to ascertain because different characters unite the genus with different groups of plants. Some evidence appears to unite *Brexia* with other woody Saxifragaceae *s. l.*, especially Escallonioideae. As noted above, Jay (1970) interpreted flavonoid data to support a close relationship between *Itea*, *Brexia*, and *Escallonia*. Pollen exine characteristics of *Brexia* (Hideux & Ferguson, 1976) are most similar to those of *Argophyllum* (Escallonioideae). A numerical analysis of many more pollen characters also supported inclusion of *Brexia* in a broadly defined Escalloniaceae, containing such additional taxa as *Itea* and *Tetracarpaea* (Hideux & Ferguson, 1976). Plouvier (1965) not only supported a *Brexia–Itea* relationship but also suggested a relationship between *Brexia* and Celastraceae because both produce dulcitol.

*Brexia* differs from both Saxifragoideae and Escallonioideae in floral morphology and anatomy. Bensel & Palser (1975a) provided a long list of floral features present in *Brexia* and absent or rare in either or both Saxifragoideae and Escallonioideae, including a completely superior ovary, five

carpels, isomerous flowers, completely connate carpels, staminodes, anther extensions, thick carpel walls, and evidence that the androecium was derived from fascicled stamens. However, because *Brexia* differed more substantially from other members of Saxifragaceae *s. l.*, Bensel & Palser (1975d) tentatively allied the genus with Escallonioideae, pending further investigation.

The close relationship between *Brexia* and *Euonymus* suggested by *rbc*L sequence data corroborates the placement of *Brexia* in Celastrales by Takhtajan (1987) and the suggestion that *Brexia* and Celastraceae are closely related based on chemical evidence (Plouvier, 1965). The five-carpellate, isomerous flowers with superior ovaries found in *Brexia* also characterize *Euonymus*. In addition, the ovules in most taxa of Saxifragaceae *s. l.* are either bitegmic and crassinucellate or unitegmic and tenuinucellate. *Brexia*, however, has bitegmic and tenuinucellate ovules, as does *Euonymus*. Many members of Saxifragaceae *s. l.* also have cellular endosperm formation; in contrast, *Brexia* and *Euonymus* have nuclear endosperm formation (Table 2). The combination of these three embryological characteristics is relatively uncommon not only in Saxifragaceae *s. l.*, but also in dicots in general (Dahlgren, 1975b; Philipson, 1974, 1977). Thus, embryological data further support a close relationship between *Brexia* and *Euonymus*.

Although *rbc*L sequence data and embryological evidence suggest a close relationship between *Brexia* and *Euonymus*, inclusion of *Brexia* in Celastraceae would be premature at this time. *Euonymus* may not be typical of Celastraceae or Celastrales. Some taxa in Celastraceae (e.g., *Celastrus*) have crassinucellate ovules (Davis, 1966), and in other characteristics the family is a very diverse group (Cronquist, 1981). Other families in Celastrales (sensu Cronquist) are also different from *Euonymus* embryologically, and the only other one for which *rbc*L sequences are available (Aquifoliaceae) is, according to *rbc*L evidence, very distantly related to *Euonymus* (Figs. 1, 5; see below). Because basic chemical data for *Brexia* are lacking, no insights into the relationships of this genus can presently be gained through comparative chemistry. It is noteworthy that Celastraceae possess a rare flavonoid type (5-deoxy flavonoids, Gornall et al., 1979). It would, therefore, be of interest to determine whether these compounds are also present in *Brexia*. Further resolution of the potential *Brexia* Celastrales alliance should await further chemical and molecular investigation of Celastrales.

*Parnassioideae and Lepuropetaloideae.* Our *rbc*L sequence evidence indicates a close relationship between *Parnassia* and *Lepuropetalon* (Figs. 2, 4). These two genera were initially allied as subfamily Parnassioideae of Saxifragaceae (Dandy, 1927). Most recent classifications consider them closely related to one another; many authors retain them in narrowly defined versions of Saxifragaceae (Cronquist, 1981; Dahlgren, 1983; Hutchinson, 1973) or in separate families in the same order (Takhtajan, 1987; Thorne, 1992). Dahlgren (1983), although allying the two genera, included them in Droserales (as the families Parnassiaceae and Lepuropetalaceae) rather than in Saxifragales.

*Parnassia* and *Lepuropetalon* share many morphological characteristics, such as a dimorphic androecium with staminodes, similar epidermal tannin sacs, commisural stigmas, loculicidal capsules, and a scanty endosperm (Spongberg, 1972). Gastony & Soltis (1977) obtained a chromosome count of $2n = 46$ for *Lepuropetalon* and established that two base chromosome numbers occur in *Parnassia* ($x = 8, 9$). Because of the dramatic difference in diploid numbers between *Parnassia* and *Lepuropetalon*, they did not consider cytological data to either confirm or deny a close relationship between the two. The complex mixtures of quercetin and kaempferol derivatives discovered in *Parnassia* by Bohm et al. (1986) clearly distinguish this genus from Saxifragoideae. Bohm et al. (1986) also found that the flavonoid constitution of *Lepuropetalon* was more similar to *Parnassia* than to any other investigated taxa of Saxifragaceae *s. l.* In pollen exine features, *Parnassia* and *Lepuropetalon* are much alike, with partial, continuous, and reticulate exines and similar endo- and ectoapertures. A numerical analysis involving many additional pollen characters did not, however, place the two close together (Hideux & Ferguson, 1976).

*Parnassia* is the better known of the two genera. Although *Parnassia* has been closely allied with Saxifragoideae in many classification schemes (Table 1), many lines of evidence do not support such a relationship. Jay (1970) claimed to have found support from flavonoids for allying *Parnassia* with Hypericaceae. In contrast, Hamel (1953) preferred to ally *Parnassia* very closely with Saxifragoideae because of similar karyotypes and because the chromosome numbers reported for *Parnassia* at that time ($2n = 16$ and 32) were also present in Saxifragoideae.

Bensel & Palser (1975a) found, however, that *Parnassia* shared very few floral characteristics with Saxifragoideae and proposed treating it as a separate family. They described *Parnassia* as hav-

ing hypogynous flowers, completely connate ovaries, mostly commissural stigmas, nectariferous staminodia, and an ancestrally fascicled androecium; all of these features are absent or rare in Saxifragoideae. Grund & Jensen (1981), in a serological investigation of seed antigens of *Parnassia*, detected no reactions with either *Saxifraga* or *Hydrangea*, suggesting distant relationships with both (they did not, however, investigate *Lepuropetalon*). *Parnassia* is also embryologically different from Saxifragoideae. It has bitegmic tenuinucellate ovules and nuclear endosperm formation, whereas bitegmic crassinucellate ovules and cellular endosperm characterize Saxifragoideae (Table 2). Thus, our *rbc*L sequence data are in agreement with several lines of biosystematic data in supporting a close relationship between *Parnassia* and *Lepuropetalon* and a distant relationship between both genera and Saxifragoideae (Figs. 2, 4).

*Parnassia* and *Lepuropetalon* are part of a well-supported clade based on *rbc*L sequence data that also contains *Brexia* and *Euonymus* (Figs. 2, 4). It is important to note that other lines of evidence suggest a close alliance among all the members of the group. The combination of embryological features found in *Brexia*, *Euonymus*, and *Parnassia* is found commonly only in Ebenales, Theales, and Primulales (Dahlgren, 1975b; Philipson, 1974, 1977; Table 2). *Brexia*, *Parnassia*, and *Lepuropetalon* also possess staminodes and, as noted by Bensel & Palser (1975a), *Brexia* and *Parnassia* are similar in having an ancestral fascicled androecium, with several small vascular bundles supplying each stamen. The diminutive *Lepuropetalon*, considered the smallest terrestrial angiosperm, is not well known in most respects. Schulze-Menz (1964) reported it as having unitegmic ovules, in which it would differ from *Parnassia* and *Brexia*. This should be confirmed, however, and the nucellus and endosperm types of *Lepuropetalon* should also be determined. A better knowledge of *Lepuropetalon* as well as of other taxa in Celastraceae should add significantly to an understanding of this alliance.

## IV. SUBFAMILIES ASSOCIATED WITH CORNACEAE

*Hydrangeoideae.* Our analysis of *rbc*L sequence data indicates that the closest relatives of Hydrangeoideae are Cornaceae and related genera (Fig. 5). There have been long-standing disagreements regarding the proper placement of the genera of Hydrangeoideae (see Table 1). Whereas Schulze-Menz (1964) and Cronquist (1981) preferred a relatively close relationship between this group of genera and Saxifragoideae, Hutchinson (1973), Dahlgren (1983), Takhtajan (1987), and Thorne (1992) allied the group (along with other woody subfamilies) with taxa that are distantly related to Saxifragoideae, such as Cornaceae or Cunoniaceae. It is significant, therefore, that *rbc*L sequence data suggest that the five genera of Hydrangeoideae analyzed are allied with Cornaceae, in agreement with the relationships suggested by Huber (1963), Dahlgren (1983), Takhtajan (1987), and Thorne (1992).

Most recent evidence has made it apparent that Hydrangeoideae are only distantly related to Saxifragoideae. Bate-Smith (1962) reported that ellagic acid was present in Saxifragoideae, but absent in Hydrangeoideae, suggesting that the two were distantly related. Jay (1970) found the same distribution of ellagic acid but concluded that Hydrangeoideae were less distantly related to Saxifragoideae. Perhaps the first to draw attention to similarities between Hydrangeoideae and Cornales was Huber (1963), who cited such shared features as scalariform perforations in the xylem and the absence of stipules and recommended placing Hydrangeoideae within Cornales.

Bensel & Palser (1975c, d) found several anatomical characteristics that distinguished Hydrangeoideae from Saxifragoideae, such as an increase in stamen numbers, highly vascularized gynoecia, absence of hypanthia, and three-trace petals with some bundles originating from the sepal planes. Krach (1977) also decided that several characteristics of Hydrangeoideae, such as a septicidal capsule, numerous seeds, reduced embryo size, and a lengthening of cell walls of the outer seed coat, indicated a distant relationship with Saxifragoideae. Palynological data also distinguish Hydrangeoideae from Saxifragoideae. Erdtman (1966) described the pollen of *Philadelphus* as being half as large as the pollen of Saxifragoideae. Hideux & Ferguson (1976) found several genera of Hydrangeoideae to be remarkably similar in exine characteristics. Their numerical analysis of additional pollen characters also indicated that Hydrangeoideae are homogeneous and well separated from Saxifragoideae.

Although the investigations discussed above all found characteristics that distinguished Hydrangeoideae from Saxifragoideae, few (e.g., Huber, 1963) proposed alternative relationships for the hydrangeoids. Grund & Jensen (1981) found that genera of Hydrangeoideae had a higher serological affinity with *Cornus* than with any of the numerous other samples tested, including *Escallonia*, *Ribes*, *Parnassia*, and representatives of Byblidaceae, Ericaceae, Caprifoliaceae, Crassulaceae, and Cunoniaceae. Significantly, they reported a low affinity

between Hydrangeoideae and several generea of Saxifragoideae. Thus, serological data clearly support Huber's contention that Hydrangeoideae are phylogenetically distant from Saxifragoideae and closely related to Cornaceae.

Additional support for a close relationship between Hydrangeoideae and Cornaceae comes from investigations of secondary chemicals, iridoids in particular. Iridoids occur primarily in sympetalous taxa, such as Dipsacales, Goodeniales, Oleales, Gentianales, Scrophulariales, and Lamiales. They also occur in Cornaceae, as well as genera often considered allied with Cornaceae (e.g., *Alangium*, *Aucuba*, *Curtisia*, *Davidia*, *Nyssa*). Significantly, iridoids have also been found in *Deutzia*, *Fendlera*, and *Hydrangea* of Hydrangeoideae (Dahlgren et al., 1981; Jensen et al., 1975; Kaplan & Gottlieb, 1982). The presence of iridoids in Hydrangeoideae, coupled with their absence in Saxifragoideae and many other taxa of Saxifragaceae *s. l.*, indicate that Hydrangeoideae are more closely allied with Cornaceae and other iridoid-producing groups than with Saxifragoideae or other members of Saxifragaceae *s. l.* Similar alliances are suggested by flavonoid data. Whereas myricetin is common in Saxifragoideae, it is rare or absent in both Hydrangeoideae and Cornaceae (Bohm et al., 1985; Gornall et al., 1979).

Most of the plant groups containing iridoids also have ovules that are unitegmic and tenuinucellate. The ovules of Hydrangeoideae are also unitegmic and tenuinucellate, distinct from the bitegmic and crassinucellate ovules of Saxifragoideae. Although some of the cornalean taxa in this analysis differ from Hydrangeoideae in having crassinucellate ovules, all have ovules that are unitegmic and most have cellular endosperm formation (Dahlgren, 1975b; Davis, 1966). Recently, Hufford (1992) presented results from a phylogenetic analysis of many morphological, anatomical, and chemical characters that supported an alliance between Hydrangeoideae and Cornales. In summary, *rbc*L evidence, in combination with chemical, embryological, morphological, and anatomical characteristics, strongly supports the separation of Hydrangeoideae from Saxifragoideae and indicates that they are probably most closely related to Cornales. The Hydrangeoideae–Cornaceae relationship is the subject of a more detailed *rbc*L sequence analysis by Xiang et al. (1993).

## V. SUBFAMILIES ASSOCIATED WITH ASTERIDAE

*Phyllonomoideae.* *Phyllonoma*, the only genus in the subfamily, is not, according to *rbc*L sequence evidence, closely allied with any other members of Saxifragaceae *s. l.* Rather, it is part of an alliance that is composed primarily of sympetalous taxa usually placed in Asteridae (Fig. 5). Members of this asterid group almost exclusively have ovules that are unitegmic and tenuinucellate (Dahlgen, 1975b; Davis, 1966), and many of them produce iridoid compounds (Fig. 5).

*Phyllonoma* is included in this group as a relative of *Helwingia* and *Ilex* (Fig. 5). *Helwingia* is usually included within Cornales (a detailed discussion of Cornaceae and related taxa is provided by Xiang et al., 1993). *Ilex* (Aquifoliaceae), although it has also been associated with Cornales (Dahlgren, 1983), is most often included in Celastrales. Our analysis of *rbc*L sequence data indicates, however, that both *Helwingia* and *Ilex* are far removed phylogenetically from the groups with which they have traditionally been allied.

Most authors have placed Phyllonomoideae with other woody members of Saxifragaceae *s. l.* The genus has frequently been considered most closely related to Escallonioideae (Table 1), but its placement is often described as uncertain. Compared with most other subfamilies of Saxifragaceae *s. l.*, Phyllonomoideae are poorly known; very little embryological, anatomical, or chemical evidence has been obtained. Palynological data are available, however, and Erdtman (1966) and Hideux & Ferguson (1976) found the pollen of *Phyllonoma* to differ from that of other saxifragaceous taxa. The combination of a complete, granulate tectum and a simple endoaperture in *Phyllonoma* was unlike the pollen of any other subfamily of Saxifragaceae *s. l.* Hideux & Ferguson (1976) also found that, based on many additional pollen features, *Phyllonoma* could not easily be accommodated in any saxifragaceous group and differed most from Escallonioideae and Hydrangeoideae. In contrast to pollen characters, seed coat features suggest that *Phyllonoma* is closely related to *Ribes* (Krach, 1977). In a revision of *Phyllonoma*, Mori & Kallunki (1977) discussed its generic relationships only briefly but also suggested that it was closely related to *Ribes*.

*Phyllonoma* has never been closely associated with *Ilex*, and it has only indirectly been associated with *Helwingia*. Nonetheless, there is evidence that corroborates the relationships suggested by *rbc*L sequence data. All three of these genera have separate petals, a feature that distinguishes them in this group of mostly sympetalous taxa. Evidence supporting the alliance of *Phyllonoma* and *Helwingia* is provided by leaf morphology and inflorescence features. Hickey & Wolfe (1975) noted that the leaves of the two genera have derived brochidodromous venation, possibly because they

share a common ancestor. Perhaps the most intriguing evidence linking *Phyllonoma* and *Helwingia* is the fact that both genera have inflorescences borne on the upper surfaces of the leaves. Besides *Phyllonoma* and *Helwingia*, epiphyllous inflorescences are found in at least 43 other genera in 24 families (Johnson, 1958; Dickinson, 1978). Most are assumed to have arisen by adnation of peduncles and petioles. Because various degrees of adnation can be found in individual families or genera, this characteristic has not been thought to be useful for phylogenetic purposes. Not all epiphyllous inflorescences are ontogenetically identical, however. Several taxa with this feature have been studied in detail. In some, the epiphyllous inflorescences have arisen from peduncle–petiole adnation: Dichapetalaceae (Stork, 1956), *Chirita* (Gesneriaceae; Johnson, 1958), and *Turnera* (Turneraceae; Johnson, 1958). The epiphyllous inflorescences of *Phyllonoma* and *Helwingia* are, however, ontogenetically different from others that have been studied because they arise from the upper surfaces of the leaf primordia (Dickinson & Sattler, 1974, 1975; Johnson, 1958). This shared characteristic adds considerable support to the alliance of *Phyllonoma* and *Helwingia*.

Additional evidence relevant to the *Phyllonoma–Helwingia–Ilex* relationship may come from secondary chemicals, chromosome data, and embryological features. *Phyllonoma*, *Helwingia*, and *Ilex* comprise one of several lineages in this primarily asterid alliance in which iridoids have not been found (Fig. 5). *Helwingia* and *Ilex* are not known to produce iridoids (Dahlgren, 1983; Dahlgren et al., 1981) but *Phyllonoma* has not been tested for iridoids. It would, therefore, be of value to determine whether *Phyllonoma* possesses iridoid compounds. The chromosome numbers of *Helwingia* ($x = 19$) and *Ilex* ($x = 20$) are similar (Raven, 1975); a chromosome count for *Phyllonoma* should also be useful. *Ilex* and most members of Aquifoliaceae have unitegmic and crassinucellate ovules, a relatively uncommon combination (Dahlgren, 1975b; Philipson, 1974, 1977). *Phyllonoma* and *Helwingia* have also been reported to have unitegmic ovules (Schulze-Menz, 1964), but their nucellar type is unknown. A finding of crassinucellate ovules in *Phyllonoma* and *Helwingia* should provide further support for this alliance.

*Escallonioideae.* As with *Phyllonoma*, *rbc*L sequence analysis places *Escallonia* in an alliance of asterid taxa (Fig. 5). Escallonioideae have most often been associated with the woody subfamilies Hydrangeoideae and Montinioideae (Table 1). Our *rbc*L sequence data indicate, however, that *Escallonia* is well separated from both. Although clearly separating *Escallonia* from all other members of Saxifragaceae *s. l.*, *rbc*L sequence data provide little support for a close alliance of the genus with any other lineage (Fig. 5).

Escallonioideae are the most morphologically diverse of the 17 subfamilies of Saxifragaceae *s. l.*, and appears to be polyphyletic. There is no consensus concerning the composition of the subfamily; several genera that have been placed in Escallonioideae (e.g., *Corokia*, *Griselinia*) have also been associated with families such as Cornaceae and Araliaceae (Eyde, 1966; Philipson, 1967).

The morphological diversity encountered within Escallonioideae has complicated attempts to determine the relationships of the group. Bensel & Palser (1975c) studied five members of Escallonioideae (*Corokia*, *Carpodetus*, *Quintinia*, *Escallonia*, and *Polyosma*) and described them as being very diverse in floral morphology and floral vascular patterns. Similarly, Hideux & Ferguson (1976) discovered that pollen morphology among genera of the subfamily was so diverse that several other subfamilies of Saxifragaceae *s. l.* could easily be accommodated within the variation.

Other evidence indicates considerable evolutionary distance between Escallonioideae and Saxifragoideae. Serological affinities of *Escallonia* are much higher with *Roridula*, *Sambucus*, *Lonicera*, *Cornus*, and Hydrangeoideae than with Saxifragoideae (Grund & Jensen, 1981). Several other features distinguish Escallonioideae from Saxifragoideae; in many instances Escallonioideae are much like Hydrangeoideae. In seed characteristics Escallonioideae and Hydrangeoideae are similar, and both groups differ from Saxifragoideae (Krach, 1977). Ellagic acid is absent from both Escallonioideae and Hydrangeoideae but present in Saxifragoideae (Bate-Smith, 1962; Jay, 1970). Iridoids are present in Escallonioideae and Hydrangeoideae but absent in Saxifragoideae (Dahlgren et al., 1981; Jensen et al., 1975; Kaplan & Gottlieb, 1982). Both Escallonioideae and Hydrangeoideae also have unitegmic, tenuinucellate ovules (Table 2).

Our *rbc*L sequence data agree in part with the above described lines of evidence by indicating that *Escallonia* is phylogenetically distant from Saxifragoideae and closely related to other taxa that produce iridoids and that have unitegmic (and usually tenuinucellate) ovules. The closest allies of *Escallonia* are not, however, Hydrangeoideae and Cornaceae (Fig. 5). There are, in fact, embryological and morphological features that parallel *rbc*L evidence in distinguishing *Escallonia* from Hydrangeoideae and/or Cornaceae. Endosperm formation is nuclear in Escallonioideae but cellular in

Hydrangeoideae and Cornaceae. Whereas ovules in Cornaceae are mostly crassinucellate, in *Escallonia* and other genera of Escallonioideae they are tenuinucellate (Table 2). Genera of Escallonioideae are also distinguished from Hydrangeoideae and Cornaceae by exhibiting haplostemonous and sympetalous tendencies (Dahlgren, 1983); these characteristics also are consistent with the placement of *Escallonia* with taxa of Asteridae.

Further resolution of the relationships of *Escallonia* is not possible at present with available *rbc*L sequence data because of the lack of evidence supporting specific alliances (Fig. 5). Given the great morphological diversity present in Escallonioideae and the poor understanding of generic relationships in the group, it will be necessary to investigate additional genera to gain a complete understanding of the systematics of the entire subfamily. Our *rbc*L sequence data have already been helpful in exploring the relationships of two genera, *Corokia* and *Griselinia*, that have been placed in Escallonioideae by some authors. Sequence data indicate that *Corokia* and *Griselinia* are not closely related to *Escallonia* or to one another (Fig. 5). It should be possible to gain a better understanding of Escallonioideae by obtaining *rbc*L sequence data from other members of the subfamily.

*Montinioideae.* *Montinia* represents still another member of Saxifragaceae *s. l.* whose affinities appear to be with taxa of Asteridae. The closest relatives of *Montinia*, according to *rbc*L sequence evidence, are Convolvulaceae and Solanaceae (Fig. 5), both of which are normally placed in Solanales (Asteridae).

Montinioideae (consisting of the two genera *Montinia* and *Grevea*) have been allied with many different taxa (e.g., Myrtaceae, Celastraceae, Cucurbitaceae, Onagraceae; see Dahlgren et al., 1977). The subfamily is most commonly allied, however, with other members of Saxifragaceae *s. l.*, especially the woody subfamilies Hydrangeoideae and Escallonioideae (Table 1). Montinioideae share several features with Hydrangeoideae and Escallonioideae that are not characteristic of many other members of Saxifragaceae *s. l.* All three subfamilies have unitegmic tenuinucellate ovules (Table 2), lack ellagic acid (Bate-Smith, 1962; Jay, 1970), and produce iridoids (Dahlgren et al., 1977, 1981; Jensen et al., 1977; Kaplan & Gottlieb, 1982).

According to *rbc*L sequence data, however, *Montinia* does not have Hydrangeoideae or Escallonioideae as closest relatives, although all three subfamilies do appear near members of Asteridae. Importantly, some more traditional lines of systematic data also do not closely link Montinioideae with Hydrangeoideae or Escallonioideae. Krach (1976) found many differences between the seeds of Montinioideae and Escallonioideae and suggested that they were distantly related. Takhtajan (1980) stated that some characteristics of Montinioideae (e.g., simple perforation plates in the xylem, unisexual flowers) indicate that they are much more advanced than either Hydrangeoideae or Escallonioideae.

Some morphological and anatomical features of *Montinia* are also present in Solanales. Both Montinioideae and Solanales have two-carpellate gynoecia and simple perforation plates in their xylem. Montinioideae are dioecious and have capsular fruits; dioecy (Levine & Anderson, 1986) and capsular fruits also occur in Solanales. Most of these shared morphological and anatomical features are, however, also found in many other taxa. Numerous features distinguish *Montinia* from Solanales; we will mention only the most obvious. In contrast to both Solanaceae and Convolvulaceae, *Montinia* has inferior ovaries, free stamens, separate petals, produces iridoids and lacks internal phloem.

Further study of Montinioideae should be useful in determining the closest relatives of this subfamily. For example, secondary chemical data may be helpful. According to Harborne & Swain (1979), Solanaceae have a unique flavonoid composition that is similar only to that of Convolvulaceae and Nolanaceae (also in Solanales). Specific chemical features shared by Solanaceae and Convolvulaceae include the presence of tropane alkaloids, otherwise known from only ten genera of six other families (Evans, 1979), and acylated anthocyanins, elsewhere found only in Lamiaceae and Polemoniaceae (Harborne & Swain, 1979). It would be useful to analyze *Montinia* for tropane alkaloids and acylated anthocyanins. In addition, Dahlgren et al. (1977) described an unusual condition in *Montinia* in which the cotyledon petioles of the seedlings are fused. This characteristic is rare in flowering plants and is almost exclusively found in herbaceous taxa. It has been described in other woody plants only in *Combretum* (Combretaceae) and in one species of *Quercus* (Fagaceae). In herbaceous taxa, fused petioles are known in four genera each of Ranunculaceae and Apiaceae and in one genus in each of three other families (de Vogel, 1980). Lubbock (1892) reported no occurrences of fused petioles in Solanales, but a more thorough examination of seedling development of Solanales might provide useful insights.

As noted by Chase et al. (1993), the misidentification of plant material should be considered a possibility, especially when relationships seem anomalous. It is significant, therefore, that our *rbc*L

sequence for a second specimen of *Montinia* confirms the results presented here.

*Vahlioideae.* According to *rbc*L sequence data, *Vahlia* (the only genus of Vahlioideae) is well separated from other members of Saxifragaceae *s. l.* and included in the same group of asterid families that contains *Montinia* (Fig. 5). Its inclusion in this group is well supported by *rbc*L sequence data. The results do not, however, indicate any close relatives for *Vahlia* in this alliance, but suggest that it is basal to several asterid taxa (Fig. 5).

*Vahlia* typically has been affiliated with other herbaceous taxa of Saxifragaceae *s. l.* (Table 1), either as a subfamily of Saxifragaceae or as a closely related family. As with *Pterostemon* and *Phyllonoma, Vahlia* is very poorly known anatomically and chemically, and although it is usually placed close to Saxifragoideae, its affinities are much in doubt. Embryological and palynological characteristics suggest that *Vahlia* is most closely related to *Parnassia.* Ovules in both genera are bitegmic and tenuinucellate (Table 2), indicating that they are separate from other members of Saxifragaceae *s. l.* According to Hideux & Ferguson (1976), *Vahlia* and *Parnassia* are also similar in many pollen characters. The chromosome numbers of *Vahlia* ($n$ = 6, 9; Hamel, 1953) are also similar to those of *Parnassia,* which has $x$ = 8 and 9 (Gastony & Soltis, 1977). Sequence evidence, however, indicates that *Vahlia* is distantly related to *Parnassia.* Determination of the relationships of *Vahlia* would benefit greatly from more detailed systematic study. Secondary chemistry investigations might help determine the affinities of *Vahlia*; since most of the other taxa in this asterid group produce iridoids, an evaluation of *Vahlia* for the presence or absence of iridoids would be especially valuable.

Broader phylogenetic analyses of Chase et al. (1993) also indicate that *Vahlia* occupies a position basal to many asterid taxa. This position of *Vahlia* is intriguing in light of the fossil record. Friis & Skarby (1981, 1982) described a highly developed, apparently saxifragaceous flower (*Scandianthus*) from the upper Cretaceous period and proposed that Saxifragaceae *s. l.* may have been well differentiated as early as the lower Cretaceous. As noted by Dahlgren (1983), the *Scandianthus* flower is virtually identical to the flower of *Vahlia,* having an inferior, bicarpellate, unilocular ovary with two pendulous placentae, five sepals and petals of approximately equal length, and two separate stigmas (Friis & Skarby, 1981, 1982). The two genera differ only in that *Vahlia* has five stamens and *Scandianthus* ten. Thus, fossil evidence in conjunction with our sequence data raise the possibility that *Vahlia* could be a relict of the ancestral type of many of these asterid families.

## Summary

Our phylogenetic analysis of *rbc*L sequences indicates that, among angiosperm families, Saxifragaceae *s. l.* may represent the most extreme example of a polyphyletic assemblage. These analyses suggest that these taxa represent at least 10 separate evolutionary lines. Furthermore, these separate lineages are distributed among most traditionally recognized subclasses of the dicots. These results are not wholly unexpected, however. Several genera and subfamilies of Saxifragaceae *s. l.* are poorly understood (e.g., Montinioideae, Vahlioideae, Lepuropetaloideae, Phyllonomoideae, Pterostemonoideae, Escallonioideae, Tetracarpaeoideae, Francooideae), and their affinities have actually been much in doubt. In addition, although members of Saxifragaceae *s. l.* are allied with at least 10 separate lineages in our results, the relationships supported by *rbc*L sequence data are in many instances corroborated by other lines of evidence. Numerous different types of data are congruent with *rbc*L-supported alliances in specific instances, but some lines of evidence (such as those derived from embryology, iridoid chemistry, serology, and floral anatomy) are especially notable for the frequency with which they agree with *rbc*L sequence results.

Our *rbc*L sequence data suggest that Saxifragaceae should be composed of only the genera included in the subfamily Saxifragoideae of Schulze-Menz (1964). Data from several sources, including intron loss in the chloroplast gene *rpl*2, restriction site analysis of chloroplast DNA, and morphology all serve to distinguish this group of genera from traditionally allied taxa of Saxifragaceae *s. l.* It seems most appropriate, therefore, to define Saxifragaceae sensu stricto (Saxifragaceae *s. s.*) as consisting only of the approximately 30 genera of subfamily Saxifragoideae, a circumscription of the family that is identical to that proposed by Takhtajan (1987) and Thorne (1992).

Sequence evidence indicates that Iteoideae, Pterostemonoideae, Ribesoideae, Tetracarpaeoideae, Penthoroideae, *Myriophyllum* (Haloragaceae), and Crassulaceae are possible close relatives of Saxifragaceae *s. s.* (Figs. 2, 3). Although sequence data provide little direct support for a monophyletic

alliance composed of these taxa, they do share several features. As reported by Bensel & Palser (1975a, b, c, d) most of these taxa are very much alike in the anatomy and morphology of their flowers. Furthermore, all of these taxa that have been studied have bitegmic crassinucellate ovules and cellular (sometimes helobial) endosperm formation. This combination of features is relatively uncommon in non-magnoliid dicots, the more common combination being bitegmic crassinucellate ovules with nuclear endosperm formation (Dahlgren, 1975b; Philipson, 1974, 1977; Table 2). Serological evidence (Grund & Jensen, 1981) also supports close relationships among many of the same taxa (Saxifragaceae *s. s.*, Crassulaceae, *Ribes*, *Penthorum*). A phylogenetic analysis of many anatomical, morphological, and chemical characters (Hufford, 1992) similarly suggests that Saxifragaceae *s. s.*, Crassulaceae, *Penthorum*, and *Tetracarpaea* are closely related.

An intriguing result of this investigation is the placement of four genera near Saxifragaceae *s. s.* that are usually included in the subclass Hamamelidae: *Cercidiphyllum*, *Daphniphyllum*, *Rhodoleia*, and *Hamamelis* (Figs. 2, 3). These genera have been described as part of the "lower Hamamelidae" (Ehrendorfer, 1989) and, although rarely mentioned as close relatives of Saxifragaceae, they have occasionally been linked with the family (Dickison, 1989). Thorne (1992) included these hamamelid taxa in his Rosanae along with Saxifragales, Rosales, and Cunoniales, as well as the "higher hamamelid" taxa Fagales and Juglandales. Dahlgren (1983) placed Saxifragaceae and many hamamelids in his Rosiflorae, considering Saxifragaceae to be connected to the hamamelid taxa through Cunoniaceae. Grund & Jensen (1981) found a high level of serological affinity between *Hamamelis* and several genera of Saxifragaceae *s. s.* Significantly, this serological affinity is as high as that observed between *Ribes* and Saxifragaceae *s. s.* or between Crassulaceae and Saxifragaceae *s. s.*

In addition to suggesting a narrow definition of Saxifragaceae and indicating several possible relatives, *rbc*L sequence data also indicate that other families often associated with Saxifragaceae *s. s.* (e.g., Cunoniaceae, Greyiaceae, Droseraceae, Cephalotaceae, Gunneraceae, Rosaceae) are not closely related to it. Although Dahlgren (1983), Takhtajan (1987), and Thorne (1992) considered Cunoniaceae to be distantly related to Saxifragaceae *s. s.*, Cronquist (1981) and Schulze-Menz (1964) placed Cunoniaceae in the same order as Saxifragaceae *s. s.* Our *rbc*L sequence evidence is in close agreement with Dahlgren (1983), Takhtajan (1987), and Thorne (1992) in suggesting a distant relationship between Saxifragaceae *s. s.* and Cunoniaceae; only Baueroideae appear close to Cunoniaceae (Figs. 2, 4).

The *rbc*L sequence data also indicate that Greyiaceae are distantly related to Saxifragaceae *s. s.* (Figs. 2, 4). This family is included in the same order or suborder as Saxifragaceae *s. s.* by almost all authors. According to *rbc*L sequence evidence, however, Greyiaceae are allied only with the herbaceous subfamily Francooideae (Figs. 2, 4), an alliance that has several lines of corroborating evidence (see discussion of *Francoa* above).

Results from analysis of *rbc*L sequences also do not indicate a close relationship between Saxifragaceae *s. s.* and Droseraceae (Fig. 1), a family allied closely with Saxifragaceae *s. s.* and other herbaceous subfamilies of Saxifragaceae *s. l.* by Dahlgren (1983), Takhtajan (1987), and Thorne (1992). *Drosera* is, according to sequence evidence, distantly related not only to Saxifragaceae *s. s.* but also to all other subfamilies of Saxifragaceae *s. l.* (Fig. 1). The position of Droseraceae based on sequence evidence (near *Nepenthes*) agrees more closely with the classifications of Cronquist (1981) and Schulze-Menz (1964). On the basis of floral morphology, Cephalotaceae, another insectivorous family, are often thought to be closely related to both Saxifragaceae *s. s.* and Crassulaceae (Nicholls et al., 1985). Sequence data of *rbc*L, however, indicate that Cephalotaceae are most closely allied not with Saxifragaceae *s. s.* or Crassulaceae but with *Platytheca* (Tremandraceae) and Cunoniaceae (Figs. 2, 4).

*Gunnera* is, according to *rbc*L sequence data, also distantly related to Saxifragaceae *s. s.* *Gunnera* has sometimes been included in Haloragaceae (Cronquist, 1981) but has often been treated as the family Gunneraceae and placed close to Saxifragaceae (Dahlgren, 1983; Takhtajan, 1987). The affinities of *Gunnera* have remained uncertain because of an unusual combination of characteristics (e.g., wind pollination, symbiotic algae, unisexual flowers, a bicarpellate unilocular ovary, solitary ovule). The basal position of *Gunnera* in the results of our analysis (Fig. 1) still make identification of its closest relatives difficult, but sequence data obviously do not indicate a relationship with Saxifragaceae *s. s.* or other subfamilies of Saxifragaceae *s. l.*

Rosaceae have been closely associated with Saxifragaceae by Dahlgren (1983) and Cronquist

(1981). Our results, however, suggest that Rosaceae are not closely related to Saxifragaceae *s. s.* but are allied with Ulmaceae, Moraceae, and Rhamnaceae (Figs. 2, 4).

The results of *rbc*L sequence analysis indicate that five subfamilies of Saxifragaceae *s. l.* (Baueroideae, Francooideae, Brexioideae, Parnassioideae, and Lepuropetaloideae) are well separated from Saxifragaceae *s. s.* and associated taxa but are still included within an alliance composed primarily of families usually placed in Rosidae (Figs. 2, 4). Baueroideae and Francooideae are, according to *rbc*L sequence evidence, both allied with families (Cunoniaceae and Greyiaceae, respectively) that have identical embryological characteristics. Brexioideae and Parnassioideae are alike in having a relatively uncommon combination of embryological characteristics: bitegmic tenuinucellate ovules with nuclear endosperm formation, features that otherwise are commonly found only in Ebenales, Primulales, and Theales (Davis, 1966; Philipson, 1974, 1977). The sequence evidence delineates a well-supported alliance that includes Brexioideae and Parnassioideae with the embryologically identical *Euonymus* (Celastraceae). These three taxa also have many similarities in floral anatomy and morphology. Although Lepuropetaloideae are poorly known embryologically, their inclusion in this alliance is well supported by many floral similarities with Parnassioideae.

Another significant result of this study is the finding that five subfamilies of Saxifragaceae *s. l.* (Hydrangeoideae, Escallonioideae, Phyllonomoideae, Montinioideae, and Vahlioideae) are, according to *rbc*L evidence, distantly related to all other subfamilies of Saxifragaceae *s. l.* (Figs. 1, 5). Sequence data suggest instead a placement of these taxa in an expanded asterid alliance (see also Olmstead et al., 1993). Other lines of evidence support these results; these five subfamilies are placed nearest to taxa that are similar in having such characteristics as iridoids and ovules that are unitegmic and tenuinucellate.

## Conclusions

Phylogenetic analysis of *rbc*L sequence data has greatly improved our understanding of the relationships among the morphologically diverse members of Saxifragaceae sensu lato. These data have: (1) shown that Saxifragaceae sensu lato are an extreme example of a polyphyletic angiosperm family, (2) suggested that Saxifragaceae be narrowly defined to consist only of approximately 30 herbaceous genera, (3) indicated possible close relatives of Saxifragaceae sensu stricto, (4) revealed that many traditional relatives of Saxifragaceae sensu stricto are only distantly related, (5) shown that some lines of evidence, especially embryology, iridoid chemistry, and serology, are frequently in close agreement with *rbc*L sequence data, and (6) identified areas in which additional data from molecular as well as more traditional investigations should increase our understanding of angiosperm systematics.

# PHYLOGENETIC RELATIONSHIPS OF THE GERANIACEAE AND GERANIALES FROM *rbc*L SEQUENCE COMPARISONS[1]

*Robert A. Price*[2,3] *and Jeffrey D. Palmer*[2]

ABSTRACT

Parsimony analyses of DNA sequence data from the chloroplast *rbc*L gene were used to assess the circumscription and phylogenetic position of the Geraniaceae, generic relationships within the family, and the affinities of the families previously assigned to the order Geraniales. The other families placed in the Geraniales in recent higher-order classifications fall into four well separated lineages, none of which appears to be closely related to the Geraniaceae. Only *Hypseocharis*, often included in the Oxalidaceae, receives strong support as a close relative to the monophyletic Geraniaceae sens. str., as suggested by Boesewinkel on the basis of seed anatomy. Sequence comparisons of *rbc*L provide the first highly resolved phylogeny of the Geraniaceae, indicating that *Pelargonium* is a sister group to the remainder of the family, that *Erodium* and *Geranium* are probable sister genera, and that *Monsonia* and *Sarcocaulon* are either sister genera or are congeneric.

The Geraniaceae sens. str., comprising the five genera *Erodium*, *Geranium*, *Monsonia*, *Sarcocaulon*, and *Pelargonium*, are of particular evolutionary interest in that they exhibit the greatest amount of variation in size and structure of the chloroplast genome known for any family of photosynthetic flowering plants. Substantial increase in the size of the inverted repeat region in at least some taxa of *Pelargonium* is exemplified by the largest known angiosperm chloroplast genome (217 kb in the cultivated geranium, *P.* ×*hortorum*), whereas the loss of one copy of the inverted repeat has resulted in an unusually small chloroplast genome of ca. 120 kb in *Erodium* and *Sarcocaulon* (Palmer et al., 1987; Price et al., 1990). Other unusual features seen in the family include multiple inversions, losses of highly conserved introns, and particularly rapid rates of sequence change in some chloroplast genes (Downie & Palmer, 1992; Downie et al., 1991; Calie et al., unpublished data).

To examine these and other interesting features of the Geraniaceae in an evolutionary context, it is necessary to obtain an independent assessment of the phylogenetic relationships of the family and its close relatives. It has proved difficult to assess generic relationships in the family using morphological or cytological characters because of the paucity of informative characters and the considerable variability within genera (see discussions in Vorster, 1990). Thus we have used sequence comparisons of the chloroplast gene *rbc*L, which has come into wide use in systematic studies of the flowering plants (see discussions in Olmstead et al., 1992; Chase et al., 1993), to attempt to elucidate phylogenetic relationships within the Geraniaceae and to determine which taxa are the most appropriate outgroups for comparison to the family.

Whereas a general consensus exists that the five genera of the Geraniaceae sens. str. are closely related, there has been considerable disagreement as to whether to include several segregate families in the Geraniaceae. The monogeneric Eurasian family Biebersteiniaceae, the monotypic family Dirachmaceae (endemic to the island of Socotra), and the small South American families Ledocarpaceae, Rhynchothecaceae, and Vivianiaceae have been included in the Geraniaceae sens. lat. by Cronquist (1981, 1988) and Thorne (1992), following the classical treatment of Knuth (1912), but excluded from the family by Dahlgren (1989), Robertson

[1] We thank M. Chase, D. Soltis, E. Conti, and J. Nugent for providing unpublished sequences, G. Zurawski for providing *rbc*L sequencing primers, J. Thomas for performing portions of the sequencing, and W. Anderson, M. Chase, M. Denton, and K. Robertson for comments on the manuscript. We are grateful to P. Peñailillo and S. Beck for field collections of South American plants critical to our analysis, and to all others who helped provide plant materials. This research has been supported by NSF grant BSR-8996262.

[3] Current address: Department of Botany, University of Georgia, Athens, Georgia 30602, U.S.A.

(1972), Takhtajan (1987), and van der Walt & Vorster (1988). Each of these segregate families differs from the Geraniaceae sens. str. by lacking one or several of its diagnostic combination of gynoecial and fruit characters (an ovary consisting of five two-ovulate locules united to an elongated stylar column, developing into a schizocarpic fruit of five one-seeded units separating from the persistent column; see Robertson, 1972) but needs to be considered as a potential close relative of the Geraniaceae. In addition, Boesewinkel (1988) has provided evidence from seed anatomy that *Hypseocharis*, an Andean genus often placed in the Oxalidaceae, may in fact be the closest relative of the Geraniaceae sens. str., and Thorne (1992) has included this genus in his subfamily Geranioideae.

Families included in the order Geraniales in the recent higher-order classifications of Cronquist (1981, 1988), Dahlgren (1989), Takhtajan (1987), and Thorne (1992) are compared in Table 1. Each of these classifications includes within the order the segregate families noted above, and all except Dahlgren (1989) include the Oxalidaceae and its segregate families Hypseocharitaceae and Lepidobotryaceae. Cronquist (1981, 1988) and Thorne (1992) also included the Balsaminaceae and the glucosinolate-producing families Limnanthaceae and Tropaeolaceae in the Geraniales, whereas Dahlgren (1989) placed the latter two families near the other glucosinolate taxa. Dahlgren (1989) also included the Zygophyllaceae and several small families segregated from it (Balanitaceae, Nitrariaceae, and Peganaceae) within the Geraniales, whereas these taxa have been otherwise assigned to the Sapindales (Cronquist, 1988), Rutales (Takhtajan, 1987), or Linales (Thorne, 1992). Older classifications by the same authors circumscribed the Geraniales still more broadly, e.g., Dahlgren (1980) and Takhtajan (1980) also included the Linaceae and the putatively closely related Erythroxylaceae and Humiriaceae in the order, and Thorne (1983) included the Malphigiaceae and putative relatives as well. As one might expect from the diversity of classifications discussed here, comparison of diagnostic features of the various families purported to be closely related to the Geraniaceae does not indicate strong support from unusual shared derived features of morphology or secondary product chemistry for any of the circumscriptions of the order (see Cronquist, 1981). The main features linking the families of Geraniales in the system of Cronquist appear to be a tendency to have 10–15 stamens and 5-parted gynoecia, neither of which is unique to the group. We have thus attempted to evaluate the relationships of these families by comparison of *rbc*L sequences from a number of different lineages of the subclasses Rosidae and Dilleniidae.

## Materials and Methods

Forty-eight taxa utilized in this study for *rbc*L sequence comparisons and their sources are listed in Table 2. Total genomic DNA was extracted from 1–3 grams of fresh leaf material or an equivalent fresh weight of silica gel-dried leaves using the modified CTAB procedure of Doyle & Doyle (1987). Leaves resistant to grinding (e.g., *Pelargonium* species) were first frozen in liquid nitrogen and then ground prior to extraction. All DNA samples were further purified and concentrated by CsCl-ethidium bromide gradient centrifugation. The complete *rbc*L gene was amplified via the polymerase chain reaction (PCR) using a 5′ primer consisting of the first 26 bases of the gene and a 3′ primer based on a 24-base portion of a stem-loop region ca. 100 bases beyond the gene (Olmstead et al., 1992).

Five taxa in the study (*Geranium grandiflorum*, *Limnanthes douglasii*, *Monsonia emarginata*, *Oxalis dillenii*, *Tropaeolum majus*) were initially sequenced from DNA cloned from PCR products using the strategy of Olmstead et al. (1992) and then rechecked by direct sequencing of double-stranded PCR products, which was used for all other taxa. DNA from PCR was purified by centrifugation in Centricon 100 filters (Amicon) for use in direct sequencing. Double-stranded DNA samples were denatured in a 95°C heat block and plunged immediately into an ice-water slurry to prevent renaturation. Sequencing was performed using the dideoxy chain termination method, utilizing primers supplied by G. Zurawksi. Six forward and six reverse primers were used for each species, and approximately 65–80% of the sequence was read from both strands.

A total of 1,402 bp of sequence was used for phylogenetic comparisons; this excluded the area of the 5′ amplification primer and any extensions of the gene beyond the length of 1,428 bp found in most seed plants. Alignment of the sequences was accomplished by comparison of the sequence of *Nicotiana tabacum*. Parsimony analyses were conducted using PAUP version 3.0q (Swofford, 1991) on Macintosh computers. To identify minimum length trees we used either the heuristic search and MULPARS options with 50 replicate random orders of taxon entry, TBR branch swapping, and steepest descent, or, in the case of the smaller analysis of Geraniaceae, the branch and bound algorithm. Bootstrap analyses (Felsenstein, 1985) and decay analyses (Bremer, 1988) were

TABLE 1. Families included in the Geraniales in recent higher-order classifications of Cronquist (1981, 1988), Takhtajan (1987), and Dahlgren (1989). The classification of the order in Thorne (1992) is the same as that of Cronquist except in that the segregate families Biebersteiniaceae, Dirachmaceae, Ledocarpaceae, and Vivianiaceae are treated formally as subfamilies of the Geraniaceae, and *Hypseocharis* is included in the subfamily Geranioideae of the Geraniaceae rather than the Oxalidaceae. The Zygophyllaceae and its segregate families Balanitaceae, Nitrariaceae, and Peganaceae are assigned to the Sapindales by Cronquist, to the Rutales by Takhtajan, and to the Linales by Thorne.

| Cronquist | Takhtajan | Dahlgren |
|---|---|---|
| Geraniaceae | Geraniaceae | Geraniaceae |
| Geraniaceae | Biebersteiniaceae | Biebersteiniaceae |
| Geraniaceae | Dirachmaceae | Dirachmaceae |
| Geraniaceae | Ledocarpaceae | Ledocarpaceae |
| Geraniaceae | Rhynchothecaceae | Ledocarpaceae |
| Geraniaceae | Vivianiaceae | Vivianiaceae |
| Oxalidaceae | Oxalidaceae | (in Linales) |
| Oxalidaceae | Hypseocharitaceae | (in Linales) |
| Oxalidaceae | Lepidobotryaceae | (in Linales) |
| Balsaminaceae | (in Balsaminales) | (in Balsaminales) |
| Limnanthaceae | (in Limnanthales) | (in Tropaeolales) |
| Tropaeolaceae | (in Tropaeolales) | (in Tropaeolales) |
| | | Balanitaceae |
| | | Nitrariaceae |
| | | Peganaceae |
| | | Zygophyllaceae |

performed using PAUP 3.0q to examine the degree of support for given branches of the cladograms. The number of additional steps required to shift particular taxa into a monophyletic group with the Geraniaceae was examined using the CONSTRAINTS option of PAUP.

## RESULTS

Sequences of *rbc*L were compared for 48 taxa (Table 2), including nine from published sources, 17 unpublished sequences assembled for the global analyses of Chase et al. (1993, provided by M. Chase, E. Conti, D. Soltis, and J. Nugent), and 22 sequences generated in this study, including 14 from the Geraniaceae sens. str. All sequences generated in this study have been deposited in the GenBank. Two sets of parsimony analyses were conducted, the first focusing on the familial and ordinal relationships of the Geraniaceae and Geraniales, and the second focusing on generic relationships within the Geraniaceae sens. str. For the ordinal level comparisons, 39 taxa were chosen to represent each of the families of the Geraniales sensu Cronquist and a variety of other families from the Rosidae and Dilleniidae. These included several groups (e.g., families of Linales, Sapindales, and Capparales) often considered to be related to the Geraniales and representatives of the families grouping with families of the Geraniales in analyses of the broader data set of *rbc*L sequences assembled by Chase et al. (1993). *Tetracentron* (Tetracentraceae) and *Gunnera* (Gunneraceae) were chosen from the Chase et al. (1993) data set as outgroups from near the base of the rosid–dilleniid lineage. The same ingroup topology was obtained when *Platanus* (Platanaceae) was included as a third outgroup.

Parsimony analysis with equal character weighting yielded a single minimum length tree of 1,609 steps (Fig. 1) with a consistency index (CI) of 0.38 excluding unique substitutions and a retention index (RI) of 0.47. The families included in the Geraniales by Cronquist (1988) are placed in five separate clades on the tree: (1) *Oxalis* and *Averrhoa* (Oxalidaceae) with Eucryphiaceae and Cephalotaceae and then linking to a larger group including the Linaceae, (2) *Tropaeolum* and *Limnanthes* in a mustard-oil containing lineage with *Brassica* and then linking to the Malvales and Sapindales, (3) *Wendtia* (Ledocarpaceae) and *Viviania* (Vivianiaceae) grouping together and then linking to the Greyiaceae and Francoaceae, (4) the Geraniaceae sens. str. grouping with *Hypseocharis*, and (5) *Impatiens* (Balsaminaceae) in a morphologically rather disparate group near the base of the tree with Fouquieriaceae and Polemoniaceae. Support for the placement of the putatively gerani-

alean taxa in these five groups is relatively strong as indicated by bootstrap values of 79–100% and decay values of four or more steps to collapse the first interior node (Fig. 1).

A series of constraint experiments was used to examine the number of additional steps required to force given taxa into a monophyletic group within the Geraniaceae sens. str. plus *Hypseocharis*. A tree of 74 more steps was needed to obtain a monophyletic group consisting exclusively of taxa from the Geraniales sensu Cronquist. The largest contribution to this increase in length came from forcing the two glucosinolate taxa *Limnanthes* and *Tropaeolum* into the Geraniales, as 36 fewer steps were required when they were no longer included in the constrained group. Conversely, 37 steps beyond the minimum were required to force these two taxa alone into a clade with the Geraniaceae. Twenty steps above the minimum were required to force the two genera of Oxalidaceae into a monophyletic group with the Geraniaceae, while only four steps above the minimum were required to produce a clade of *Viviania*, *Wendtia*, and the Geraniaceae.

The Geraniaceae sens. str. are well supported as a monophyletic group in our analyses, with bootstrap values of 99–100% both in Figure 1 and in additional analyses in which all of our sequences for the family were compared to ten or more outgroup taxa. Outside of *Hypseocharis*, however, which is linked strongly to the Geraniaceae sens. str. by a branch of 25 steps and a bootstrap value of 100%, there is only weak support for the association of any specific taxa with the family. *Crossosoma* (Crossosomataceae) is placed as the next closest outgroup to the family in the minimum length tree, but only one additional step is required to collapse this node, and the associated bootstrap value in this analysis is only 26%. An alternative position for *Crossosoma* at one step more than the minimum is as an isolated taxon forming the first node interior to *Heuchera* and *Itea* near the base of the rosid–dilleniid group.

Based upon the results of the preceding higher-level analysis, a more detailed analysis was undertaken to examine generic relationships in the Geraniaceae using *Hypseocharis* as the outgroup. A single minimum length tree of 330 steps with a CI of 0.68 excluding unique substitutions and an RI of 0.79 was obtained from parsimony with equal weighting (Fig. 2). As in the broader analysis, *Pelargonium* forms a sister group to the remainder of the family. Three of the genera of the family (*Pelargonium*, *Geranium*, and *Erodium*) appear to be monophyletic on the basis of the *rbc*L data, while *Monsonia* and *Sarcocaulon* were represented by only single species in this analysis. *Geranium* and *Erodium* appear as sister genera to one another and then to *Monsonia* plus *Sarcocaulon*. The latter two taxa are supported as a monophyletic group by 100% bootstrap values, in agreement with their close morphological relationship.

With the exception of the closely related species pair *Geranium maderense* and *G. palmatum*, each of the taxa from the large genera *Geranium* and *Pelargonium* included in Figure 2 represents a different section. In *Geranium*, the three sections assigned to subgenus *Robertium* by Yeo (1984),

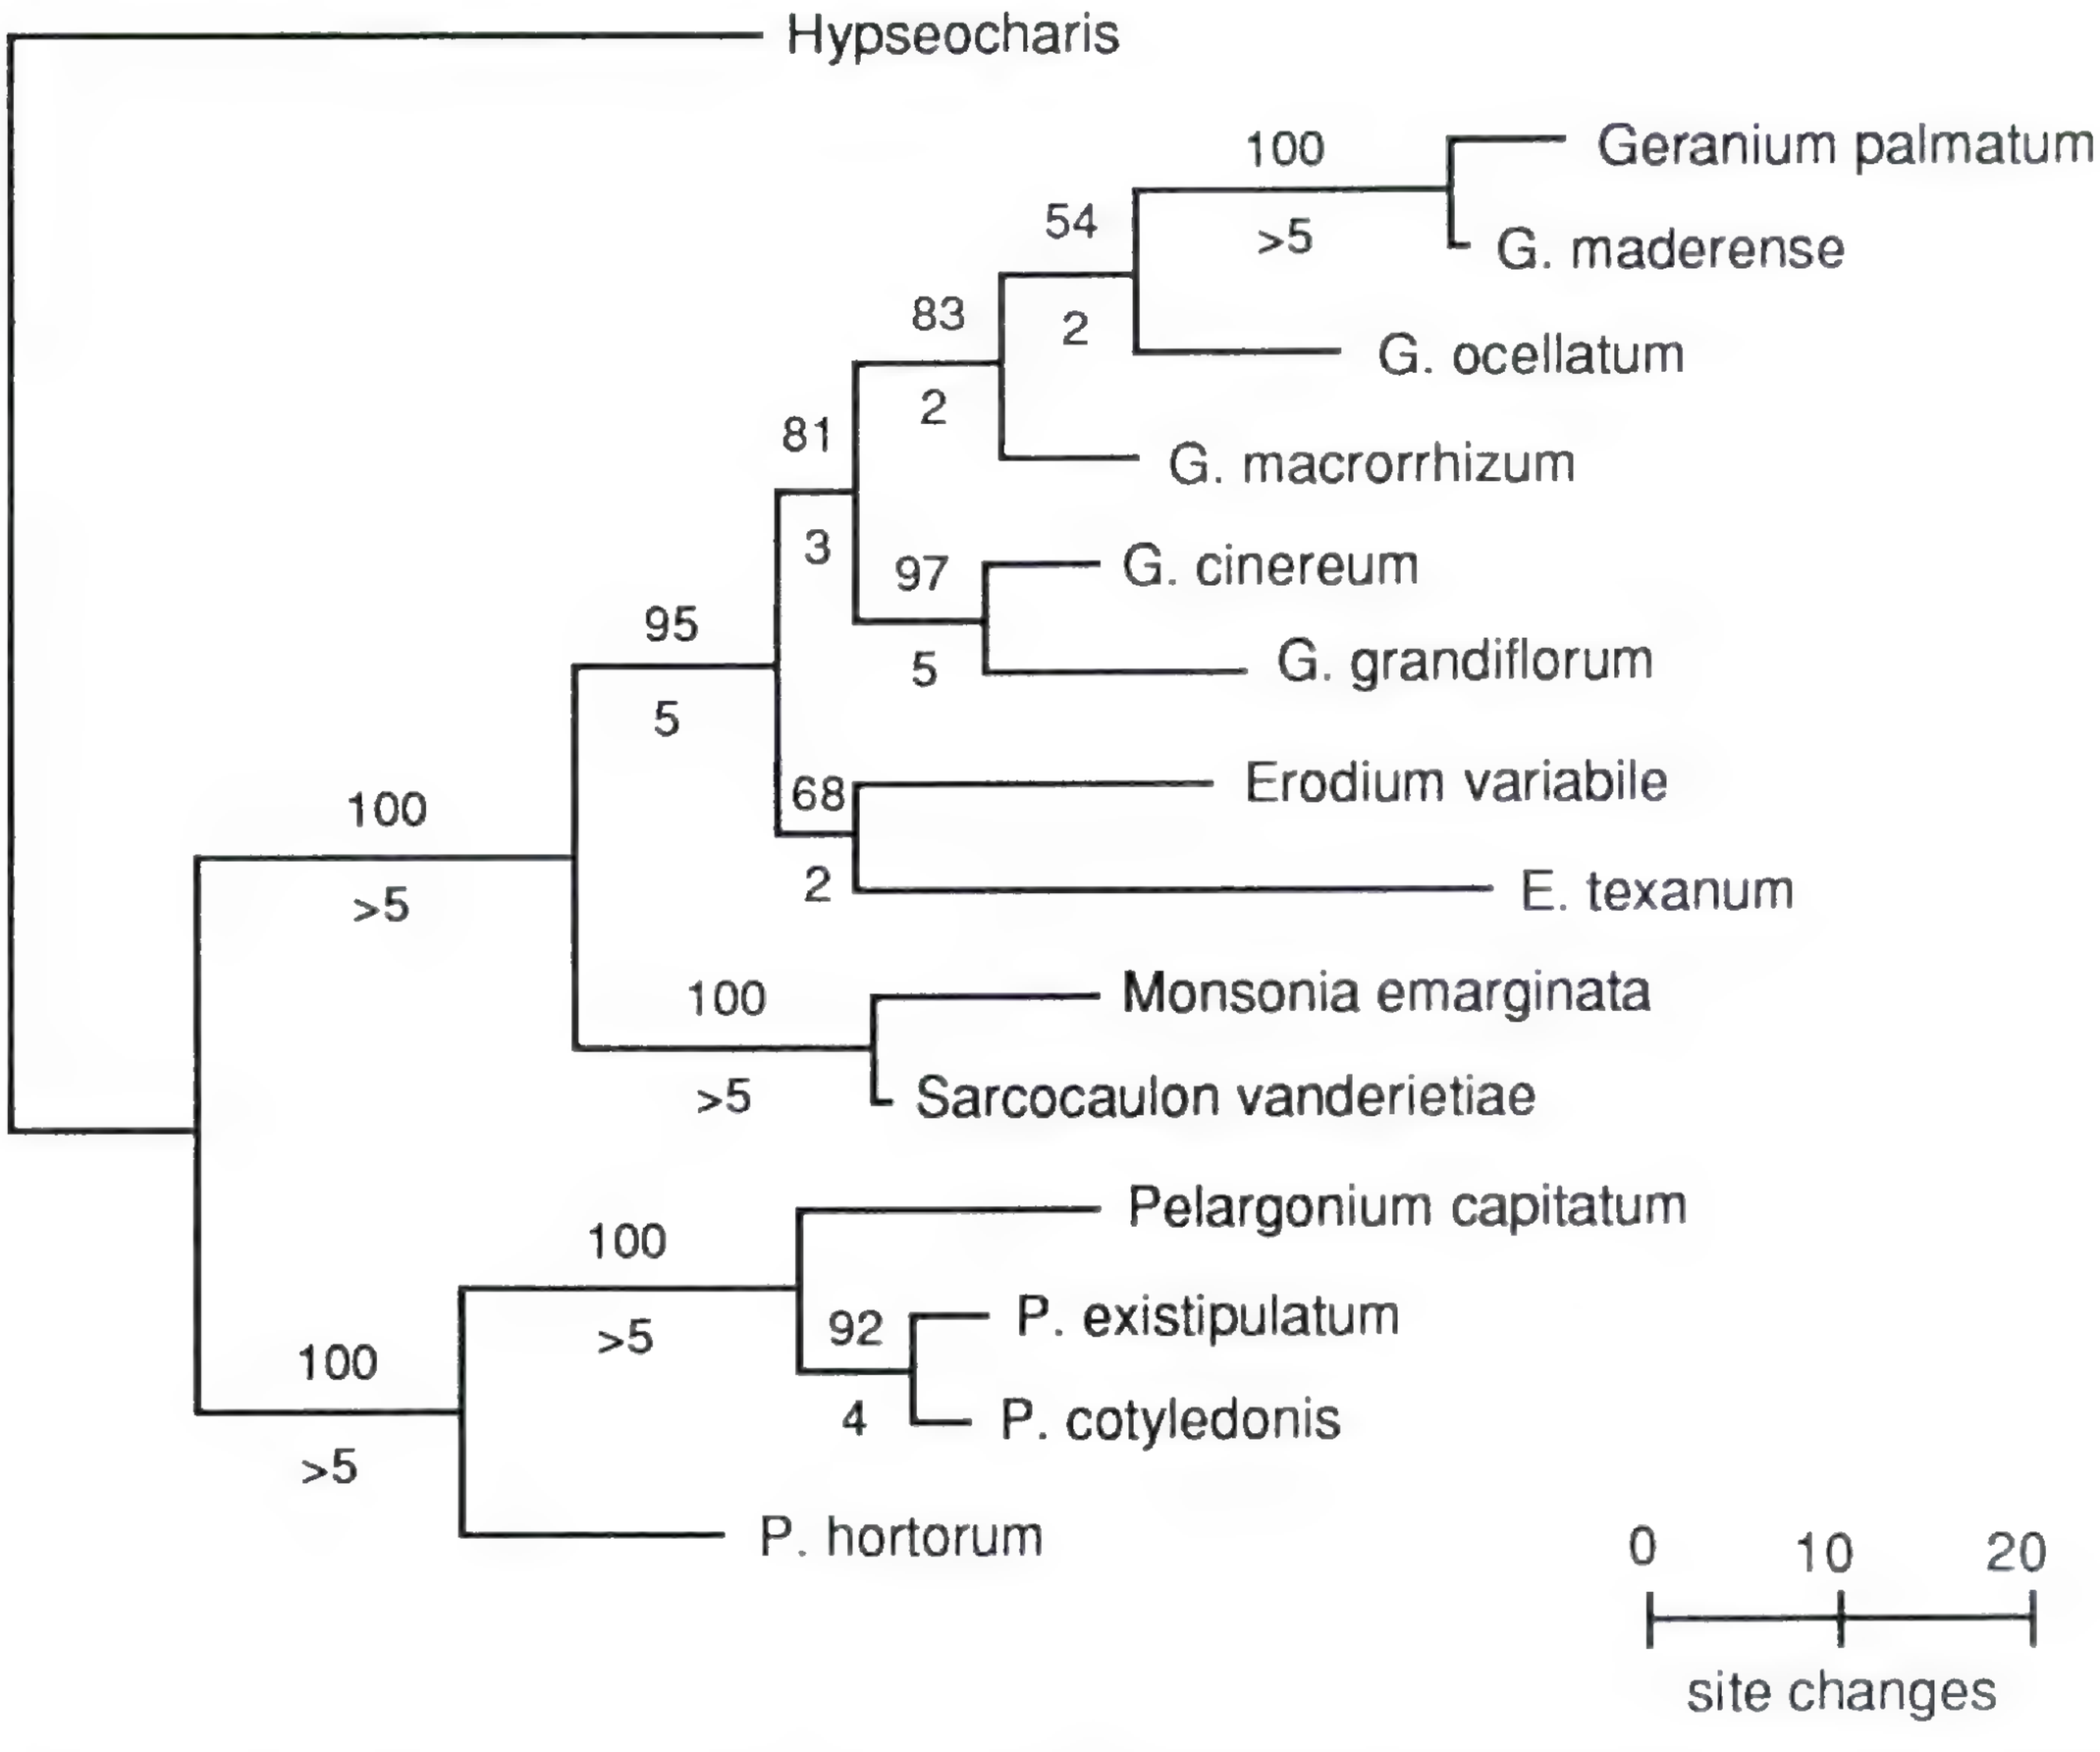

FIGURE 2. The single minimum length Fitch parsimony tree obtained for taxa of Geraniaceae based on comparison of *rbc*L sequences (length = 330 steps, RI = 0.79). Bootstrap values out of 250 replicates are indicated above the branches and decay values are indicated below them.

represented by *G. ocellatum*, *G. maderense* plus *G. palmatum*, and *G. macrorrhizum*, are placed together in a monophyletic group, whereas the individual representatives of subgenus *Geranium* (*G. grandiflorum*) and subgenus *Erodioideae* (*G. cinereum*) group together. The numbers of site changes and associated bootstrap values seen in comparisons within *Erodium*, *Geranium*, and *Pelargonium* are often high and suggest that substantial resolution among other infrageneric groups may be obtained using the *rbc*L gene. One result of particular interest is the unequivocal placement of *Pelargonium cotyledonis*, unusual for the genus in its radially symmetrical flowers and reduced nectar spur, in a position nested within the genus.

## DISCUSSION

### EVALUATION OF SUPPORT FOR BRANCH PATTERNS

In Figures 1 and 2, we compare bootstrap values, decay values, and branch lengths for the various branches of our cladogram. The bootstrap values and decay values are positively correlated, but the correspondence between the two is not monotonic. As an example, the range of bootstrap values corresponding to particular decay values in Figure 1 are as follows: one added step (11–42%, mean = 23%), two added steps (45–85%, mean = 58%), three added steps (53–79%, mean = 66%), four added steps (66–89%, mean = 79%), five added steps (80–87%, mean = 84%), >five

←

FIGURE 1. The single minimum length Fitch parsimony tree obtained from comparison of families of Geraniales and possible relatives using *rbc*L sequence data (length = 1,609 steps, RI = 0.47). Taxa assigned to the Geraniales in the classification of Cronquist (1981) are indicated by dots. Bootstrap values out of 250 replicates are shown above the branches, and decay values (numbers of additional steps needed for a branch to collapse) are given below the branches. The taxa of Geraniaceae included in this analysis are *Erodium* ×*variable*, *Geranium grandiflorum*, *Monsonia emarginata*, *Pelargonium* ×*hortorum*, and *Sarcocaulon vanderietiae*.

added steps (79–100%, mean = 97%). The bootstrap and decay values both appear to provide reasonable indications of which branches on the tree are poorly supported and which are strongly supported, whereas the interpretation of intermediate values is likely to be ambiguous in either case. Displaying both bootstrap and decay values is instructive, since they indicate different aspects of the support for the nodes in the tree and thus tend to reinforce one another. The large amount of computational time required to determine all trees of given lengths more than five steps above the minimum length currently imposes a limit to the precision obtainable with decay analysis. Computational constraints also significantly limit the number of taxa that can be readily evaluated with either decay or bootstrap analysis, leaving only branch lengths and detailed examination of the character distribution to evaluate the support for particular branches when large numbers of taxa are compared. Branch lengths on a given minimum length tree may or may not correspond well to bootstrap values and decay values, presumably depending on the frequency of homoplasy for the characters supporting and internal to a given branch. For example, branch lengths of nine to ten characters in Figure 1 have bootstrap values ranging from 25 to 100% and decay values ranging from one to >five, whereas the bootstrap and decay values correspond much more closely to one another.

## RELATIONSHIPS OF THE GERANIALES

Our results do not provide any substantial support for close relationships of any taxa other than *Hypseocharis* to the Geraniaceae sens. str. The Geraniaceae also group with *Crossosoma* and then with *Greyia*, *Francoa*, and *Viviania* in one of the global analyses of Chase et al. (1993) and in some of the analyses of Morgan & Soltis (1993), but our results would indicate that the character support for the relationships of these groups to the Geraniaceae is weak. While the Geraniaceae are clearly placed in the core group of Rosidae in our analysis (and those of Chase et al., 1993, and Morgan & Soltis, 1993), additional analyses with more of the segregate taxa included and with a larger set of molecular characters will probably be necessary to assess rigorously the precise position of the family within the subclass.

The placement of *Limnanthes* and *Tropaeolum* in a clade of glucosinolate-producing taxa is a consistent feature of *rbc*L sequence comparisons (see particularly Rodman et al., 1993, which includes almost all of the glucosinolate families). Most recent higher-order classifications have placed the Limnanthaceae and Tropaeolaceae in the Geraniales or adjacent orders (see Table 1). However, the occurrence of erucic acid (a compound characteristic of the core capparalean group of glucosinolate taxa) in the Limnanthaceae and Tropaeolaceae seems suggestive of a close relationship between these families and the other glucosinolate taxa, as suggested by Dahlgren (1975). A cladistic analysis of morphological characters by Rodman (1991) placed the Tropaeolaceae within the glucosinolate lineage in a position similar to its placement in the *rbc*L sequence comparisons of Rodman et al. (1993), whereas the morphological trees placed the Limnanthaceae between the Geraniaceae plus Oxalidaceae and the glucosinolate taxa in association with Balsaminaceae. Link (1992) has compared the Limnanthaceae to the Geraniales for a series of floral and embryological characters and concluded that there was no strong evidence favoring a close relationship between them. Thus, because of the high degree of internal consistency of the *rbc*L data (as indicated by the bootstrap values of 94% and 100% in Fig. 1) we favor the inclusion of the Limnanthaceae and Tropaeolaceae within the clade of glucosinolate taxa.

The apparently arbitrary nature of the delimitation of the subclasses Dilleniidae and Rosidae is emphasized by the placement of the Tropaeolaceae and Limnanthaceae (from Cronquist's Rosidae) in a group of glucosinolate taxa largely assigned to the Dilleniidae. As noted by Olmstead et al. (1992) and Chase et al. (1993), the Dilleniidae appear to be a polyphyletic group arising from several separate lineages of Rosidae. As shown in Figure 1, and also Chase et al. (1993) and Rodman et al. (1993), the closest relatives of the glucosinolate lineage appear to be the Malvales (usually assigned to the Dilleniidae) and the Sapindales (usually assigned to the Rosidae).

The position of *Impatiens* (Balsaminaceae) outside of the main lineage of Rosidae and far removed from any other putative groups of Geraniales is unexpected, but appears to be robust to the choice of outgroup and ingroup taxa in the analysis. In the broader *rbc*L analysis of Chase et al. (1993) the Balsaminaceae are placed in a group of rather disparate taxa primarily composed of Ericaceae and other families from the Dilleniidae of Cronquist, but also including the Polemoniaceae (generally assigned to the Asteridae). As discussed by Cronquist (1981), the morphological evidence linking the Balsaminaceae to the Geraniales is weak. The Balsaminaceae differ from the Geraniaceae in embryological features, having tenuinucellate ovules

and cellular endosperm (which are, however, found in the Ericales) rather than crassinucellate ovules and nuclear endosperm.

The separation of the Oxalidaceae from the Geraniaceae in the *rbc*L analysis is contrary to the results of the cladistic analysis of Rodman (1991) and to the recent higher-order classifications of Cronquist (1988), Takhtajan (1987), and Thorne (1992). Our results are in better accord with the groupings of Dahlgren (1989), who placed the Oxalidaceae in the order Linales. The support for the exclusion of the Oxalidaceae from the Geraniales in the *rbc*L analysis is strong, since 20 additional steps are required to force the two families into an adjacent position on the tree, whereas the morphological evidence linking the two families is relatively weak. The two families are similar in generally having 10 to 15 stamens with basally connate filaments, but differ in that the Oxalidaceae have separate styles, abundant endosperm, tenuinucellate ovules, and capsular fruits, whereas the Geraniaceae have fused styles, scant or absent endosperm, crassinucellate ovules, and a specialized type of schizocarpous fruits (see Cronquist, 1981). Boesewinkel (1988) demonstrated that *Hypseocharis*, while often assigned to the Oxalidaceae, has crassinucellate ovules and scant endosperm along with fused styles and is also similar to the Geraniaceae in details of seed wall anatomy not seen in the Oxalidaceae. *Hypseocharis* is also much more similar to the Geraniaceae than the Oxalidaceae in its floral vasculature and has a staminal arrangement similar to that of *Monsonia* and *Sarcocaulon* (Rama Devi, 1991). Thus, *Hypseocharis* appears to be most similar to the Geraniaceae sens. str. in morphology, in exact agreement with the results of our analysis, rather than being intermediate between Oxalidaceae and Geraniaceae. The features shared by *Hypseocharis* and Oxalidaceae (e.g., capsular fruits and the absence of a stylar column) can readily be explained as shared primitive features found in a wide range of rosid taxa. Our results are consistent with the traditional placement of the woody genus *Averrhoa* (the cultivated starfruit) along with *Oxalis* in the Oxalidaceae. The longer branch length leading to *Oxalis* on the cladogram in Figure 1 (44 vs. 13 steps) is striking and would seem to imply a faster rate of sequence change in the shorter-lived herbaceous genus.

Our results provide support for the exclusion of the segregate families Ledocarpaceae and Vivianiaceae from the Geraniaceae, since they are linked robustly to Greyiaceae and Francoaceae instead. Study of additional members of Vivianiaceae and Ledocarpaceae will be necessary before evaluating whether both of these families and the other South American segregate family Rhynchothecaceae should be treated as three separate families. Preliminary data from seed anatomy reported by Boesewinkel (1988) indicate that *Viviania* and also *Dirachma* (Dirachmaceae) are not similar to *Hypseocharis* and the Geraniaceae sens. str. Airy Shaw (1966) earlier suggested that the Socotran genus *Dirachma* is related to the South African family Greyiaceae, presumably on the basis of similar fruit morphology.

In contrast, *Biebersteinia* (the sole genus of the Eurasian family Biebersteiniaceae) appears to be relatively similar to the Geraniaceae in both seed and fruit morphology (Boesewinkel, 1988) and is clearly in need of further evaluation from both morphological and molecular standpoints to assess its relationship to the Geraniaceae. Our results, taken together with those of Boesewinkel, suggest that *Hypseocharis* may appropriately be included in the Geraniaceae as a monogeneric subfamily, while *Biebersteinia* could represent a third subfamily. Further sampling will be needed to assess rigorously the delimitation of the Geraniaceae and Geraniales, but a conservative approach would be to include only *Hypseocharis*, *Biebersteinia*, and the Geraniaceae sens. str. within the order.

### RELATIONSHIPS WITHIN THE GERANIACEAE

Our results agree with morphological data in indicating that the Geraniaceae sens. str. is a well defined monophyletic group. The group is also supported as monophyletic by the loss of the intron in the plastid gene *rpl*16 (Downie & Palmer, 1992), a character that has not yet been examined in *Hypseocharis*. Within the family, our study provides the first available phylogenetic framework. Only the close relationship between *Monsonia* and *Sarcocaulon* has been strongly supported by morphological data. These genera have extremely similar flowers that differ from the rest of the Geraniaceae sens. str. (but resemble *Hypseocharis*) in having 15 stamens rather than 10 or fewer. *Monsonia* and *Sarcocaulon* also share the loss of the highly conserved *rpl*2 intron, otherwise seen throughout the family (Downie et al., 1991). These two genera may appropriately be treated as congeneric, since they differ primarily in that *Sarcocaulon* is a stem succulent and generally has spinescent persistent leaf bases, whereas *Monsonia* is neither succulent nor spiny. Our results do not agree with the suggestion of Rama Devi (1991), on the basis of similarity in staminal arrangement and vasculature, that *Monsonia* and *Sarcocaulon*

are more closely related to *Hypseocharis* than to other genera of Geraniaceae.

The basal split between *Pelargonium* and the rest of the Geraniaceae sens. str., which is well supported in our analyses, has not been predicted based on morphology but is consistent with the much greater level of morphological diversification within *Pelargonium* than in the rest of the family. *Pelargonium* is distinct from the rest of the family in having a nectar spur at the base of the flower (a derived character based on outgroup comparison to *Hypseocharis*) and generally has bilaterally rather than radially symmetrical flowers (a derived feature otherwise observed only in some members of the genus *Erodium*). One of the two species of *Pelargonium* with radially symmetrical flowers (*P. cotyledonis*) appears to be nested within the genus on the basis of our *rbc*L comparisons, suggesting that radial symmetry here represents a reversal from bilateral symmetry. The substantial number of base substitutions observed among representatives of four of the sections of *Pelargonium* augurs well for efforts to use sequence information from the *rbc*L gene to examine relationships among the 14 currently recognized sections of the genus (see van der Walt & Vorster, 1988; Albers et al., 1992) and to assign to section those species of uncertain affinity. Comparisons of the gene among species from the majority of the sections are currently in progress.

The sister-group relationship between *Geranium* and *Erodium* indicated by our results is neither strongly supported nor contradicted by information from morphology and cytology (cf. Yeo, 1984). *Geranium* has a relatively unspecialized floral morphology, but exhibits specialized seed-discharge mechanisms in subgenus *Geranium* and subgenus *Robertium*, whereas *Erodium* often exhibits floral zygomorphy but has the unspecialized "*Erodium*-type" of seed discharge (Yeo, 1984). These two genera do have in common a primarily Northern Hemisphere distribution, whereas *Monsonia*, *Sarcocaulon*, and *Pelargonium* have distributions centered in southern Africa (van der Walt & Vorster, 1988; Yeo, 1984).

The phylogenetic framework that we have obtained from *rbc*L comparisons allows us to begin to examine the likely history of structural changes in the chloroplast genome. Our results suggest that there have been separate losses of a copy of the inverted repeat region in the chloroplast genome in *Erodium* and *Sarcocaulon* and probably separate expansions of the inverted repeat in *Geranium* and *Pelargonium* (see Price et al., 1990). Examination of the plastid genome in *Hypseocharis* will be important in indicating the primitive condition in the family, while comparative studies in the other genera may indicate features of the genome that are associated with these structural changes.

# TRIBAL RELATIONSHIPS IN ONAGRACEAE: IMPLICATIONS FROM *rbc*L SEQUENCE DATA[1]

*Elena Conti,*[2] *Anthony Fischbach,*[3] *and Kenneth J. Sytsma*[2]

ABSTRACT

The evolutionary relationships among the seven tribes of Onagraceae, the most intensively studied family of intermediate size, have been examined from morphological and molecular perspectives. Previous cladistic analyses of chloroplast (cp) and nuclear ribosomal (nr) DNA restriction sites, nuclear-encoded *rbc*S amino acid sequences, nrRNA nucleotide sequences, and morphological characters, produced trees that agree in defining the tribe Jussiaeeae as the sister group to the rest of the family. However, the relationships among the rest of the tribes are not completely resolved by these analyses. Cladistic analyses of sequence data from the chloroplast encoded *rbc*L gene produced results that bear on two major issues: (i) intertribal relationships within Onagraceae, and (ii) congruence with other cladistic analyses. Sequences of *rbc*L were obtained from all tribes of Onagraceae and from three families that have been proposed as sister taxa of Onagraceae on the basis of other molecular and morphological evidence (Lythraceae, Punicaceae, Trapaceae). Phylogenetic analysis of *rbc*L sequence data produced a single most parsimonious tree, both Fitch and weighted, that defines three strongly supported monophyletic groups within the family: all tribes except Jussiaeeae; Onagreae and Epilobieae; and, most interestingly, Fuchsieae and Circaeeae. The formation of this last clade corroborates the results of the cpDNA restriction site and of the nrRNA sequence data. The data also indicate an apparent slowdown in the rate of *rbc*L sequence divergence in the woody *Fuchsia* lineage relative to the herbaceous *Circaea* lineage. The placements of monogeneric tribes Lopezieae and Hauyeae are not strongly supported. The topology of the *rbc*L tree basically confirms that of the cpDNA restriction site tree. Among the other cladistic analyses, the nrRNA sequence survey produced the tree closest to the *rbc*L tree, followed in order by the *rbc*S amino acid sequence tree, the nrDNA restriction site tree, and the morphological tree.

The Onagraceae consist of seven tribes, 15 genera, and 652 species; six tribes are monogeneric and one (Onagreae) includes nine genera (Hoch et al., 1993; Table 1). Onagraceae presumably originated in West Gondwanaland (the oldest fossil records are from Brazil and California) and reached their highest degree of diversification in North America (Raven & Axelrod, 1974; Raven, 1988). Raven (1988) pointed out that the pollen of Onagraceae is so distinctive it can be recognized in the fossil record from the Late Cretaceous (73–65 mya).

The inclusion of Onagraceae in Myrtales is not questioned (Johnson & Briggs, 1984), but the family is somewhat isolated in the order. The Onagraceae are set off from other families in the order by their peculiar syndrome of morphological and embryological characters: epigynous flowers (Dahlgren & Thorne, 1984); pollen grains with viscin threads (Patel et al., 1984; Skvarla et al., 1976) and peculiar structure of the pollen wall ("paracrystalline beaded" ektexine; Raven, 1988); 4-nucleate *Oenothera*-type embryo sac formation (Tobe & Raven, 1983); abundance of calcium oxalate raphides in vegetative cells (Carlquist, 1975); and presence of septa dividing the sporogenous tissue in the anthers (Tobe & Raven, 1986). The isolation of the family in Myrtales is emphasized by Thorne (1992), who defined Onagraceae as the sole family in suborder Onagrinae.

The Onagraceae are the most intensively studied family of intermediate size from both systematic

[1] For collections of leaf material, we thank Peter Raven and Peter Hoch, Missouri Botanical Garden, and James Affolter, formerly of Berkeley Botanical Garden. Jeffrey Palmer provided clones of *rbc*L for probing of southern transfers. Richard Olmstead gave sequences for 5′ and 3′ primers for amplifying *rbc*L. Gerard Zurawski kindly provided internal primers for sequencing *rbc*L. We thank David Baum and James Rodman for fruitful discussions on phylogenetic analyses, Charles Delwiche for invaluable computer assistance, and James Smith for making DNA extracts available. Kandis Elliot provided the artwork. Critical reading of earlier drafts by Peter Raven and Peter Hoch was invaluable. The support of the Wisconsin Alumni Research Foundation and the National Science Foundation (BSR-8516573 and BSR-9020055) to K. J. Sytsma is also gratefully acknowledged. This paper represents a portion of the Ph.D. research of E. Conti.

and evolutionary perspectives (Raven, 1988; Sytsma & Smith, 1992). Detailed studies exist for morphology–anatomy (Eyde, 1982, on flowers; van Vliet & Baas, 1984, on xylem); embryology (Tobe & Raven, 1983); palynology (Patel et al., 1984); reproductive biology (Raven, 1979); phytochemistry (Averett & Raven, 1984; Dahlgren & Thorne, 1984); and molecules (Bult & Zimmer, 1993; Crisci et al., 1990; Martin & Dowd, 1986; Sytsma & Smith, 1992; Sytsma et al., 1991b).

The cladistic analyses carried out on such data have produced cladograms based on chloroplast DNA (cpDNA) restriction sites (Sytsma et al., 1991b), nuclear ribosomal RNA (nrRNA) sequences (Bult & Zimmer, 1993), nuclear ribosomal DNA (nrDNA) restriction sites (Crisci et al., 1990), amino acid sequences of the nuclear-encoded small subunit of ribulose bisphosphate carboxylase (*rbc*S; Martin & Dowd, 1986), and morphology (Hoch et al., 1993). These trees are congruent in indicating *Ludwigia* (tribe Jussiaeeae) as the sister group to the rest of the family but show some disagreement in the relationships among the other tribes. *Ludwigia* possesses a number of plesiomorphic features, including the absence of a floral tube beyond the ovary and the presence of up to seven parts in its floral whorls. The relationships among the rest of the tribes are not clear, except that the other four monotypic tribes (Fuchsieae, Circaeeae, Lopezieae, and Hauyeae) exhibit a greater number of plesiomorphic features than do either Epilobieae or Onagreae (nine genera).

The remarkable amount of morphological and molecular information available for the Onagraceae, although often conflicting, will provide the framework for comparisons with sequence data of the plastid-encoded large subunit of ribulose bisphosphate carboxylase (*rbc*L) described in this study. The two goals of this phylogenetic analysis of Onagraceae are: (1) to derive a detailed set of relationships among the tribes of Onagraceae using *rbc*L sequence data; (2) to determine congruence between the *rbc*L cladogram and that obtained from cpDNA restriction site mapping analysis, and subsequently from nrRNA sequence, *rbc*S amino acid sequence, nrDNA restriction site, and morphology data sets. The *rbc*L and cpDNA restriction site mapping data sets for the Onagraceae are mutually inclusive for taxa but completely exclusive for characters (i.e., no restriction enzymes mapped recognize variable sites within *rbc*L).

The applicability of *rbc*L sequence information to resolving relationships within families has seldom been tested (but see Doebley et al., 1990, on Poaceae; Soltis et al., 1990, on Saxifragaceae for studies in which intrafamilial relationships have been examined in part). A separate, detailed analysis is planned to examine the global implications of all data sets for the family (Sytsma et al., in prep.).

## Methods

Twelve species, representative of the seven tribes of Onagraceae and of three myrtalean outgroups, are considered in the present study. Table 1 lists the nine species of Onagraceae employed in this analysis. Two species of *Ludwigia* (*L. peruviana* (L.) Hara of sect. *Myrtocarpus* and *L. peploides* (HBK) Raven of sect. *Oligospermum*), representatives of divergent lines in the genus (Eyde, 1981), were sampled because *Ludwigia* is universally indicated as the sister genus to the rest of the family.

Total DNAs of all but *Oenothera* were extracted according to the method of Smith et al. (1991) from leaves kept at −80°C. For nine of these 12 taxa, excluding *Oenothera*, *Clarkia*, and *Epilobium*, the chloroplast *rbc*L gene was amplified by the polymerase chain reaction (Mullis et al., 1986; Erlich, 1989), using 'AmpliTaq' kits, a Perkin-Elmer Cetus Thermal Cycler, a 5′ primer that anneals to the first 26 base pairs of the gene and a 3′ primer that anneals to a flanking region downstream from the 3′ end. Therefore, for these nine taxa, it was possible to obtain the entire *rbc*L nucleotide sequence with the exclusion of the first (but generally highly conserved) 26 nucleotides.

The DNAs of two of the remaining three species, *Epilobium angustifolium* L. and *Clarkia xantiana* A. Gray, were digested with *EcoR*I (which cuts 10 base pairs internal to the 5′ end and 21 base pairs internal to the 3′ end of the *rbc*L gene) and ligated into pUC19 (later transferred into Bluescript-psk). Plasmids containing the *rbc*L insert (using purified segments of *rbc*L from *Nicotiana* as heterologous probes) were recovered from transformed colonies and purified over cesium chloride gradients. For these two species, the first 10 and the last 21 base pairs are thus missing in the cloned segments. The last 21 missing base pairs were later obtained for *Clarkia xantiana* following PCR amplification of total DNA as described above. The *rbc*L sequence for *Oenothera elata* HBK (ex *O. hookeri*) published by Winter & Herrmann (1988) was utilized. Because this *rbc*L gene was cloned using *EcoR*I, the last 21 base pairs of *Oenothera* are lacking, as with *Epilobium*.

Sequence data were obtained by the Sanger dideoxy method (Sanger et al., 1977) on double-stranded in-vitro amplified products (Gyllensten, 1989) using internal primers (provided by G. Zurawski) and Sequenase 2.0 (United States Biochemical). In most instances, DNA fragments up to 300 nucleotides long were resolved on 6% acrylamyde gels, but 5% Long Ranger gels (AT Biochem) were employed in order to separate DNA fragments up to 500 nucleotides long. These longer fragments were obtained by using a proportion of 1.5 μl extension mix to 1 μl termination mix (both provided in the USB-Sequenase kit) in the termination reactions. The critical step in the method of sequencing directly off the gene-cleaned, double stranded *rbc*L gene involves a heat shock immediately followed by a cold shock (James E. Anderson, pers. comm.). The annealing mixture, formed by the *rbc*L DNA template and the primer, is boiled for three minutes to denature the double stranded DNA, and then plunged into liquid nitrogen. The labeling mixture is then added to the annealing mixture while the latter is thawing in the tube held between fingers. The termination reactions are performed according to the instructions of the USB-Sequenase kit.

Sequences were directly aligned onto a reference sequence template of the *rbc*L sequence of *Nicotiana tabacum* L. and, subsequently, of *Clarkia xantiana*. To ascertain that the 12 sequences obtained belonged to coding genes, the nucleotide sequences were translated to the corresponding amino acid sequences with the TRANSLATE command in the University of Wisconsin-Genetics Computer Group (UW-GCG) package. Missing nucleotide positions are listed in the legend of Table 2.

The phylogenetic analyses were performed using the parsimony algorithms and tree analysis options of the PAUP 3.0r program (Swofford, 1991) on a Macintosh IIsi computer. Only putatively informative characters were included in the analyses; autapomorphic characters were added later to the terminal branches of the resulting most parsimonious phylogram. Various approaches were followed, including Fitch (1971) parsimony (with and without the third codon position), character state-weighting, decay analysis, randomization of trees, and analysis of constrained trees. The ACCTRAN (accelerated transformation optimization) option was employed in all analyses. BRANCH AND BOUND search was used to find the most parsimonious Fitch trees, for bootstrap analysis, decay analyses, and analyses employing character state stepmatrices. Bootstrap analysis (see Felsenstein, 1985, 1988) was performed on the matrix of the potentially informative characters to provide a sense of the support of each clade in the resulting majority rule trees. We are aware of the limitations and possible misuse of the bootstrap procedure (see Sanderson, 1989; Wendel & Albert, 1992), but believe that bootstrap analysis (and decay analysis, see below) can provide useful insight concerning how this data set supports different clades.

The decay analysis was accomplished by saving

TABLE 2. Data matrix of the 86 informative characters resulting from the *rbc*L sequences of the 12 taxa examined. Codon positions other than the third are indicated in the top row (bold face). Nucleotide positions identical to the positions of *Clarkia* are indicated by a dot. Missing nucleotide positions are indicated by "?". Additional noninformative nucleotide positions missing from the entire *rbc*L data set are: *Clarkia*: 705; *Punica*: 391–393, 636–638; *Lythrum*: 1074, 1075, 1282, 1283, 1341, 1342; *Ludwigia peruviana*: 392, 393; *L. peploides*: 392, 393; *Hauya*: 392; *Fuchsia*: 902, 903; *Circaea*: 87; *Lopezia*: 250, 663, 696, 720–725, 1072. Information on the length of the *rbc*L sequences and their GenBank accession numbers is listed in the Appendix at the end of this issue.

all the trees that are *n* steps longer than the shortest tree. The resulting strict consensus trees indicate which clades collapse to an unresolved polytomy at each extra step, thus providing a measure of the robustness of the monophyly of each clade in the minimal tree (see Bremer, 1988; Graham et al., 1991; Mishler et al., 1991; Smith & Sytsma, 1990, for examples).

The stepmatrix described in Albert et al. (1993; see also Albert & Mishler, 1992) was employed for character-state weighting. This stepmatrix takes into consideration known transition versus transversion biases for each position in the codon by assigning different weights to transitions and transversions for each position. In order to reflect lower probability of occurrence, transversions are weighted more than transitions: the highest weight is assigned to transversions in the second codon position, the second highest to transversions in the first codon position, and the lowest to transversions in the third codon position. An additional analysis of the *rbc*L data involved the deletion of all third codon-position changes.

Phylogenetic signal in the *rbc*L data was examined by performing the option RANDOM TREES in PAUP. Hillis (1991) provided critical values for g1 statistics (a common measure of left skewness of a distribution) of tree length distributions for up to eight taxa ($P < 0.05$ and $P < 0.01$). In order to compare the results of *rbc*L trees randomization with the critical values provided by Hillis, the three outgroup taxa (*Punica granatum* L., *Trapa natans* L., *Lythrum hyssopifolia* L.) and one taxon of Onagraceae were eliminated from the 12 taxa included in this *rbc*L study. As the monophyly of Jussiaeeae is not under dispute (see also results below), *Ludwigia peploides*, one of the two taxa representing this tribe, was eliminated from the data set. The frequency distribution of lengths of 10,000 random unrooted trees for the eight taxa left was analyzed.

The topology and lengths of other published trees for Onagraceae using different data sets were investigated by user tree options in PAUP. The choice and number of taxa represented in these alternative trees did not always match those of the present *rbc*L study. Therefore, in cases such as with the nrDNA restriction site tree (Crisci et al., 1990), where Lopezieae is absent, missing taxa were placed as in the *rbc*L tree. In this way the number of extra steps required to force the *rbc*L sequence data onto the topologies generated from the other data sets was minimized.

*Punica granatum* (Punicaceae), *Lythrum hyssopifolia* (Lythraceae sensu stricto) and *Trapa natans* (Trapaceae) were used for global outgroup comparison (Maddison et al., 1984). Based on cladistic analysis of morphological features, Johnson & Briggs (1984) indicated that the sister group to the Onagraceae includes Lythraceae sensu lato and/or Trapaceae, the latter a monotypic family. Lythraceae are characterized by several plesiomorphic features and by a wide range of morphological variation that suggest a central position in the order Myrtales (Dahlgren & Thorne, 1984). Both Johnson & Briggs (1984) and Dahlgren & Thorne (1984) included other small families within Lythraceae, most notably the monogeneric family Punicaceae. *Punica* consists of only two species, *P. granatum*, the pomegranate, and *P. protopunica* Balf. f., which may resemble the wild ancestor of the cultivated pomegranate (Dahlgren & Thorne, 1984). Most authors treat Punicaceae as a separate family, but wood anatomy and other morphological data suggest an inclusion within Lythraceae (Bridgewater & Baas, 1978).

## Results

The 12 *rbc*L sequences analyzed for this study contain 195 variable nucleotide positions; of these, 109 are autapomorphies, leaving 86 informative characters. Among the 195 variable positions, 137 (70.3%) are third codon positions, 34 (17.4%) are first codon positions, and 24 (12.3%) are second codon positions.

The data matrix of the 86 informative characters used in the phylogenetic analysis is shown in Table 2. The last informative character is position 1408, indicating that no variation is found among the last 20 nucleotides of the 10 taxa sequenced to the end of the gene. Therefore, it can be assumed that the only informative character missing for the two cloned genes of *Oenothera elata* and *Epilobium angustifolium* is position 1408.

Of the 86 putatively informative characters, 69 (79.7%) are binary characters, 15 (17.8%) are 3-state characters, and two (2.4%) are 4-state characters. Therefore, the minimum number of character-state changes possible (i.e., no homoplasy present) with this data set is 105. The informative changes are distributed differently, as expected, among the codon positions: 63 (73.2%) third codon-position changes, 16 (18.6%) first codon-position changes, and only seven (8.1%) second codon-position changes. The transition:transversion ratio among all possible changes between

states is 1.51, versus the expected value of 0.5, which implies approximately a three-fold transition bias.

The intertribal pairwise distance, based on overall sequence similarity, between Fuchsieae and Circaeeae is lower (1.7%) than the intergeneric distance between *Clarkia* and *Oenothera* (1.9%) in the tribe Onagreae (Table 3). The highest *rbc*L sequence divergence (5.2%) within the family Onagraceae is found between *Ludwigia peploides* (tribe Jussiaeeae) and *Epilobium angustifolium* (tribe Epilobieae). Including the outgroup taxa, the highest divergence (6.7%) is seen between *Lythrum hyssopifolia* (Lythraceae) and *Epilobium angustifolium* (Onagraceae).

The g1 value of −0.8849 obtained for the distribution of 10,000 random trees is much smaller than the critical value of −0.47 ($P < 0.01$) furnished by Hillis (1991) for eight taxa, thus providing strong evidence that phylogenetic signal is present in the *rbc*L data set. To assess if evolutionary "noise" was introduced by nucleotide changes occurring at the third codon position, the distributions of 10,000 random trees were re-examined by using only third codon-position changes (g1 = −0.8406) and by eliminating all third codon-position changes (g1 = −1.0066). These g1 values indicate that only an insignificant amount of "noise" is introduced by changes at the third codon positions.

The analysis of the informative *rbc*L sites yielded a single most parsimonious Fitch tree (Fig. 1). The tree is 168 steps long, with a Consistency Index (CI) of 0.625 and a Retention Index (RI) of 0.670. The CI value is considerably higher than the CI of about 0.3 expected for 12 taxa in a molecular data set (Sanderson & Donoghue, 1989). The numbers of apomorphies and the bootstrap values supporting each branch are reported on the Fitch tree (= majority rule tree from bootstrap analysis); the number of additional autapomorphies (not included in the original data set; Table 2) are indicated in parentheses for the terminal branches of the tree (Fig. 1). The fundamental features of the tree, such as the numbers of apomorphies supporting each branch, the numbers of consistent (i.e., CI = 1) apomorphies, transitions and transversions, codon positions, bootstrap values and decay order, are summarized in Table 4.

The lowest bootstrap value of the tree (44%) indicates the placement of *Hauya* between the tribe Jussiaeeae and the rest of the family as the weakest branch. This result agrees with the observation that only five changes support this placement of *Hauya* and that only two of these are consistent. The second weakest branch in the tree is the placement of *Lopezia* as the sister group to the clade formed by Epilobieae and Onagreae. This placement of *Lopezia* is supported by a low bootstrap value (56%) and by five changes, only one of which is consistent (one less than *Hauya*). The weak placements of *Hauya* and *Lopezia* are further reflected in the loss of resolution in the consensus tree of trees one step longer (Fig. 2A). The third weakest branch of the tree is that defining the tribe Onagreae (represented by *Clarkia* and *Oenothera*), which is recovered as a monophyletic clade in only 70% of the replications. The Onagreae clade is supported by five changes, of which only one is consistent (see Table 4). The monophyly of the

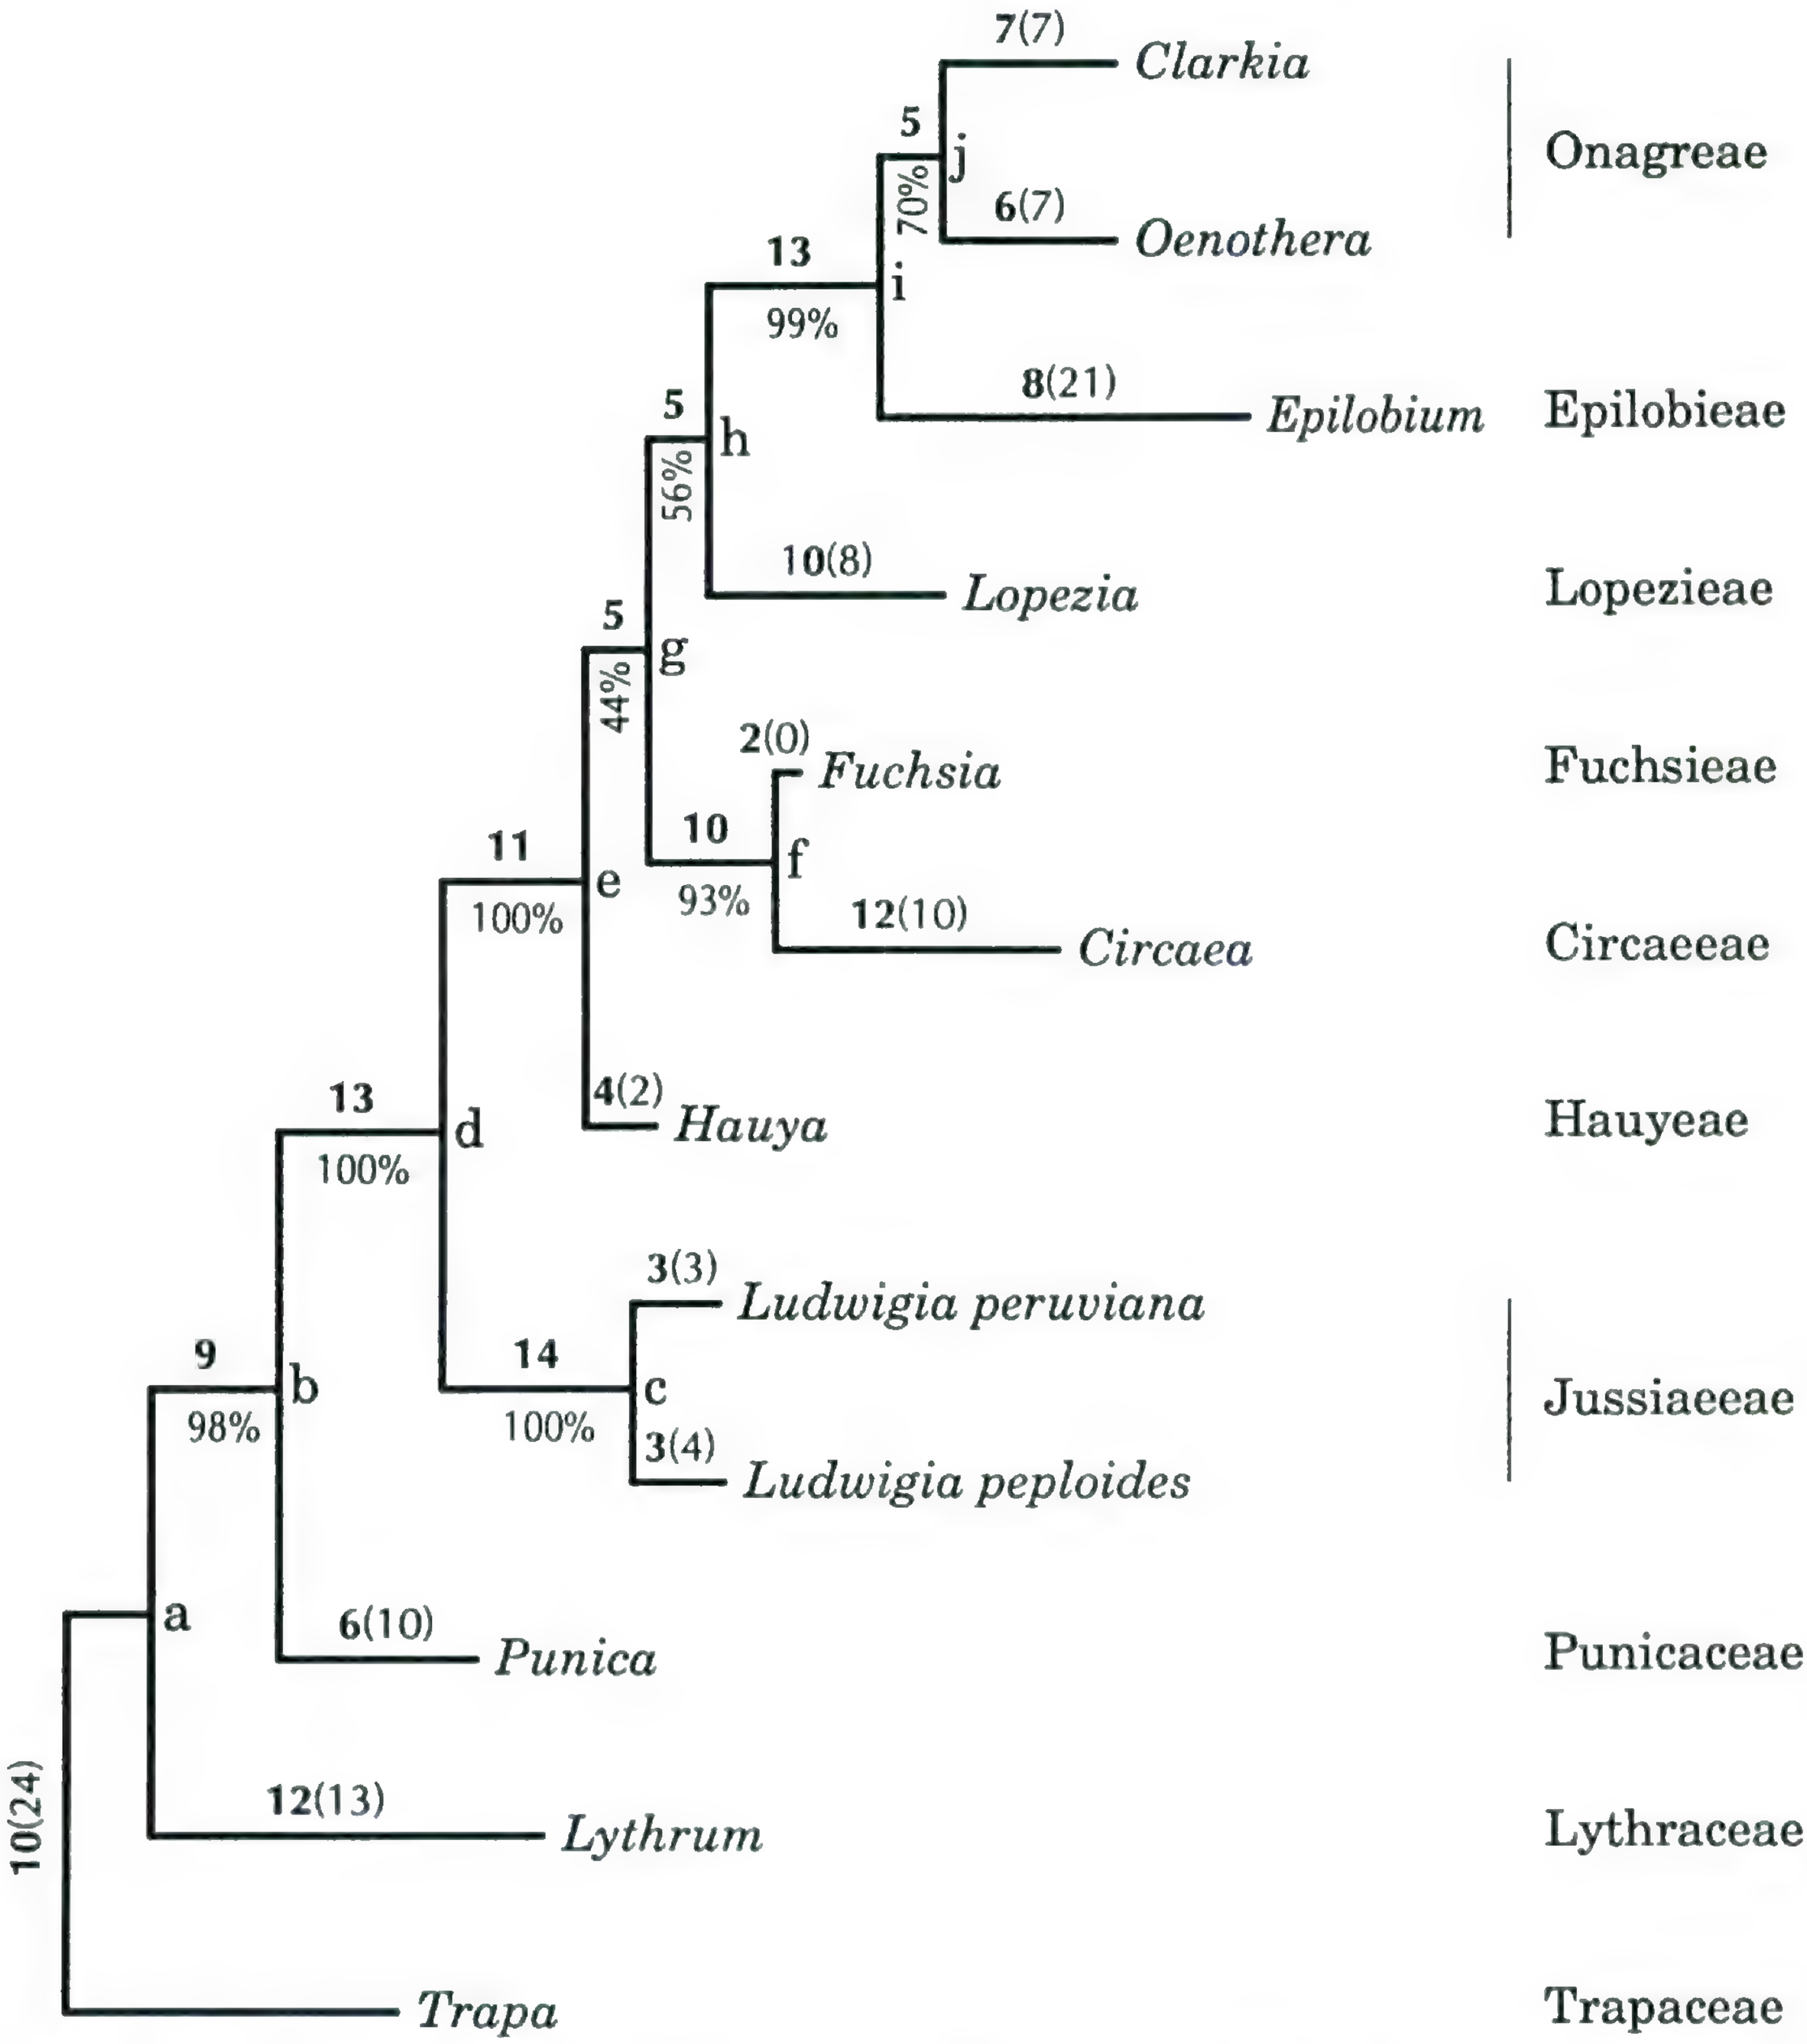

FIGURE 1. The most parsimonious, 168-step tree (represented here as a cladogram with branch lengths) resulting from analysis of *rbc*L sequences of nine taxa of Onagraceae and three outgroup families. *Punica*, *Lythrum*, and *Trapa* are used as simultaneous outgroups. The numbers of apomorphies supporting each clade are indicated in boldface above each branch. The numbers of autapomorphies in the terminal branches are indicated in parentheses. Bootstrap values are reported below the branches. Each node is identified by a small letter. The topology of the weighted tree is identical.

Onagreae is lost in the decay analysis at trees two steps longer (Fig. 2B).

All the remaining clades of the tree are strongly supported by the bootstrap (BS) analysis: (i) all Onagraceae exclusive of *Ludwigia* (BS = 100%); (ii) the two representatives of *Ludwigia* (BS = 100%); (iii) Onagreae–Epilobieae (BS = 99%); (iv) Punicaceae as the sister group to Onagraceae (BS = 98%); (v) *Fuchsia–Circaea* (BS = 93%). These high bootstrap values are correlated with the number of changes supporting these clades (see Fig. 1).

Decay analysis supports the strength of these clades. The monophyly of Onagraceae is lost at

eight (= 4.8%) extra steps (176 steps; 78 trees), when *Lythrum* and *Punica* form a polytomy with Onagraceae (Fig. 2E). Two clades, Onagreae–Epilobieae and Jussiaeeae, survive the breakdown of the familial clade (Fig. 2E). The monophyly of the tribe Jussiaeeae is especially well supported: this clade is lost only at 13 (7.7%) extra steps (Fig. 2G). Of these changes, a large proportion (nine, or 64%) is not affected by homoplasy, and six (42%) are transversions.

The analysis of constrained trees clearly indicates that the topology of the *rbc*L tree is closest to that of the tree based on chloroplast DNA restriction sites; only one extra step is necessary in order to reach the topology of the cpDNA restriction site tree (Fig. 3B). The second closest tree (Fig. 3C: two extra steps) is the nrRNA sequence tree, followed by the *rbc*S amino acid sequence tree (Fig. 3D: eight extra steps), the nrDNA restriction site trees (Fig. 3E: 10 extra steps for the Dollo parsimony, 50% majority rule consensus tree and 12 extra steps for the Wagner parsimony, 50% majority rule consensus tree), and, finally, the morphological tree (Fig. 3F: 14 extra steps).

The application of the character-state stepmatrices simultaneously to the first, second, and third codon position yields the same tree obtained by simple Fitch parsimony (Fig. 1). Elimination of all the changes that occur at the third codon position produces four equally parsimonious trees. In the strict consensus tree (Fig. 4) Onagreae and Onagraceae become paraphyletic groups (respectively, *Oenothera* forms a clade with *Epilobium*, and *Punica* falls within Onagraceae). Additionally, *Lopezia*, *Hauya* and *Punica* collapse to a polytomy with the Jussiaeeae clade and the clade formed by the rest of Onagraceae.

## Discussion

Cladistic analyses of *rbc*L sequence variation, using Fitch or weighted character-state parsimony, provide a single most parsimonious tree (Fig. 1) for Onagraceae and outgroup families. Many of the clades defined in this tree are strongly supported by bootstrap and decay analyses. On the other hand, trees produced by eliminating third codon positions portray evolutionary relationships difficult to support based on other lines of evidence (Fig. 4). This result suggests that changes at the third codon position in *rbc*L, far from producing mere evolutionary noise, are phylogenetically informative within Onagraceae.

The *rbc*L sequence data permit a re-evaluation of evolution within Onagraceae and allow for com-

Table 4. Summary of the major features of the most parsimonious tree in Figure 1. The nodes are indicated by small letters (see tree of Fig. 1). The acronyms are the same used in the legend of Table 3. The number of autapomorphies in the terminal branches (indicated in parentheses in the tree of Fig. 1) is not reported in this table. The numbers reported for the decay order indicate the number of extra steps necessary to collapse a branch to a polytomy. na = not applicable; BS = bootstrap.

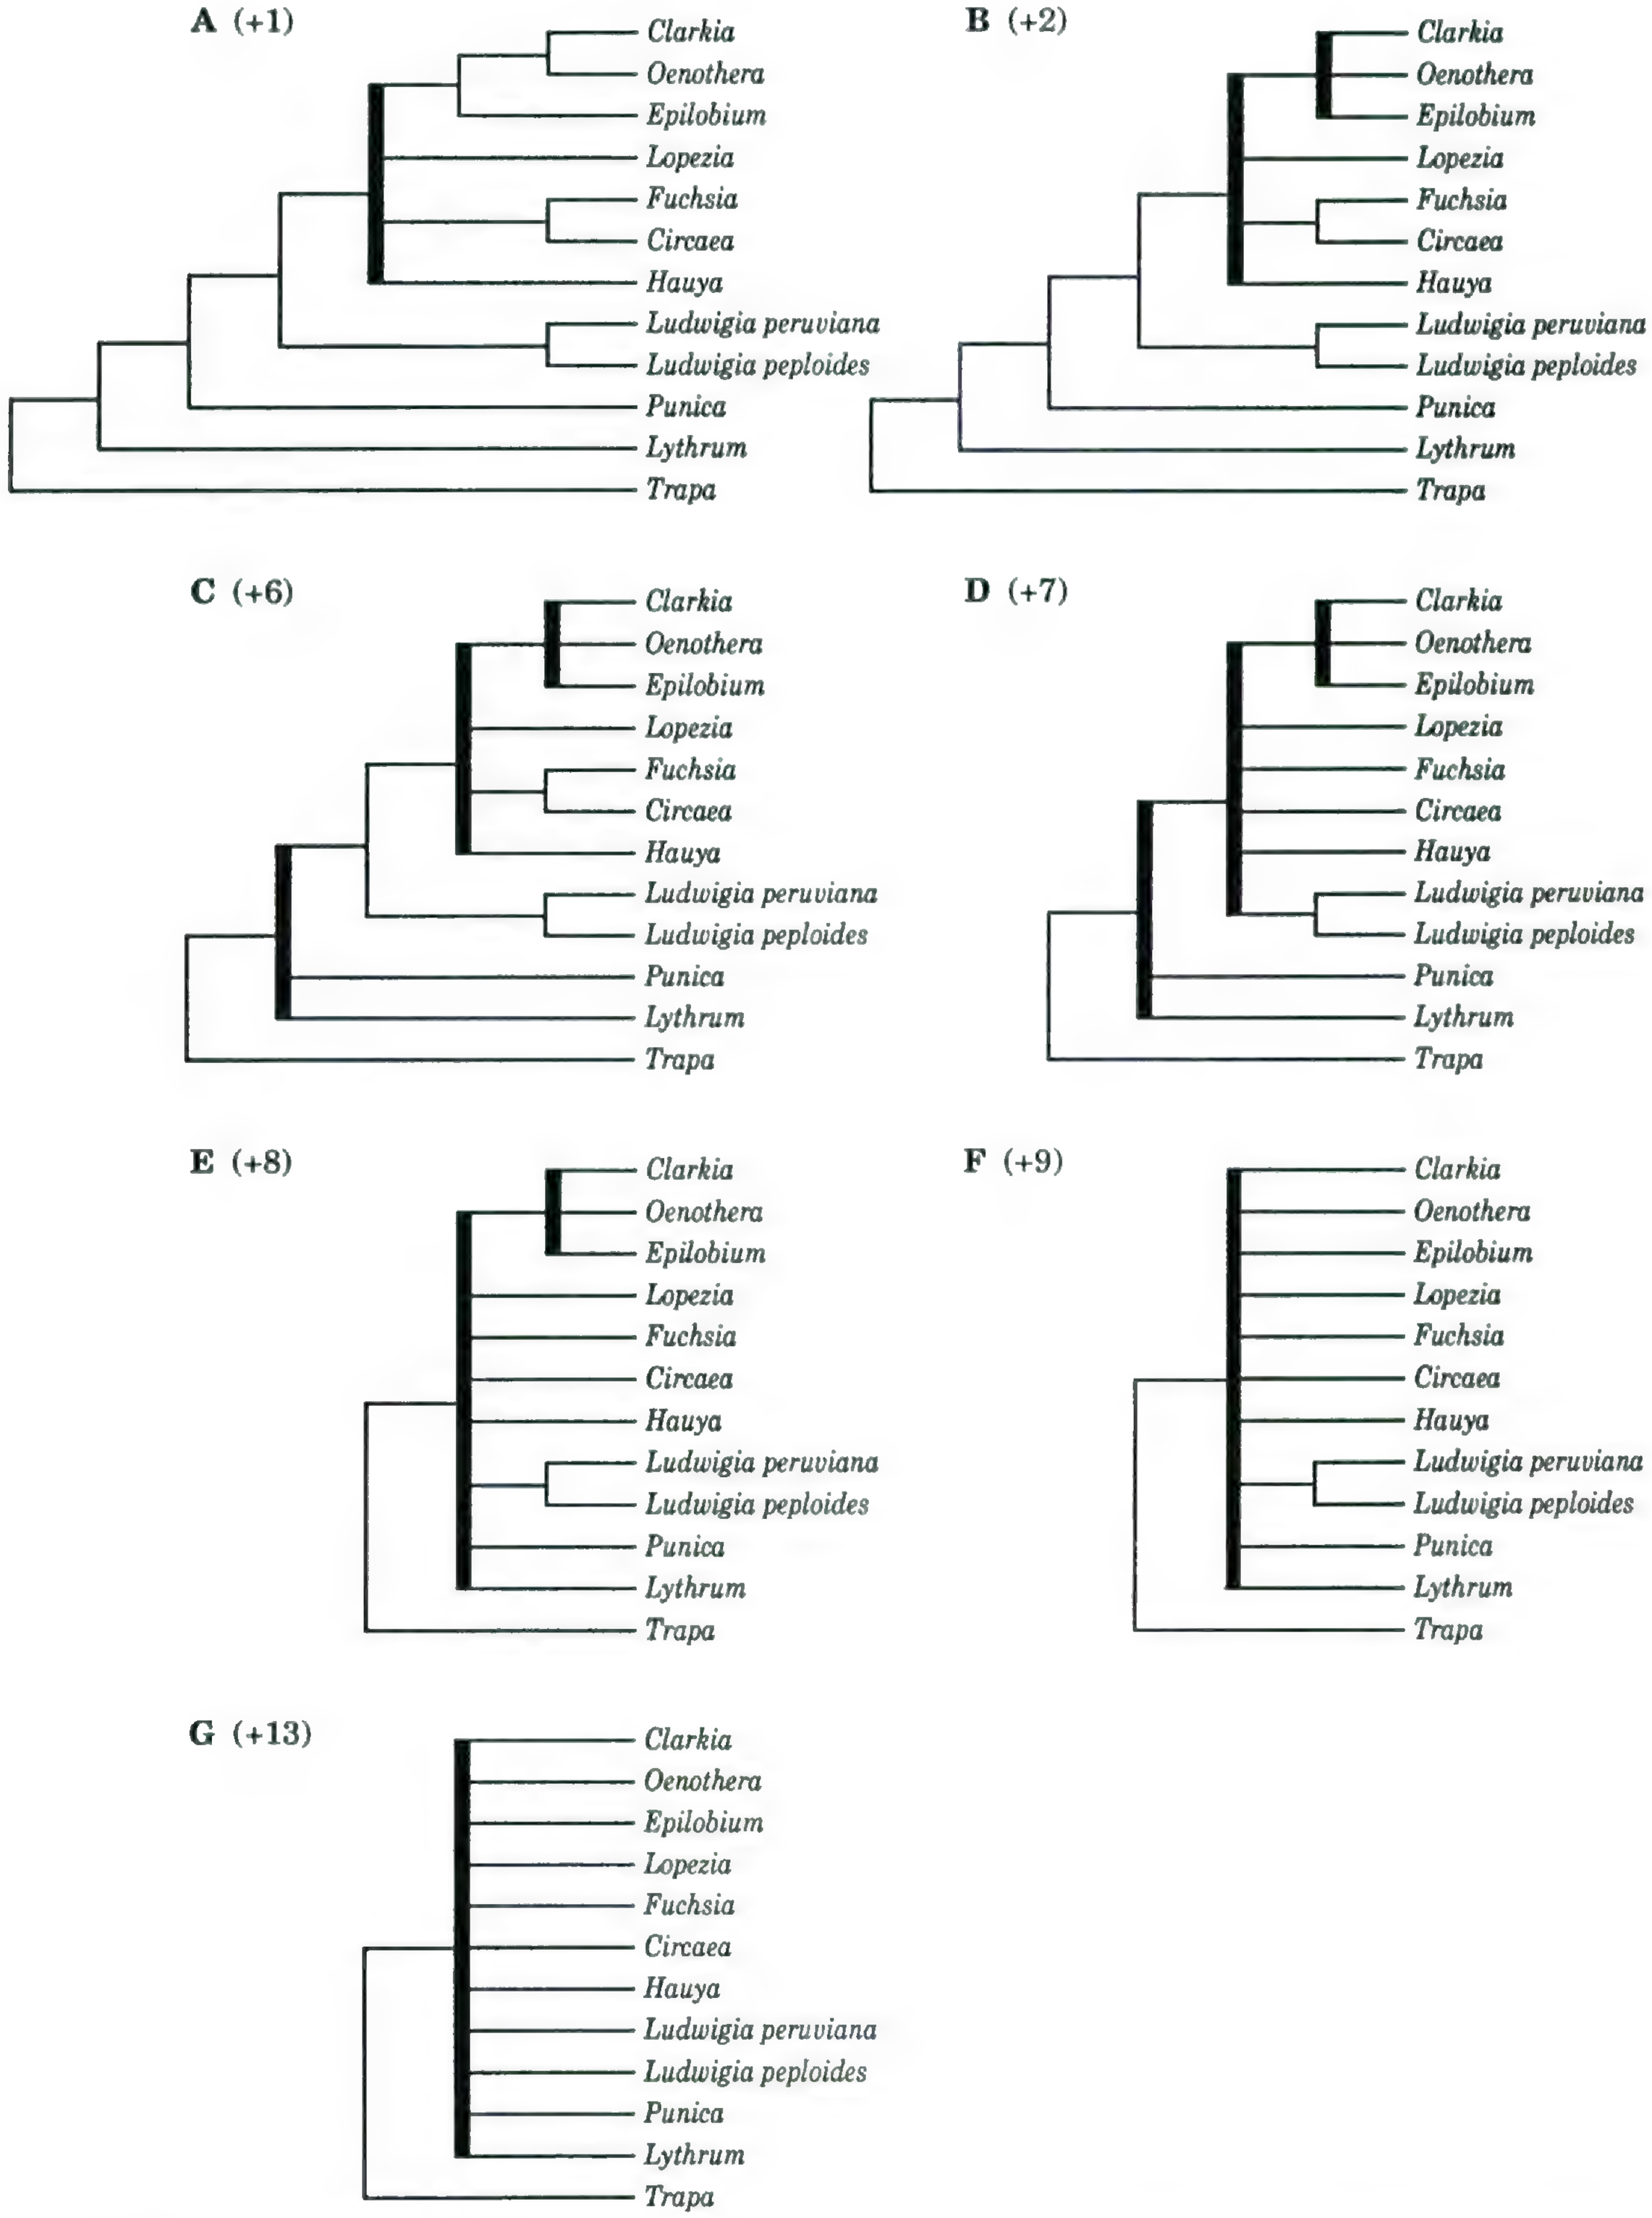

FIGURE 2. Decay analysis of the most parsimonious, 168-step tree. The number of extra steps at which each clade decays is reported in parentheses. Solid bars indicate the polytomies formed by the collapse of each monophyletic group in trees longer than the 168-step tree.

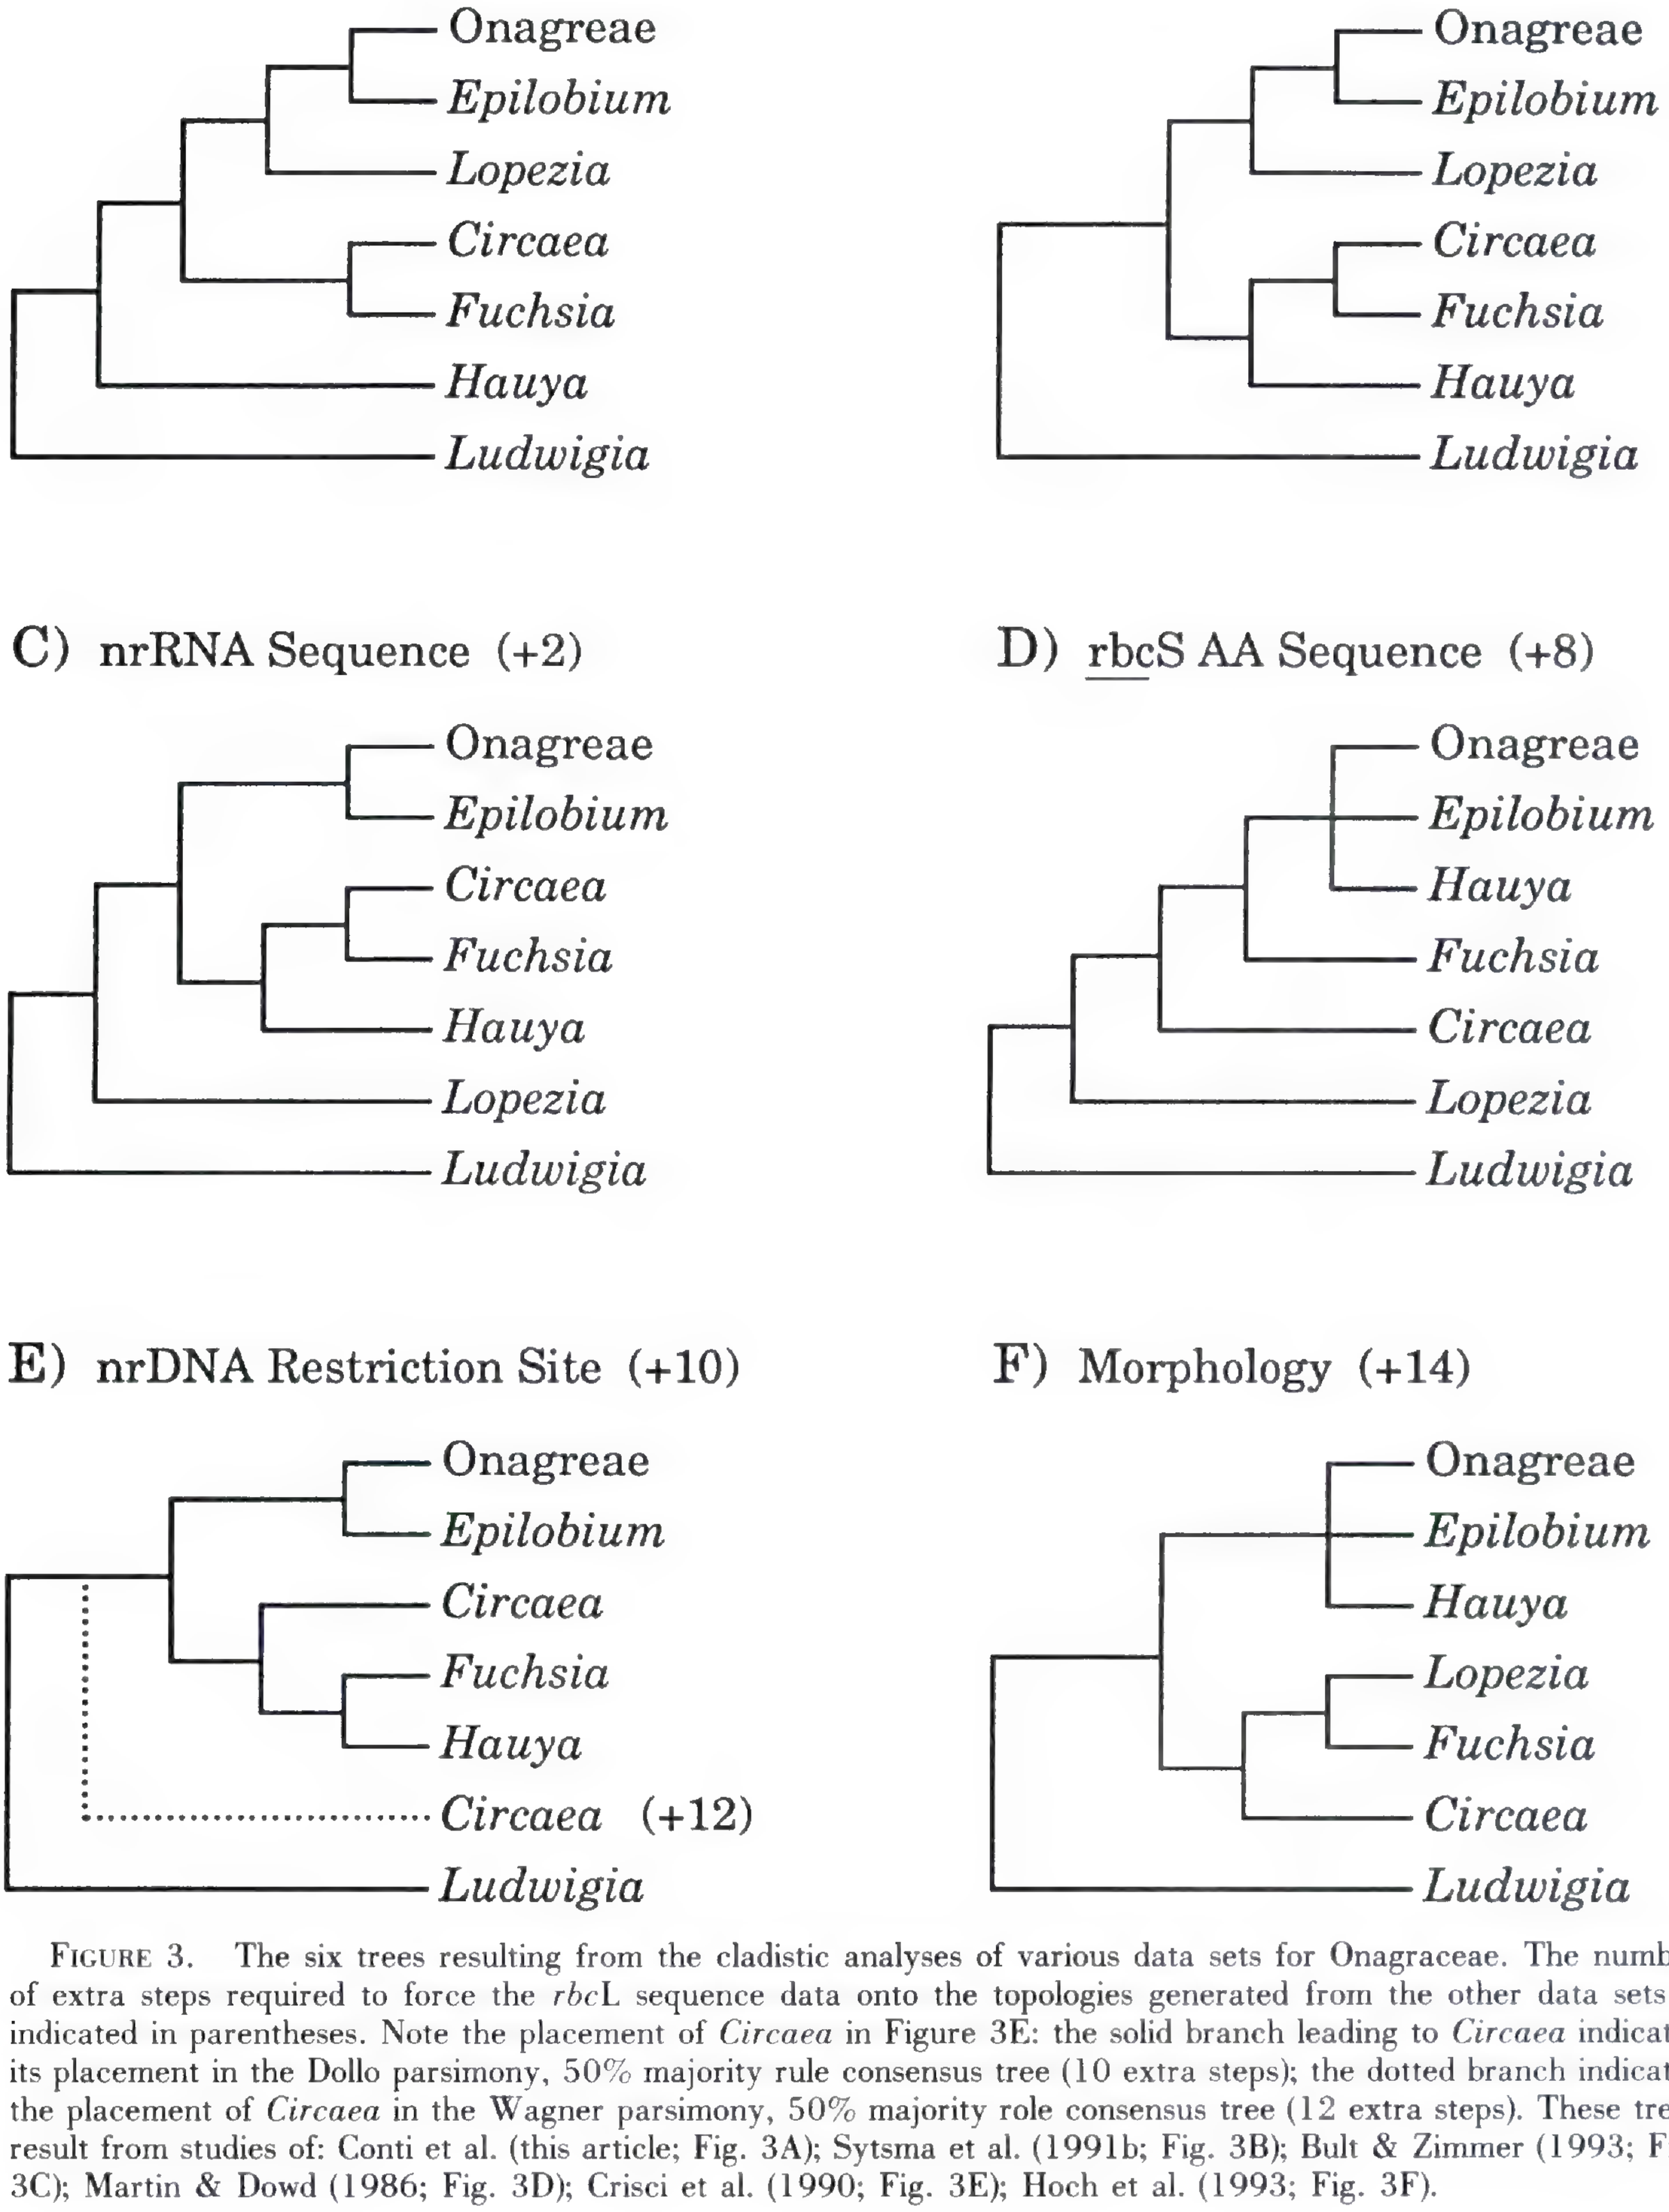

FIGURE 3. The six trees resulting from the cladistic analyses of various data sets for Onagraceae. The number of extra steps required to force the *rbc*L sequence data onto the topologies generated from the other data sets is indicated in parentheses. Note the placement of *Circaea* in Figure 3E: the solid branch leading to *Circaea* indicates its placement in the Dollo parsimony, 50% majority rule consensus tree (10 extra steps); the dotted branch indicates the placement of *Circaea* in the Wagner parsimony, 50% majority role consensus tree (12 extra steps). These trees result from studies of: Conti et al. (this article; Fig. 3A); Sytsma et al. (1991b; Fig. 3B); Bult & Zimmer (1993; Fig. 3C); Martin & Dowd (1986; Fig. 3D); Crisci et al. (1990; Fig. 3E); Hoch et al. (1993; Fig. 3F).

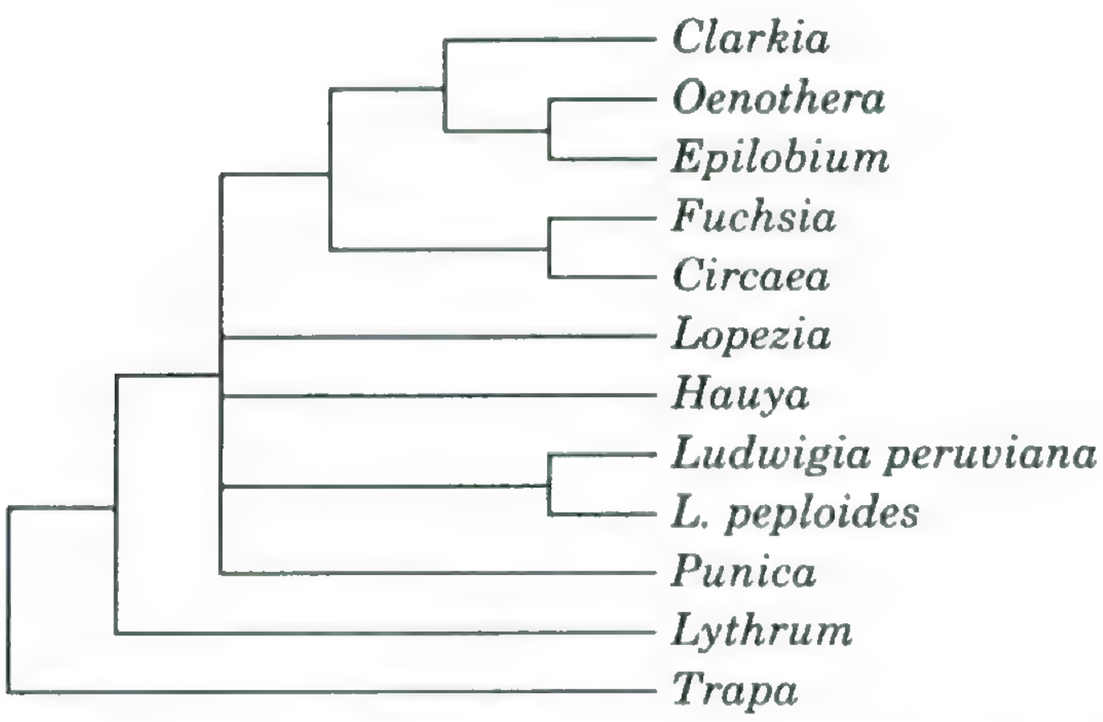

FIGURE 4. Strict consensus tree of the four most parsimonious trees resulting from elimination of third codon positions in *rbc*L sequences.

parisons of congruence between the single *rbc*L tree and those generated from a variety of other data sets, both molecular and morphological.

### 1. INTERTRIBAL RELATIONSHIPS IN ONAGRACEAE

The Fitch tree (Fig. 1) strongly supports three monophyletic tribal groups within the family: (i) all tribes except Jussiaeeae; (ii) Fuchsieae and Circaeeae; (iii) Onagreae and Epilobieae. The placements of Hauyeae and Lopezieae are less well supported. The most parsimonious *rbc*L tree agrees with all other data sets (Fig. 3) in placing *Ludwigia* (sole genus of the tribe Jussiaeeae) as sister to all other Onagraceae (with a bootstrap value of 100%, 11 informative characters, seven of which are consistent, and a decay index of 13).

*Ludwigia* appears to retain a number of plesiomorphic morphological features, including presence of up to seven parts in the floral whorls, as opposed to the typical four-merous flowers of the other Onagraceae (Eyde, 1981, 1982; Hoch et al., 1993), massive, ovuliferous placentas, minor vascular bundles, and absence of a constriction in the floral tube beyond the ovary. *Ludwigia* shares the plesiomorphic *Met-Lys* N-terminal amino acids of the nuclear-encoded *rbc*S polypeptide with all other angiosperm taxa (mostly from Myrtales) analyzed by Martin & Dowd (1986), whereas the rest of Onagraceae are clearly set apart from *Ludwigia* by the distinctive and synapomorphic *Phe-Asn* N-terminus.

*Ludwigia* is also distinguished from the rest of Onagraceae by autapomorphies, most notably the unique nectary position. The location of the nectaries of *Ludwigia* around the base of the style, inside the anthers (instead of on the floral tube, outside the anthers, as in all other Onagraceae), induced Eyde to conclude that epigyny evolved independently in the two main evolutionary lines of Onagraceae, namely *Ludwigia* and the rest of the family (Eyde, 1982; Raven, 1988).

A major achievement of the *rbc*L sequence data in elucidating the relationships among tribes in Onagraceae is the definition of the clade Fuchsieae–Circaeeae. *Fuchsia* and *Circaea* are quite distinctive morphologically. *Fuchsia* is generally shrubby or treelike, mostly with large, bird-pollinated flowers, and has a Gondwanaland distribution (although with some distinctive sections in North America: Berry, 1982; Raven, 1979, 1988). *Circaea*, on the other hand, is herbaceous, small-flowered, fly-pollinated, and has a Laurasian distribution. Morphologically the two genera each exhibit numerous autapomorphies, share none or a few derived states with other tribes, and are thus not linked in phylogenetic analyses of morphological characters (Hoch et al., 1993). Additionally, if one considers the relatively low sequence divergence (1.7%) between Circaeeae and Fuchsieae (versus 1.9% between *Clarkia* and *Oenothera* in the tribe Onagreae: see Table 3), the implications of these results with respect to biogeography and perhaps rates of morphological divergence are considerable.

The woody *Fuchsia* lineage has undergone a seven- to eleven-fold slowdown in *rbc*L sequence divergence relative to the herbaceous *Circaea* lineage (with DELTRAN and ACCTRAN transformations, respectively; see Fig. 1). A low amount of chloroplast DNA divergence (as measured by *P* values using restriction site data) between two, morphologically distinct species of *Fuchsia* (a tree versus a scrambling liana) has already been noted (Sytsma et al., 1991a; Sytsma & Smith, 1992). *Fuchsia* and *Hauya*, the other genus of Onagraceae that includes shrubs and trees, actually show the lowest amount of intertribal *rbc*L sequence divergence (1.4%; see Table 3), even though they are not supported as a clade. Both tribes have few autapomorphies not due to homoplasy (two in *Fuchsia*, four in *Hauya*; see Fig. 1). The apparent slow rate of *rbc*L sequence divergence in both the woody Fuchsieae and Hauyeae is also reminiscent of that reported for the Palmae (Wilson et al., 1990).

The third well supported clade includes Onagreae (nine genera) and Epilobieae. These two tribes exhibit many more apomorphic features than do the other tribes (Raven, 1979, 1988; Hoch et al., 1993). The derived nature of these two tribes is suggested by their placement in a terminus of the *rbc*L phylogram (Fig. 1).

Within the Onagreae–Epilobieae clade, the

branch supporting the monophyly of Onagreae (represented by *Clarkia* and *Oenothera*) is not very robust (Figs. 1, 2B). The weak support of the monophyly of Onagreae is reflected in the *rbc*S amino acid sequence tree (Fig. 3D) and the morphology tree (Fig. 3F: strict consensus tree of the seven most parsimonious trees), which both place the Onagreae in an unresolved trichotomy with Epilobieae and Hauyeae.

Raven (1979) indicated that *Clarkia* (now including *Heterogaura*; see Lewis & Raven, 1992), as well as *Epilobium*, share derived character states, unique in the family, such as a dry, papillate stigma and four-lobed stigmas with the lobes in the commissural position. The presence of commissural stigmas was explained by Eyde (1982) as related to the evolution of protandry in these two genera. Further sampling of Onagreae and Epilobieae for *rbc*L sequence data would furnish an independent test for the possible paraphyly of Onagreae (Raven, 1979; Hoch et al., 1993) and for the phylogenetic interpretation of these unique morphological characters (Baum & Larson, 1991; Coddington, 1988).

The placement of Hauyeae between Jussiaeeae and the rest of Onagraceae is the weakest branch of the *rbc*L tree, with a low bootstrap value (44%), five synapomorphies (only two of which are consistent), and the collapse to a polytomy at just one extra step from the shortest tree (Fig. 2A). *Calylophus* and *Gaura* (both Onagreae; chromosome number $x = 7$) share some apparently derived embryological features with the otherwise generalized *Hauya*, which has the basic chromosome number $x = 10$.

The second weakest branch in the *rbc*L Wagner tree is the placement of *Lopezia* as the sister group of Onagreae–Epilobieae, supported by five synapomorphies, of which only two are consistent.

## 2. CONGRUENCE WITH OTHER CLADISTIC ANALYSES

The picture of phylogenetic relationships within Onagraceae resulting from the *rbc*L sequence data can be compared with the evolutionary scenarios provided by both molecular and morphological studies (see Hillis, 1987; Sytsma, 1990; Donoghue & Sanderson, 1992).

The placement of Hauyeae between Jussiaeeae and the rest of Onagraceae as seen in the *rbc*L tree is incongruent with the cpDNA restriction site tree and the nrRNA sequence tree, which are indicated as the closest to the *rbc*L cladogram (respectively at one and two extra steps) by the analysis of constrained trees (Fig. 3). The cpDNA and the nrRNA trees agree in placing Hauyeae as the sister tribe to the clade Fuchsieae–Circaeeae. The nrDNA restriction site tree does not corroborate the topology of the nrRNA sequence tree, in that the former places Hauyeae as the sister tribe to Fuchsieae. Both morphological and *rbc*S amino acid sequence data indicate that Hauyeae, Onagreae, and Epilobieae form a tight group (Fig. 3D, F).

The *rbc*L sequence data corroborate the cpDNA restriction site data (Sytsma et al., 1991b) and the nrRNA sequence data (Bult & Zimmer, 1993) in defining the Fuchsieae–Circaeeae clade. In the nrRNA sequence tree, however, the Fuchsieae Circaeeae clade is less robust than in the *rbc*L tree, since it is supported by only four synapomorphies, three of which are homoplasious. There is no agreement concerning the phylogenetic relationships of *Fuchsieae* and *Circaeeae* among the nrDNA tree, the *rbc*S tree, and the morphological tree. The placement of Circaeeae in the two consensus trees resulting from nrDNA restriction site data is unstable. In fact, the 50% majority rule consensus tree based on Dollo parsimony indicates Circaeeae as the sister tribe to the clade Fuchsieae–Hauyeae, whereas the consensus tree based on Wagner parsimony places Circaeeae as the intermediate tribe between Jussiaeeae and the rest of Onagraceae (see Fig. 3E).

There is agreement between the *rbc*L sequence tree (Fig. 3A) and the cpDNA restriction site tree (Fig. 3B), both maternal trees, in indicating Lopezieae as the sister tribe to the clade Onagreae Epilobieae. On the other hand, the two nuclear genome trees, based on nrRNA nucleotide and *rbc*S amino acid sequence data, place *Lopezia* between *Ludwigia* and the rest of Onagraceae. The morphological tree defines Lopezieae as the sister tribe to Fuchsieae on the basis of a single trait (lack of starchy pollen). No nrDNA restriction site data are available for Lopezieae. The shifting placements of Lopezieae in the trees resulting from different data sets, especially the discrepancy between the two maternal and the two biparental trees, suggest the possible occurrence of ancient chloroplast capture in this tribe (see Smith & Sytsma, 1990; Rieseberg & Brunsfeld, 1992). Further sampling of the genus for *rbc*L sequences and additional sequence data of nuclear genes may help to resolve the relationships of Lopezieae with the rest of the family.

# NUCLEOTIDE SEQUENCES OF THE *rbc*L GENE INDICATE MONOPHYLY OF MUSTARD OIL PLANTS[1]

*James Rodman,[2] Robert A. Price,[3] Kenneth Karol,[4] Elena Conti,[4] Kenneth J. Sytsma,[4] and Jeffrey D. Palmer[3]*

ABSTRACT

Nucleotide sequences for the chloroplast *rbc*L gene were obtained from representatives of 11 of the 15 plant families known to produce glucosinolates (mustard oil glucosides). Parsimony analyses indicate that these constitute two widely separated groups and thus imply two independent origins of the mustard oil/myrosin cell syndrome. A strongly supported, major group comprises the mustard family Brassicaceae and its near relatives Capparaceae, Resedaceae, and Tovariaceae along with such morphologically diverse taxa as Bataceae, Bretschneideraceae, Caricaceae, Limnanthaceae, Moringaceae, and Tropaeolaceae. The second mustard oil group is restricted to the euphorbiaceous genus *Drypetes*. *Akania*, the subject of an independent *rbc*L analysis, pairs with *Bretschneidera*, and these are collateral with *Tropaeolum* at the base of the major mustard oil clade. Gyrostemonaceae, *Pentadiplandra*, and Salvadoraceae have not been analyzed for *rbc*L sequences. The gene data corroborate many aspects of Rodman's recent cladistic analysis based predominantly on morphological characters; together the molecular and morphological evidence support Dahlgren's radical classification of an expanded order Capparales.

Flowering plants produce a remarkable array of so-called secondary metabolites, e.g., alkaloids, cyanogens, mustard oils, and phenolics. Such natural products often have beneficial (spices, medicinals) or deleterious (allergens, poisons) effects on humans. The evolutionary origins and diversification of secondary metabolites are poorly known, with instances of parallel or convergent evolution suspected for many of them (Giannasi & Crawford, 1986). Their use as taxonomic markers (often under the rubric of "micromolecular characters") is widespread and of long standing, but it raises a suspicion of circularity. Classification schemes, interpreted as evolutionary scenarios, are used to explain the origins and changes in micromolecules, which may have been incorporated into the database used to construct those very classifications. An independent set of characters is required to evaluate the phylogenetic utility and reliability of micromolecular data.

Mustard oil glucosides or glucosinolates, the compounds that release distinctive pungent principles in radish, mustard, and capers (Fenwick et al., 1983), provide a classic example of taxonomically useful micromolecules (Ettlinger & Kjaer, 1968; Kjaer, 1973; Rodman, 1991a, b). Characteristic of 14 families of dicots and of the genus *Drypetes*, usually allied with Euphorbiaceae, the compounds are structurally diverse and amenable to rapid chromatographic analysis (Rodman, 1978, 1981). They are demonstrably useful as population- and species-level markers (Al-Shehbaz, 1973; Rodman, 1974; Rodman et al., 1981; Al-Shehbaz & Al-Shammary, 1987) and have been employed in studies of hybridization (Rodman, 1980; Kruckeberg et al., 1982), migration (Rodman, 1976, 1986), and insect–plant interactions (Rodman & Chew, 1980; Louda & Rodman, 1983). The biosynthesis of glucosinolates is known in broad outline and is thought to be a unitary pathway in all these plants (Glover et al., 1988; Boufford et al., 1989). However, little enzymological data exist to evaluate the presumed homology of mustard oil biosynthesis; this is conspicuously so for *Drypetes*, placed in a family otherwise lacking mustard oils but well known for its cyanogenic glycosides (Rodman, 1981).

[1] For collections of leaf material, we are grateful to Ihsan Al-Shehbaz, Robert Hirano, Hugh Iltis, and Ching-I Peng. Gerard Zurawski (DNAX Inc.) provided us with valuable internal *rbc*L primers, and Richard Olmstead kindly provided primers for PCR amplification. Mark Chase, James Manhart, Jackie Nugent, and Jeff Rettig generously made available their unpublished sequences for critical taxa. Chuck Delwiche proved adept in computer matters as did Kandis Elliot with graphics. National Science Foundation grants BSR-9020055 (K. J. Sytsma) and BSR-8996262 (J. D. Palmer) are also gratefully acknowledged.

TABLE 1. Two recent and contrasting classifications of mustard oil plants, implying either convergence (Cronquist, 1981, 1988) or unique origin/parallelism (Dahlgren, 1975a, 1977) for the mustard oil/myrosin cell syndrome. Where nonglucosinolate families are included in the order, an "etc." follows the name of the glucosinolate taxa. *Drypetes* (including *Putranjiva*) is the only genus of Euphorbiaceae known to produce glucosinolates. Both authors associate the genus *Pentadiplandra* with the family Capparaceae (treated as a separate family in Rodman, 1991a, b).

Mustard oils are typically accompanied by a unique catabolic enzyme called myrosinase (Bones et al., 1991), which is sequestered or concentrated in specialized idioblasts known as myrosin cells (Jørgensen et al., 1977; Jørgensen, 1981). The origin and taxonomic distribution of the glucosinolate-myrosinase trait present a challenging question: Has glucosinolate biosynthesis evolved once or repeatedly? Are the mustard oil plants a monophyletic lineage or a polyphyletic assemblage?

The classification of mustard oil plants has attracted the attention of numerous phylogenetically inclined taxonomists. Rodman (1991a) identified 18 different schemes published in the 20th century, three of which have been discussed in detail for their bearing on glucosinolate evolution (Rodman, 1981). Two of these classifications (Table 1) provide contrasting end-points on the spectrum of recent taxonomic interpretation of these plants: Cronquist (1981, 1988) and Dahlgren (1975a, 1977). Cronquist's view, shared probably by a majority of taxonomists, would imply convergence for glucosinolates in several orders of his dicot subclasses Dilleniidae and Rosidae. To force an interpretation of unique origin in the context of Cronquist's classification would necessitate multiple instances of biosynthetic loss or repression in numerous lineages. Dahlgren, in contrast, lumped most mustard oil taxa into a single large order Capparales, excluding only *Akania*, Caricaceae, and the genus *Drypetes* of Euphorbiaceae. He placed Caricaceae in an order Violales that he affiliated with Capparales, and in turn he allied these with Euphorbiales. Dahlgren (1975a, 1977) originally associated *Akania* with Sapindales but later (Dahlgren et al., 1981) suggested an affiliation with Caricaceae. Thus, Dahlgren's scheme permits the interpretation that glucosinolate biosynthesis arose once in a stem lineage to these three orders with subsequent loss or repression in the remaining Violales and in all Euphorbiales except *Drypetes*. An alternative evolutionary scenario from Dahlgren's classification would postulate two or three parallel origins within a closely related group of dicots (Rodman, 1981). Although Dahlgren (1980, 1983) later retreated from his original view of an expanded Capparales, the earlier classification provides a striking contrast to the convergence and polyphyly implied by so many traditional schemes such as Cronquist's.

Recent cladistic and phenetic studies of mustard oil taxa provide the first explicit evaluation of variant classifications of these plants (Rodman, 1991a, b). Ninety characters were assembled for the cladistic analysis, including anatomical and morphological (vegetative and reproductive), chromosomal, palynological, phytochemical, and ultrastructural features; morphological characters, broadly defined, predominated in this data set. The results were in striking agreement with Dahlgren's (1975a, 1977) broad concept of an expanded order Capparales. A clade of core Capparales (Brassicaceae, Capparaceae, Resedaceae, and Tovariaceae) was joined with Gyrostemonaceae and in turn allied with Bataceae, Salvadoraceae, and the nonglucosinolate *Koeberlinia*. Diagnostic features for this group include: vestured pitting; curved embryo in seed; dilated cisternae of the endoplasmic reticulum; floral tetramery; myrosin cells; and glucosinolates of several biosynthetic types. On the basis of less compelling character evidence, the clade was joined successively by: sister taxa Moringaceae + Tropaeolaceae; then sister taxa *Akania* + *Bretschneidera*; and then sister taxa Caricaceae + *Pentadiplandra*. Cladistic linkages among the mustard oil taxa held whether glucosinolates were

incorporated as characters into the analysis or not. *Drypetes* remained the most distant mustard oil taxon. Limnanthaceae, linked to Balsaminaceae, provided a second likely instance of convergence for glucosinolates.

An independent evaluation of taxonomic relationships of mustard oil plants is here provided by a comparative analysis of nucleotide sequences from the chloroplast gene for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (*rbc*L). Theoretical and practical reasons for the phylogenetic value of *rbc*L have been discussed (Ritland & Clegg, 1987; Palmer et al., 1988; Clegg & Zurawski, 1992), and an increasing number of empirical studies attests to the utility of *rbc*L sequence data (Doebley et al., 1990; Soltis et al., 1990; Les et al., 1991; Donoghue et al., 1992; Giannasi et al., 1992; Kim et al., 1992; Olmstead et al., 1992; Rettig et al., 1992). Gene sequence data provide a large number of variable, homologous characters (nucleotide site positions) that promise ample resolving power across a broad range of taxa. Three assumptions are here made in accepting *rbc*L sequence data as informative about plant phylogeny: (1) the *rbc*L gene is representative of the plant's genome, at least the (often) maternally inherited chloroplast component; (2) nucleotide site differences among the taxa reflect a conservative history of evolutionary change, with parallel or convergent mutations not great enough to obscure phylogenetic linkages; and (3) one or two taxa can represent large families because sequence differences within families are less than those between families. In the long run these assumptions will be evaluated against our increasing knowledge of plant genome diversity.

## Materials and Methods

For our study, *rbc*L nucleotide sequences of ca. 1,400 bases each were assembled for 33 taxa. Nine of these are here reported as new: *Bretschneidera sinensis*, *Capparis hastata*, *Carica papaya*, *Cleome hasleriana*, *Drypetes roxburghii*, *Koeberlinia spinosa*, *Moringa oleifera*, *Reseda alba*, and *Tovaria pendula*. Four published sequences were drawn from GenBank (Bilofsky et al., 1986): *Amaranthus hypochondriacus*, *Gossypium hirsutum*, *Plumbago capensis*, and *Spinacia oleracea*. The rest were either generously provided by others or are published elsewhere (Table 2). Ten of the known glucosinolate-producing families plus the genus *Drypetes* are represented in our analysis. *Akania* is the subject of an independent *rbc*L report (Gadek et al., 1992). The remaining mustard oil taxa, Gyrostemonaceae, Pentadiplandraceae, and Salvadoraceae, have not been sequenced. *Koeberlinia*, usually allied with Capparaceae, has been reported to develop myrosin cells (Gibson, 1979); it has been analyzed for glucosinolates but with negative results (Ettlinger & Kjaer, 1968; Rodman, 1981). Here it is treated as its own family (see Rodman, 1991a, b). Recently, the thiocyanate or isothiocyanate breakdown products of presumptive parent glucosinolates were reported from two species of *Phytolacca* (Phytolaccaceae) and from one of *Bursaria* of Pittosporaceae (Daxenbichler et al., 1991). If confirmed, these would constitute novel and remarkable additions to the list of known mustard oil taxa (Ettlinger, 1987; Rodman, 1991a). Until such confirmation, however, caution is justified. Claims of glucosinolates in Plantaginaceae (Cole, 1976) and in Sterculiaceae (Gill et al., 1984) have been disputed (Larsen et al., 1983; Bjerg et al., 1987, respectively) and remain unconfirmed. None of these families is represented in our study (but see Chase et al., 1993).

For eight of the nine new sequences, methods of analysis were as follows (for *Koeberlinia spinosa* methods are described by Price & Palmer, 1993; GenBank accession numbers for the nine new sequences reported here are listed in Table 2). Total genomic DNA was extracted from fresh or frozen leaves (or green twigs for *Koeberlinia*) by a modified hot CTAB procedure (Doyle & Doyle, 1987). Polymerase chain reaction (PCR) using commercial "AmpliTaq" enzyme kits (see Erlich, 1989; Williams, 1989) and a Perkin-Elmer Cetus Thermal Cycler were employed to amplify the *rbc*L DNA, making use of flanking 5′ and 3′ primers provided by Richard Olmstead. The forward 5′ primer extends 26 bases into the presumptive coding region of the gene from the AUG start codon; consequently, that 26-mer portion of our new sequences was coded as blank for the computer analyses. The resulting PCR product was cleaned with commercial "Gene-Clean" and aliquots were run on short 1.0% agarose gels to confirm the presence of a single band at ca. 1.4 kilobases when visualized by staining with ethidium bromide under ultraviolet light.

Direct dideoxy sequencing from the double-stranded PCR product was done using a modification of published methods (Korneluk et al., 1985; Zhang et al., 1988; Kusukawa et al., 1990) developed by Elena Conti (Conti et al., 1993). We used commercial "Sequenase Version 2.0" kits with sulfur-35 radiolabelled dATP in concert with internal forward and reverse primers made available by Gerard Zurawski. About half the complete sequence from forward primers was confirmed by using reverse primers. Products of the sequencing

TABLE 2. Sources of *rbc*L nucleotide sequences for mustard oil taxa (marked by an asterisk: Ettlinger, 1987; Rodman, 1991a) and putative relatives, arranged according to Cronquist's (1981) system (except for Koeberliniaceae).

reactions were run on 6% polyacrylamide gels or on commercial 5% "Long Ranger" gels, and the results were visualized by autoradiography. Sequences were read and base changes coded by hand against a tobacco *rbc*L template. Sequences were entered into the University of Wisconsin Genetics Computer Group package of programs (Devereux et al., 1984) to check for protein translation and internal restriction enzyme sites as a test of sequence authenticity.

For phylogenetic analysis of the sequence data, we created a matrix of 33 taxa and 1,428 characters, choosing to terminate the *rbc*L sequence at position 1428 in order to maintain conformity with the general analysis (Chase et al., 1993). Also, sequences beyond position ca. 1430 were variable and difficult to align, whereas alignment was easily done by inspection for the rest of the gene.

Phylogenetic relationships were inferred using a maximum parsimony strategy implemented with Swofford's PAUP computer programs (Swofford, 1991; see Sanderson, 1990); these generate "Fitch" parsimony trees with unordered nucleotide data (Fitch, 1971). Results are thus directly comparable to those derived from the predominantly morphological data set analyzed with PAUP in the recent cladistic study (Rodman, 1991b). We used the TBR and MULPARS options in our search procedure. We are aware of controversies over the best methods of estimating or inferring phylogenetic relationships (Sober, 1988; Swofford & Olsen, 1990); nevertheless, we consider the maximum parsimony approach to be reasonable and defensible (see Hillis et al., 1992). Sequences from 13 mustard oil taxa are included in our data set, usually one genus per family. Both genera of Limnanthaceae, *Floerkea* and *Limnanthes*, are in-

cluded; we are not aware of any published confirmation of glucosinolates in *Floerkea*, but the fresh leaves produce a mild "horseradish" taste when chewed from which we infer their presence. To these we added sequences from 20 putative relatives or outgroups. With the many potential outgroups treated here, we adopted a strategy of "simultaneous resolution" (Maddison et al., 1984); this avoids the assumption that mustard oil taxa must form a monophyletic group. Three considerations affected our choices of outgroup taxa. (1) We wanted to evaluate traditional taxonomic relationships for various mustard oil plants (e.g., *Batis* allied with centrosperms; *Bretschneidera* allied with Sapindales; Caricaceae allied with Violales such as Passifloraceae; Limnanthaceae and Tropaeolaceae allied with Geraniaceae and/or Balsaminaceae; *Drypetes* allied with Euphorbiaceae). (2) We wished to take advantage of results from prior studies (Olmstead et al., 1992) and from the general *rbc*L analysis (Chase et al., 1993) that suggested malvalean and sapindalean affinities with Capparales. (3) We wanted to use several outgroup taxa in order to avoid artifactual linkages induced by distant or isolated taxa, the "long edges [branches] attract" effect (Hendy & Penny, 1989).

The robustness of resulting trees was evaluated in various ways: bootstrapping (Felsenstein, 1985; Sanderson, 1989) with PAUP's heuristic search algorithm; "decay analysis" (Bremer, 1988; for an example see Smith & Sytsma, 1990) to explore the topology of trees one to several steps longer than the most parsimonious trees found under the heuristic search procedure; and a branch-and-bound exhaustive search with a reduced set of 14 taxa. A codon-position weighting scheme, with weights and stepmatrix values calculated by Albert et al. (1993), was also used with the PAUP-heuristic search. The scheme differentially weights changes at first, second, and third codon positions, relying upon ratios derived empirically from a large data set of protein-coding genes. When consensus trees were generated, the strict ("Nelson") consensus option was used (Swofford, 1985: CONTREE documentation) unless otherwise noted.

## Results

With the PAUP-heuristic search procedure and with *Heuchera* and *Penthorum* (Saxifragaceae) selected as outgroups, we obtained two equally parsimonious trees with the unweighted data, of length = 1,604 steps or site changes and with a consistency index (Kluge & Farris, 1969) of 0.39 (excluding unique substitutions). These are reasonable outgroup choices in light of results from the general *rbc*L study (Chase et al., 1993) that place them in a clade collateral to all mustard oil taxa and their near relatives. Figure 1A shows the two equally parsimonious trees. Numbers of nucleotide substitutions (branch lengths) are indicated for the topology that matches the single tree obtained by the weighted analysis; with the better f-ratio (= 0.2995; see Swofford & Maddison, 1987) this is our preferred tree of the two. All the mustard oil taxa form a monophyletic lineage excepting only *Drypetes*, which links near *Euphorbia* and *Passiflora*. The sister group to the major mustard oil clade is an alliance of malvalean (*Gossypium*) and sapindalean taxa (*Acer*, *Ailanthus*, *Bursera*) as discovered in recent analyses (Olmstead et al., 1992; Chase et al., 1993). There are 522 variable site positions for these taxa, of which 351 (or 25% of the 1,428 sites) provide cladistically informative changes.

Several results appear noteworthy, the first two being in accord with traditional taxonomic judgments, but all the rest contrary to traditional alignments. (1) Brassicaceae, Capparaceae, Resedaceae, and Tovariaceae are closely related and form what can be called "core Capparales." (2) *Drypetes* links near *Euphorbia* and *Passiflora* and not close to other mustard oil taxa. (3) Limnanthaceae fall within the major glucosinolate clade and do not link with either Balsaminaceae (represented by *Impatiens*) or Geraniaceae (represented by sister taxa *Geranium* + *Pelargonium*; see Price & Palmer, 1993). (4) *Batis* falls within the major glucosinolate clade and does not link with either Centrospermae (represented by sister taxa *Amaranthus* + *Spinacia*) or sapindalean taxa. (5) *Bretschneidera* links near the base of the glucosinolate clade and not with Sapindales (represented by *Acer*, *Ailanthus*, and *Bursera*). (6) *Carica* links near the base of the glucosinolate clade and not with Violales (represented by *Passiflora*). (7) *Tropaeolum* also links near the base of the glucosinolate clade and not with Geraniaceae or Oxalidaceae (represented by *Oxalis*; see Price & Palmer, 1993). All but one of these findings are corroborated by the recent cladistic analysis based on a predominantly morphological data set (Rodman, 1991b).

To assess the robustness of these findings, we ran the PAUP-bootstrap procedure (Swofford, 1991) and performed decay analyses (Donoghue et al., 1992) to accumulate trees one to five steps longer than the two parsimonious trees originally obtained. The decay values were obtained by holding all trees of 1,609 steps and fewer using PAUP; these trees were then sequentially filtered one step

shorter at a time, and with each filter a strict consensus tree was generated. Branches that did not collapse at 1,609 steps were scored as greater than +5 steps. Figure 1B presents bootstrap results (as percentages of 100 replicates) and the number of steps (additional nucleotide substitutions) required to collapse each node for our preferred tree. At 1,609 steps (+5 changes) there were 2,319 trees; 1,608 (+4) there were 905; 1,607 (+3) there were 320; 1,606 (+2) there were 98; and at 1,605 steps (+1) there were 21. We did not pursue decay analyses beyond five steps because the computations require too much time. The major mustard oil clade is strongly supported with a bootstrap value of 93% and a requirement for more than five additional steps to dismember the clade. Likewise, *Drypetes* is strongly allied to *Euphorbia* and *Passiflora* in a separate lineage (bootstrap value = 81%, decay index > 5 steps). Taxon sampling in this portion of our tree is sparse, however, and resolution of the phylogenetic relationships of *Drypetes* will likely require sampling even greater than that summarized in the general analysis (Chase et al., 1993). Within the major glucosinolate clade, strong linkages are shown in the pairing of *Floerkea* + *Limnanthes* (100%), *Bretschneidera* + *Tropaeolum* (98%), and in the clade of Limnanthaceae with *Batis*, *Koeberlinia*, and the core Capparales (99%). Within core Capparales, *rbc*L sequence data provide only weak support for resolution of component families, including the union of Brassicaceae with a paraphyletic Capparaceae [((*Brassica*, *Cleome*), *Capparis*)]. Linkages among nonglucosinolate taxa (e.g., sapindalean, myrtalean, centrospermous) are generally commensurate with results from the general analysis (Chase et al. 1993), but no great emphasis should be placed on our specific results because taxon sampling is sparse.

The robustness of the major glucosinolate clade following bootstrapping and decay analysis encouraged further study of this subset. Designating *Gossypium* as root (the nearest outgroup from the initial analyses), we ran a 14-taxon subset with the branch-and-bound option of PAUP, claimed to guarantee finding the most parsimonious tree if the data set is not too large (Swofford, 1991). A single tree of length = 488 steps and consistency index = 0.59 (excluding autapomorphies) was obtained. The topology was identical to that of the relevant portion of our preferred tree (Fig. 1A) with ingroup relationships fully resolved and with *Bretschneidera* + *Tropaeolum* collateral to the remaining mustard oil taxa. Cladistic relationships among taxa *within* the major glucosinolate clade, therefore, are robust in the face of different outgroup assignments.

## Discussion

Nucleotide sequences from the *rbc*L gene support recognition of a major glucosinolate clade and of a second lineage restricted to the euphorbiaceous genus *Drypetes*. The *rbc*L phylogeny is largely congruent (Fig. 2) with the published cladogram of mustard oil taxa derived from a predominantly morphological character set (Rodman, 1991b, fig. 2). For the core Capparales (Brassicaceae, Capparaceae, Resedaceae, and Tovariaceae) and their sister group (Bataceae + Koeberliniaceae) the two trees are perfectly congruent. The *rbc*L data suggest that Capparaceae are paraphyletic, however; and Gyrostemonaceae and Salvadoraceae remain to be sequenced. At the base of the major glucosinolate clade, sister-group relationships differ between the *rbc*L and morphology trees, with Limnanthaceae (*Floerkea* and *Limnanthes*) presenting the most serious discrepancy.

The unexpected position of Limnanthaceae in the *rbc*L tree is unlikely to reflect misidentifications. Both genera of the family were sequenced (in separate laboratories), the pairing of *Floerkea* and *Limnanthes* is strong (only 17 site differences between them, the smallest in our data set), and their position in the major mustard oil clade is robust. Furthermore, an additional molecular character not included in this analysis supports alliance of Limnanthaceae with Capparales. The *rbc*L gene of *Floerkea* and *Limnanthes* and their sister clade (*Batis* with *Koeberlinia* + core Capparales) does not terminate at position 1428 (as do most other taxa including the basal glucosinolate taxa Caricaceae, Bretschneideraceae, Moringaceae, and Tropaeolaceae) but contains two additional codons before the stop signal. The stop codon, seen in most taxa at positions 1426–1428, has been replaced by one coding for aspartic acid in Limnanthaceae and their sister clade, with subsequent valine (alanine in *Tovaria*) and stop codons. This structural change in the gene ending is not apparent in our data set (because we chose to terminate sequences at 1428), but it is a synapomorphy reinforcing the inclusion of Limnanthaceae within a distinctive glucosinolate subclade. The prior cladistic study (Rodman, 1991b) was interpreted as providing "suggestive but not yet compelling" character evidence for linkage of Limnanthaceae with Balsaminaceae, a traditional taxonomic opinion (Cronquist, 1981, 1988). Bootstrap analysis of the morphology-based result (performed by re-running the data in PAUP-

**1a**

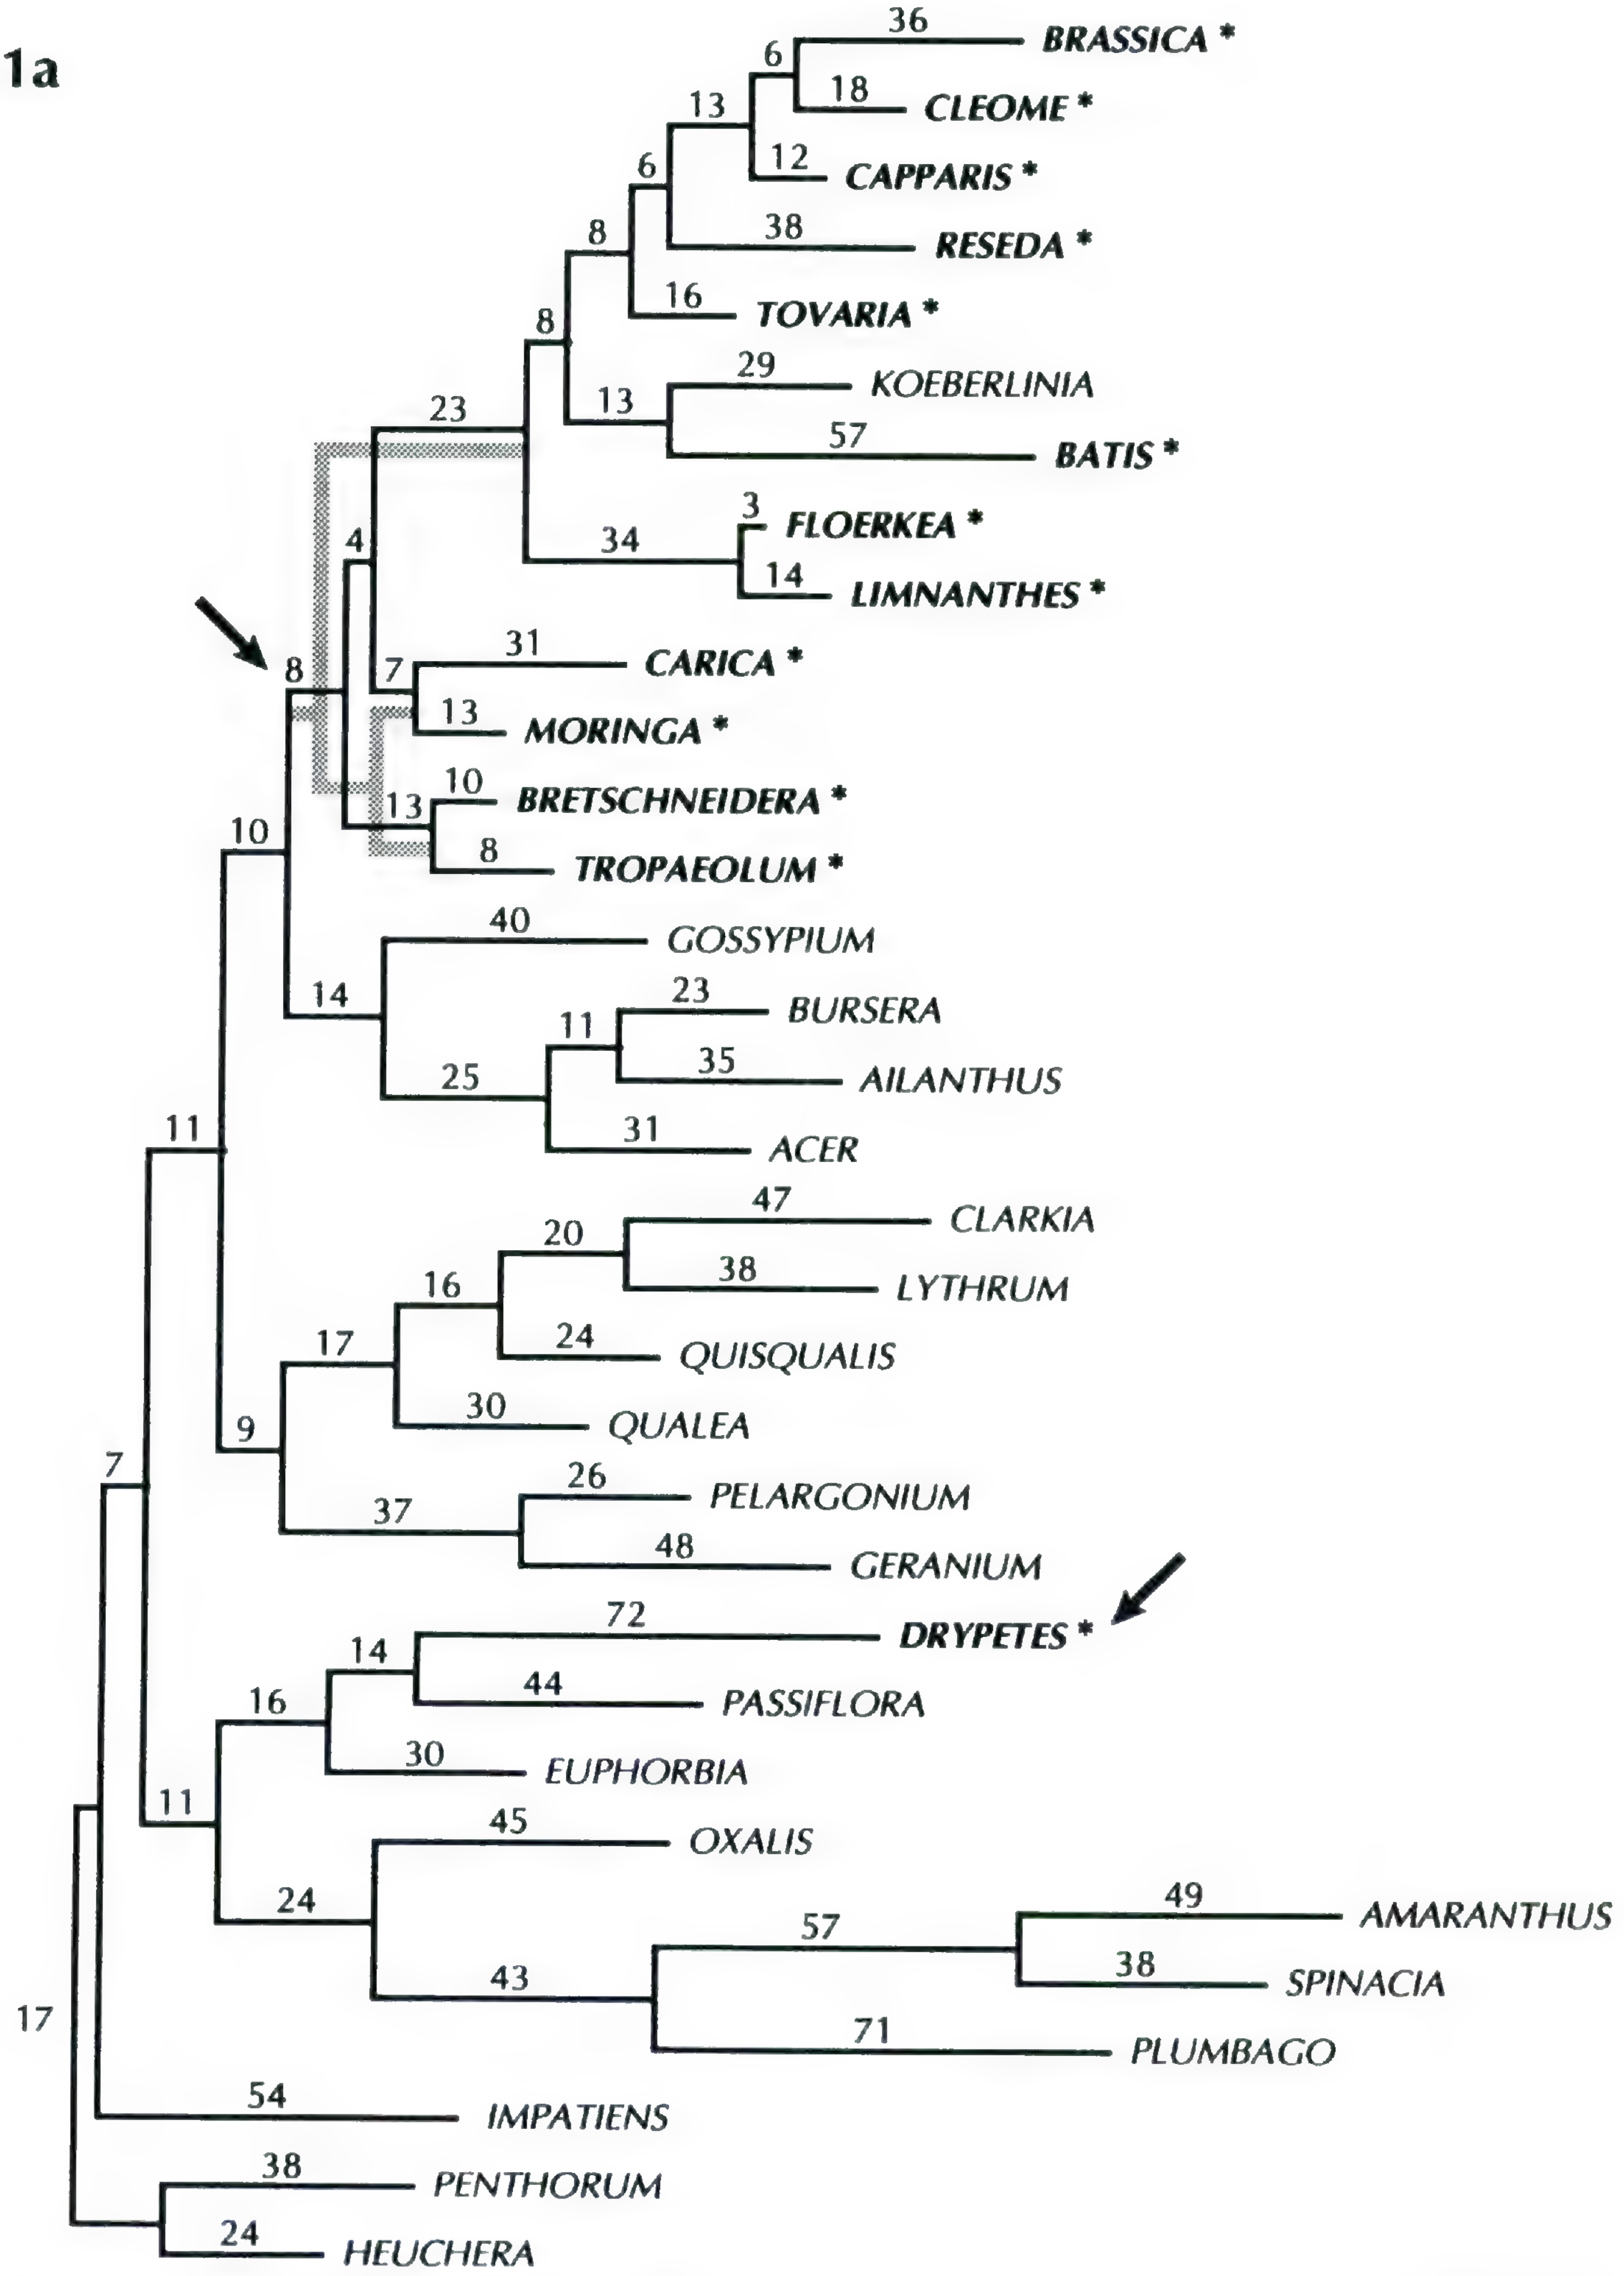

FIGURE 1a. The two equally parsimonious trees for mustard oil taxa (names in boldface marked by asterisks) and putative relatives, of length = 1,604 steps and CI = 0.39, found by analysis of *rbc*L sequences using the PAUP-heuristic search algorithm (ACCTRAN option). The two mustard oil lineages are marked by arrows. The preferred tree, solid lines with branch lengths (number of nucleotide substitutions) above, has the lower f-ratio and is identical in topology with the single tree generated by using the Albert et al. (1993) weighting scheme.

**1b**

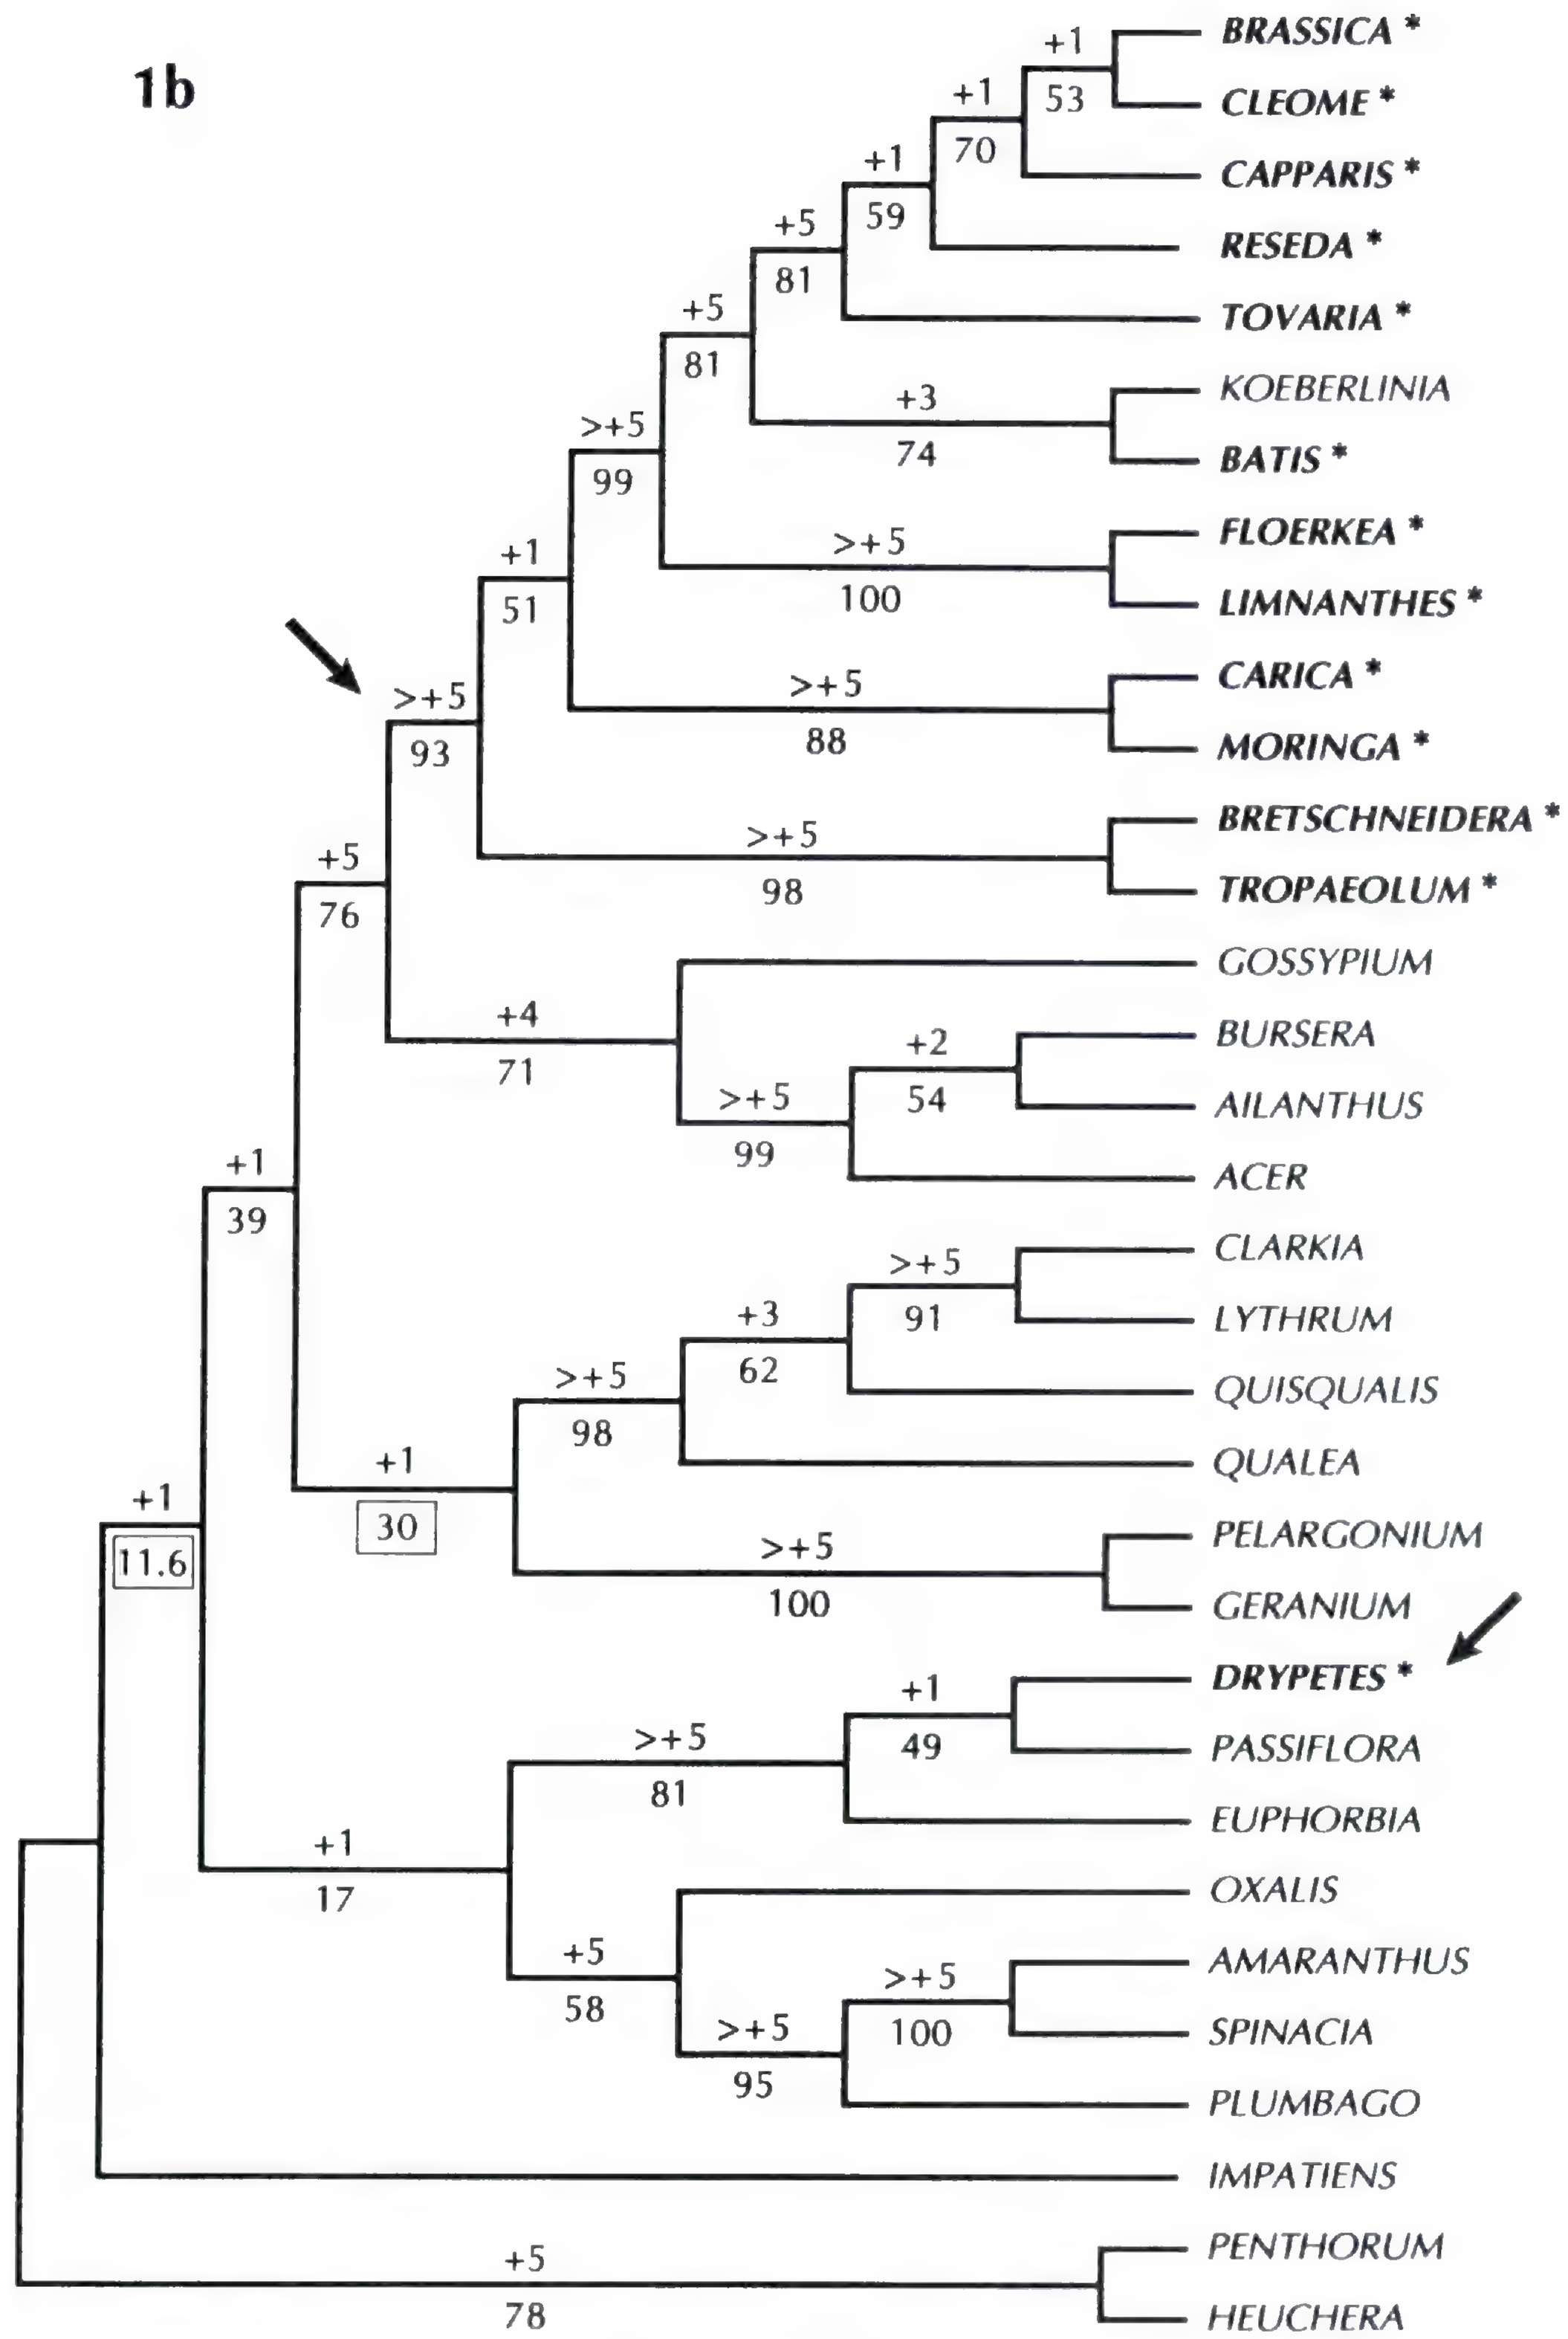

FIGURE 1b. Bootstrap values (percentage of 100 replicates, below branch) and decay index values (number of changes required to collapse the node, above branch) mapped on the preferred parsimonious tree. Asterisks (and boldface) mark mustard oil taxa; arrows indicate the two mustard oil lineages. For two areas with bootstrap values boxed the topology is not in accord with the bootstrap majority-rule consensus tree: in 42% of the replicates myrtalean taxa are collateral to glucosinolate taxa + *Gossypium* + sapindalean taxa; the geranialean taxa are then collateral to all of these with a bootstrap value of 39%. The other discrepancy involves *Impatiens*, which is collateral to the clade of *Drypetes–Euphorbia–Passiflora* in 35% of the bootstrap replicates; this quartet is then collateral to centrosperms + *Oxalis* in 17% of the replicates.

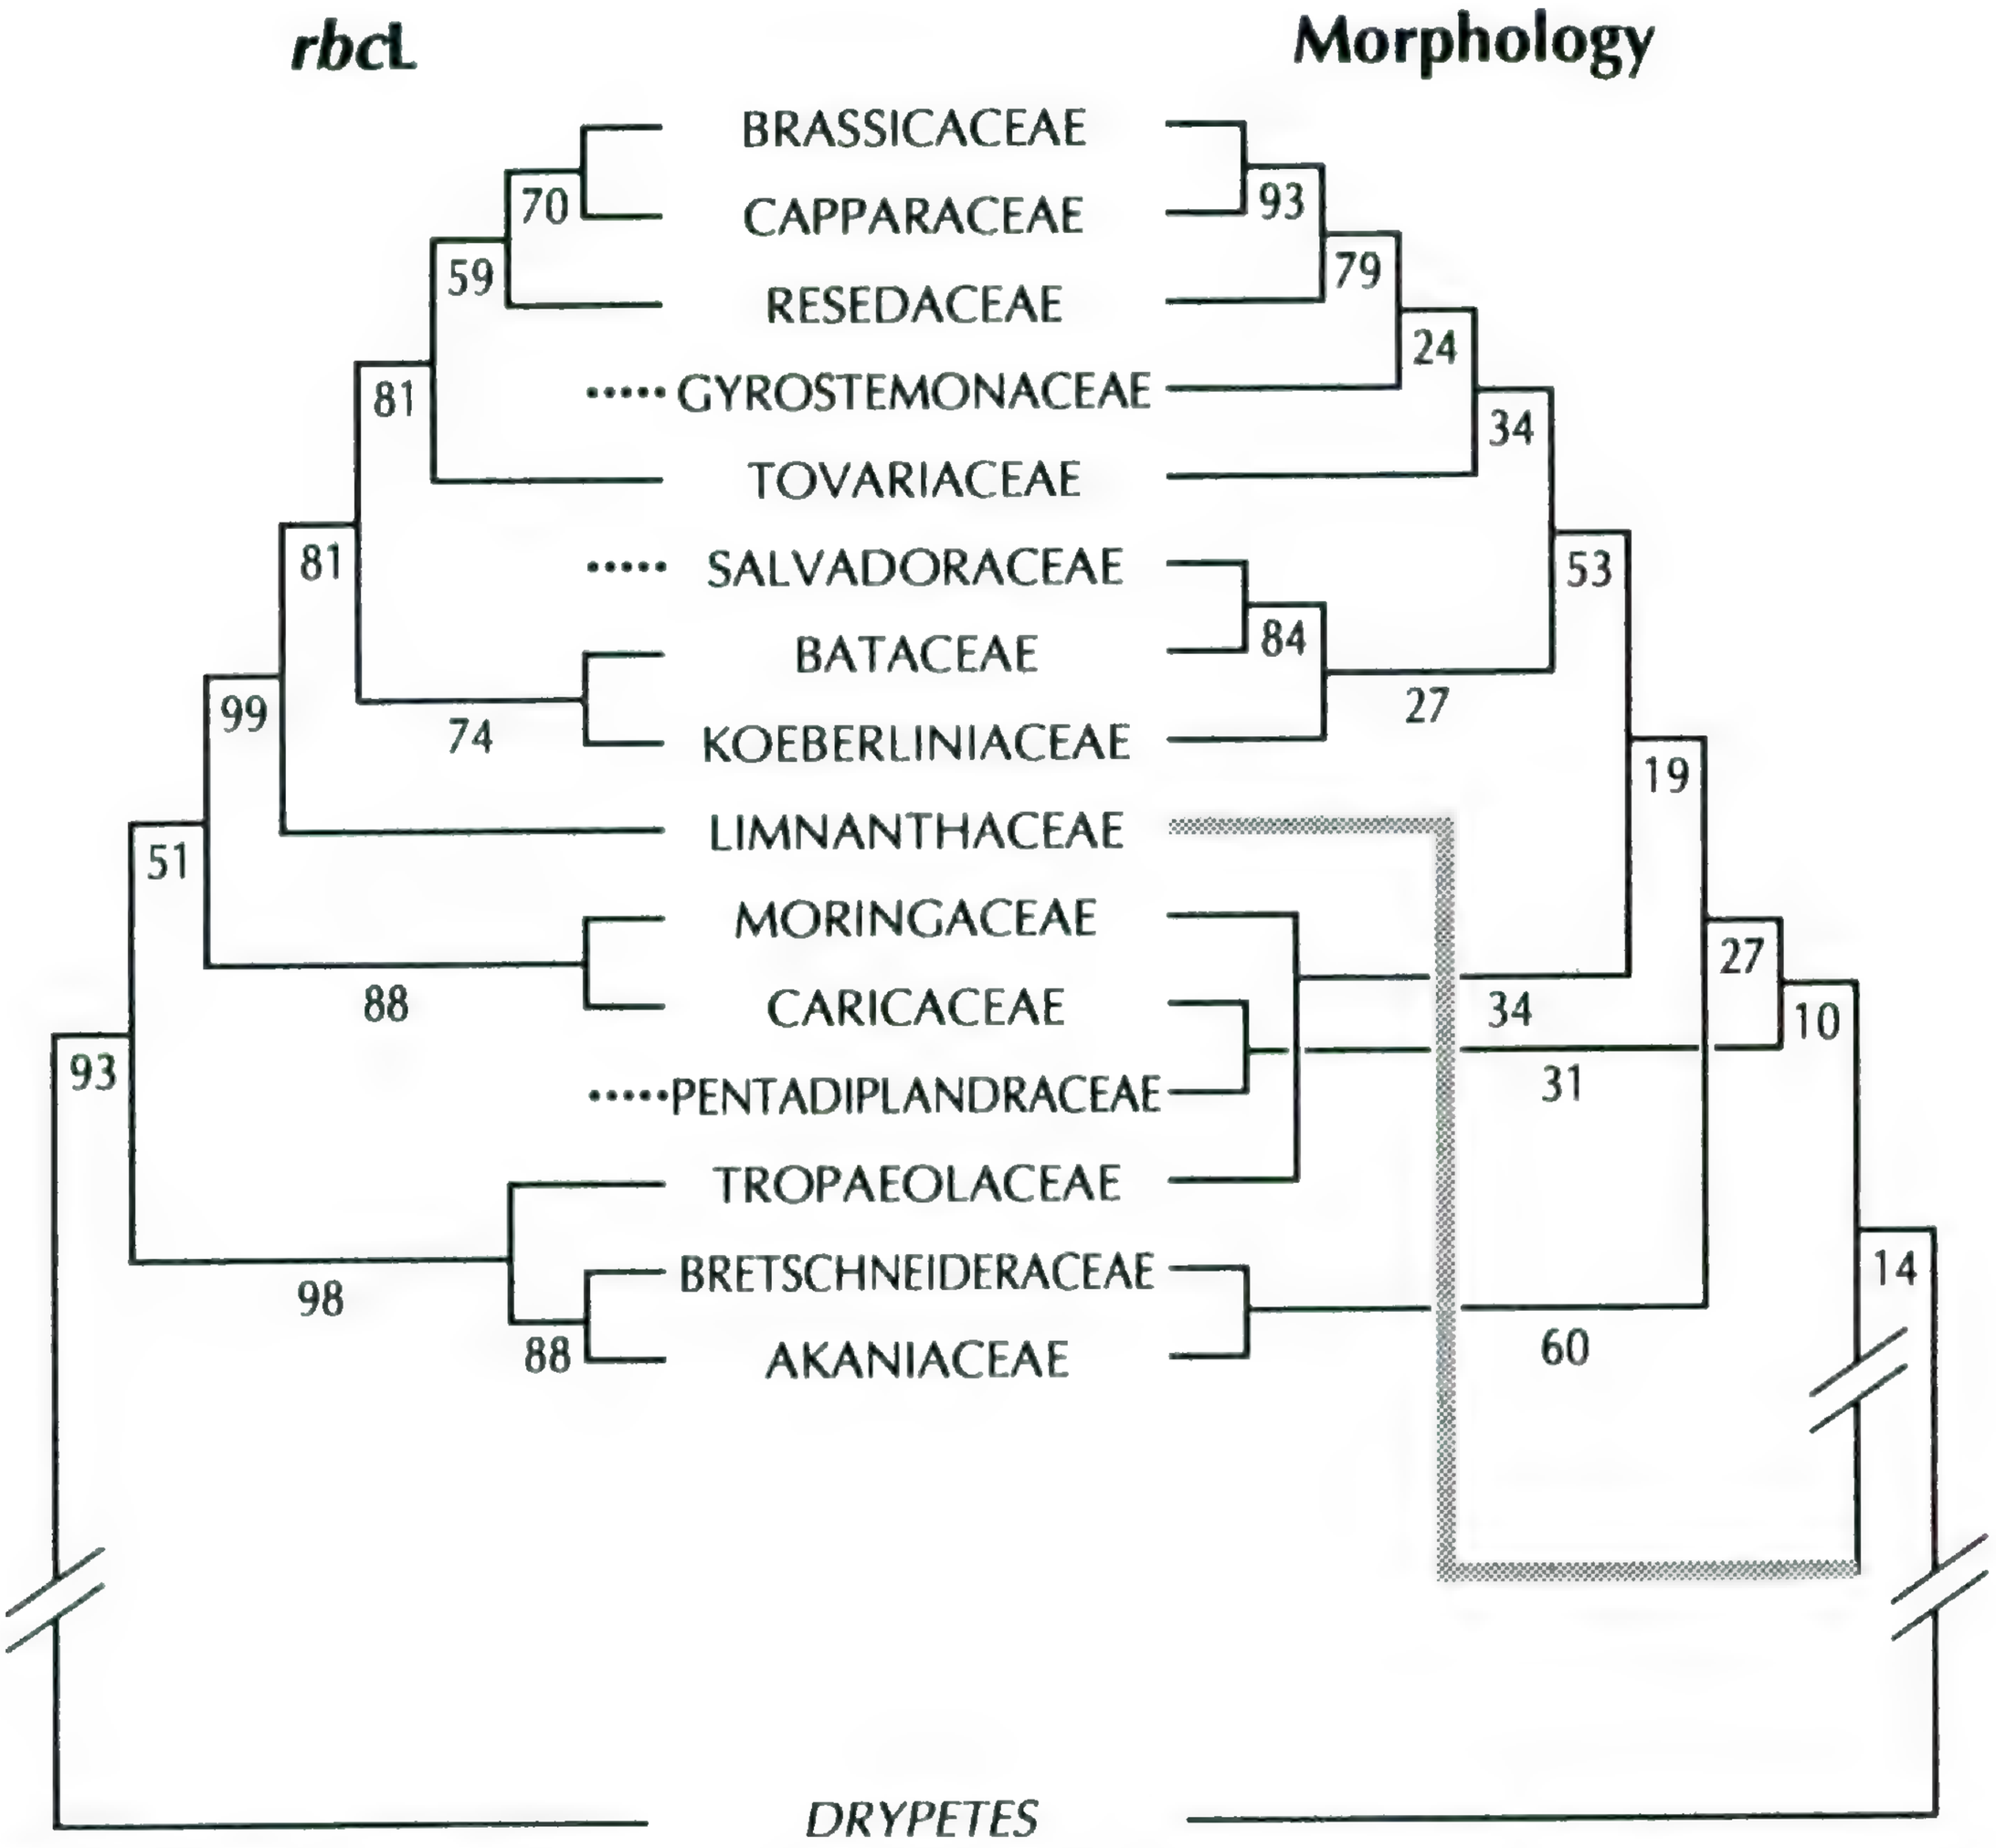

FIGURE 2. Comparison of the most parsimonious tree derived from *rbc*L sequence data (Fig. 1) with that from a prior cladistic study of predominantly morphological characters for the mustard oil taxa (Rodman 1991b, fig. 2). *Akania* has been incorporated in the *rbc*L tree from study of Gadek et al. (1992); Gyrostemonaceae, *Pentadiplandra*, and Salvadoraceae have not been sequenced. Breaks in lines indicate presence of intervening nonglucosinolate taxa. Bootstrap values (percentage of 100 replicates) are indicated for each branch; for the morphology tree, the published data set (Rodman, 1991a) was run in PAUP-version 3.0s to obtain bootstrap values.

version 3.0s) indicates that the union of Balsaminaceae + Limnanthaceae is weak, with a value of 23%. That character evidence is now called into question, as indeed it had been earlier by workers troubled with ambiguous homologies in embryology (Dahlgren, 1975b) and floral morphology (Hofmann & Ludewig, 1985; see Link, 1992). When we force Limnanthaceae into its *rbc*L-based position (using the TOPOLOGY option of PAUP: Swofford, 1985) and run the predominantly morphological data set, we obtain a tree eight steps longer than the most parsimonious ones found originally (Rodman, 1991b). Reduced homoplasy in phytochemical features (e.g., erucic acid and glucosinolate biosynthesis) is countered by increased homoplasy for morphological and chromosomal characters. The complementary test, running the *rbc*L data with Limnanthaceae forced into its morphology-based position as sister group to *Impatiens* (Balsaminaceae), results in an increase of 34 nucleotide changes over the 1,604-step trees. For *rbc*L data, potentially confounding events besides experimental error include introgression, lineage sorting, and mistaken orthology (Rieseberg & Soltis, 1991; Doyle, 1992). We consider all of these unlikely in the present case because of the taxonomic depth involved and the effectively single-copy evolution of the chloroplast genome (Palmer et al., 1988). Additional molecular data (especially nuclear genes) and evaluation of the chromosomal, morphological, and palynological homologies should reconcile the matter. At present we favor the *rbc*L

result because of the strength of its internal support compared to the weaker case in the morphology-based tree.

Character support for a major glucosinolate lineage had been judged weak in the prior cladistic study (Rodman, 1991b, table 1). That clade encompassed all the mustard oil taxa (plus *Koeberlinia*) except *Drypetes*, linked with Euphorbiaceae, and Limnanthaceae, linked with Balsaminaceae (Fig. 2). Only four homoplastic transformations were found to distinguish the stem lineage of this large mustard oil assemblage (presence of phenylalanine-derived glucosinolates, loss of anthocyanins, loss of methylated flavonols, and presence of myrosin guard cells). Bootstrap analysis reveals very weak support from the morphology data set, only 10% compared to 93% in the *rbc*L data. The sequence data thus provide independent and robust corroboration of a major mustard oil lineage. The results invite further scrutiny of the character homologies discussed by Rodman (1991a), particularly the anatomical and embryological features noted by Dahlgren (1975b).

In combination, the molecular and morphological results for the mustard oil taxa strongly support Dahlgren's (1975a, 1977) early classification of a greatly expanded Capparales. The inclusion of *Akania* (Gadek et al., 1992) and *Bretschneidera*, of *Batis* (an exoneration of Pulle's iconoclastic opinion: Eckardt, 1959), and of *Tropaeolum* departs radically from traditional taxonomic schemes and provides further evidence that Cronquist's (1981, 1988) subclasses Dilleniidae and Rosidae are not natural groups. Our results further suggest that Caricaceae and Limnanthaceae join the major glucosinolate clade. That would leave but a single outlying glucosinolate taxon. A distant *Drypetes*, phylogenetically linked near Euphorbiaceae, may thus constitute a remarkable example of molecular convergence. Both myrosin cells and glucosinolates of several biosynthetic types co-occur in *Drypetes*, as they do throughout the major mustard oil clade (*Koeberlinia* provides the single, fascinating exception). This conjoint anatomical-biochemical system remains an evolutionary mystery, albeit a mystery now limited to two branches of the angiosperm tree.

The deeply embedded position of *Koeberlinia* well within the major glucosinolate lineage (Fig. 1) further reinforces the idea (Rodman, 1981, 1991a, b) that it alone among members of this clade has lost or repressed the biochemical capacity to synthesize glucosinolates. Consistent with this interpretation, *Koeberlinia* has been reported to possess myrosin cells (Gibson, 1979).

The *rbc*L phylogeny creates novel linkages at the base of the major mustard oil clade, affiliations with little support in traditional taxonomic treatments of these plants. Linkages among these same taxa differ in the morphology-based tree, but bootstrap values are weaker (Fig. 2) and character support was judged weak as well (Rodman, 1991b, table 1). Caricaceae, for example, paired with the unsequenced *Pentadiplandra*, are basal in the morphology tree but with a bootstrap value of only 31%, whereas *Carica* and *Moringa* unite in the *rbc*L tree with robust support from bootstrap and decay analyses (Fig. 1B). We note, moreover, that our unpublished restriction-enzyme maps of chloroplast DNA demonstrate remarkable phenetic similarity between *Carica* and *Moringa*, especially in the conservative inverted-repeat region of the molecule. *Akania* (Gadek et al., 1992) and *Bretschneidera*, traditionally allied with Sapindales, are collateral with *Tropaeolum* in a strongly supported branch at the base of the major glucosinolate clade in our *rbc*L tree; hence, they are cladistically close to malvalean and sapindalean sister groups. Several phytochemists (see Kjaer, 1973) have proposed a biosynthetic linkage between the sulfur containing glucosinolates and cyanogenic glycosides; the widespread occurrence of cyanogens in Sapindales (Saupe, 1981) and of sulfated flavonoids in Malvales (Young, 1981) may prove more than coincidental. Likewise, the report of *Akania*, a genus currently restricted to Australia, in the Paleocene flora of Patagonia (Gandolfo et al., 1988) reduces the implausibility of a cladistic relationship with Andean Tropaeolaceae. Certainly these taxa are dissimilar in habit (Rodman, 1991a), but they may come to be seen as phenetically distant remnants of an early diversification of glucosinolate lineages. Sequence data from Gyrostemonaceae, *Pentadiplandra*, and Salvadoraceae are needed to complete the survey of all glucosinolate taxa, to resolve linkages among members of the major mustard oil clade, and to evaluate the double-origin hypothesis for glucosinolate biosynthesis proposed here.

Although much has been written about possible conflicts between molecular and morphological data in the study of phylogeny (Sytsma & Smith, 1988; Sytsma, 1990), this important theoretical problem is often obscured by a poor choice of examples employing incommensurable methodologies (e.g., Vickery & Wullstein, 1987; see Donoghue & Sanderson, 1992). Often, intuitively assessed morphological findings are compared to taxometrically analyzed molecular data, usually to the detriment of the former. In the current study, in which we have applied similar cladistic methods to both molecular

and morphological data, the results prove congruent in many areas of the topology and complementary in the strength they bring to particular lineages (Fig. 2). The morphological data provide stronger resolution of some terminal groups (e.g., within core Capparales) whereas *rbc*L data provide stronger resolution of relationships among basal glucosinolate clades, as judged by comparison of bootstrap values. In general, the strength of a data set of either type will depend on the number of robust characters that can be brought to bear at a particular taxonomic level. A major benefit of gene sequence data lies in the relative ease with which homology determinations can be made for numerous characters, compared to morphological data. It is for this reason that we favor the position of Limnanthaceae in the *rbc*L tree rather than the morphology-based result.

Finally, the results provide a commentary on the third assumption underlying our analysis: one or two samples can represent large families in *rbc*L phylogenies. Sequences for *Floerkea* and *Limnanthes* would seem reassuring in this context; published comparisons of several congeneric and confamilial taxa are similarly reassuring (Doebley et al., 1990; Hudson et al., 1990). But these results only beg the question: Is the family being represented a natural unit in the first place? The "Capparaceae" prove instructive. *Tovaria*, often treated as a subfamily of capers (Thorne, 1981, 1992), proves to be basal to a clade in which *Brassica* and *Reseda* are nested whether molecules or morphologies are studied. The nonglucosinolate *Koeberlinia*, often treated with capers as a subfamily also (Thorne, 1981, 1992), affiliates with *Batis* and Salvadoraceae (Rodman, 1991b), and *rbc*L data place it with *Batis*. *Cleome* links with *Brassica*, and these affiliate with *Capparis*, suggesting paraphyly for the Capparaceae even when pared of Koeberliniaceae and Tovariaceae. A more general message emerges. Whether one or few samples prove representative in *rbc*L surveys is contingent upon the monophyly of the terminal taxa. For many angiosperm families that cannot be taken for granted (Hershkovitz, 1989; Rodman, 1990; Soltis et al., 1990; Cantino, 1992; Donoghue et al., 1992).

# A PARSIMONY ANALYSIS OF THE ASTERIDAE SENSU LATO BASED ON *rbc*L SEQUENCES[1]

*Richard G. Olmstead,*[2] *Birgitta Bremer,*[3] *Kathy M. Scott,*[4] *and Jeffrey D. Palmer*[4]

ABSTRACT

A parsimony analysis of 156 representative sequences of the Asteridae sensu lato and 28 outgroup sequences was conducted using a two-tiered approach. First, an analysis of the entire group, including 105 sequences, examined relationships among major lineages within the Asteridae s.l.; subsequently, several clades within the larger group were examined individually in greater detail by including more sequences for the group in question. The search strategy was designed to discover multiple islands of equal parsimony using the heuristic search routine in PAUP. In the broad search and in each more detailed search of subclades, multiple islands were found that imply substantially different relationships. The results suggest a monophyletic Asteridae s.l., comprising the Ericales, Primulales, Ebenales and relatives of the Dilleniidae sensu Cronquist; Cornales, Apiales, and Hydrangeaceae of the Rosidae sensu Cronquist; and the conventionally circumscribed Asteridae. Within the Asteridae s.l., 11 groups were congruent between islands and are designated as follows: (1) Cornales, (2) ericalean clade, (3) *Garrya* clade, (4) *Ilex* clade, (5) Apiales, (6) Dipsacales, (7) Asterales s.l., (8) Gentianales, (9) Solanales, (10) Boraginales, and (11) Lamiales s.l. The only grouping between the level of these 11 clades and the whole Asteridae s.l. that is congruent between islands is the clade consisting of the Gentianales, Solanales, Boraginales, and Lamiales s.l., i.e., the Lamiidae of Takhtajan.

Most recent constructs of the subclass Asteridae (e.g., Cronquist, 1981; Takhtajan, 1987) represent reduced groups of the former Gamopetalae (de Candolle, 1813), which was characterized primarily by fused corollas (see Wagenitz, 1977, 1992, for a more complete review of the development of ideas about the Asteridae). A series of traits interferes with the usefulness of the simple dichotomy of fused versus free petals in defining major groups in the "higher" dicots (i.e., the tricolpate clade of Donoghue & Doyle, 1989), including number of stamen whorls and their position relative to corolla lobes (Dahlgren, 1983); embryological characters, such as one versus two integuments and the crassi- versus tenuinucellar condition in the ovule (Dahlgren, 1975); and, more recently, the distribution of secondary chemicals, particularly iridoids (Jensen, 1992). A "group" defined on the basis of any one of these traits will be incongruent with a "group" defined on the basis of any other (Wagenitz, 1977).

Conventional approaches to classification often proceed by *defining* groups on the basis of one or a few clearly defined traits, with additional traits used to refine groups and establish subgroups. In contrast, phylogenetic classification relies on the identification of derived traits to *discover* groups that are hypothesized to be monophyletic. Molecular approaches to systematics have become popular, in part, because they usually are well suited to phylogenetic analysis. Another reason for the popularity of molecular systematics is that phylogenetic hypotheses generated by molecular data generally are independent of the morphological traits in which many evolutionary biologists are interested.

With the combination of phylogenetic systematics and molecular methods, plant systematics has entered a new period of discovery. With respect to the Asteridae, we are not simply testing hypotheses set forth by previous workers (e.g., Cronquist, 1981; Dahlgren, 1980; Takhtajan, 1987; Thorne, 1992); instead we are discovering groups, and those groups may or may not reflect traditional classifications. However, we are indebted to pre-

[1] This research has been supported by NSF grants BSR-8717600 to J. Palmer and BSR-9107827 to R. Olmstead and NFR (Swedish Natural Science Research Council) grant B-BU 1487 to B. Bremer. Thanks are extended to D. Swofford and D. Maddison for helpful discussions of PAUP search strategies, to Steven Wagstaff for critical reading of the manuscript, and to the several researchers who have contributed *rbc*L sequences of the Asteridae s.l., particularly K. Kron and M. Chase (Ericales and related groups), Q.-Y. Xiang, D. Morgan, and D. Soltis (Apiales, Cornales, Hydrangeaceae, and relatives), M. Hedren and M. Chase (Acanthaceae), and H. Michaels (Asterales).

vious workers for providing a framework for sampling in molecular studies. It is fortunate that there has been disagreement among conventional angiosperm phylogeneticists, or else our sampling may have been biased. The possibility of biased sampling combined with the limited body of data yet produced by molecular systematists means that interpretations should be made with caution. Suggestions made today (e.g., based on *rbc*L sequences) may be viewed in the not-too-distant future as we view those of 19th-century botanists. The results reported here fall into three classes: (1) results congruent with traditional classifications, (2) results resolving relationships of taxa ambiguously placed in traditional classifications, and (3) novel results wherein the sequence data are in apparent conflict with conventional data. To be treated properly, these novel results should be considered as starting points for further studies, in which both morphological *and* molecular data are re-examined and supplemented with additional data.

Recent efforts at discovering a monophyletic Asteridae (Downie & Palmer, 1992; Hufford, 1992; Olmstead et al., 1992) identified a large clade containing the Asteridae sensu stricto and several elements generally excluded from traditional circumscriptions of the group, including the Apiales, Ericaceae, Fouquieriaceae, Cornaceae, Hydrangeaceae, Loasaceae, and Columelliaceae. Olmstead et al. (1992) referred to this clade as the Asteridae sensu lato and identified four major lineages comprising the group, with relationships unresolved among them. The four lineages were the (1) ericalean clade (Ericaceae, Polemoniaceae, Fouquieriaceae), (2) cornalean clade (Cornaceae, Hydrangeaceae), (3) Asteridae sensu Takhtajan (1987) plus Apiales (Asterales, Campanulales, Goodeniales, Menyanthaceae, Dipsacales, Apiales), and (4) Lamiidae sensu Takhtajan (1987) (Gentianales, Solanales, Boraginales, Lamiales, and Scrophulariales). Restriction site analysis of the cpDNA inverted repeat region (Downie & Palmer, 1992) for the Asteridae s.s. and putative relatives concurred in finding a cornalean group, a group consisting of Polemoniaceae and Fouquieriaceae (Ericaceae was not sampled), and the Lamiidae (Takhtajan, 1987). Hufford (1992) identified a large Corniflorae asterid group including a cornalean clade, an ericalean clade (excluding Polemoniaceae), and a conventional asterid clade (including Pittosporaceae and Columelliaceae).

Current work presented here and in accompanying papers represents another step toward discovering the best circumscription of the Asteridae sensu lato and groups within it. This series of papers is a fitting follow-up to the "Phylogeny of Asteridae" symposium proceedings published in this journal (Ann. Missouri Bot. Gard. 79(2), 1992), containing as it does papers on groups belonging to the Asteridae s.s. (Michaels et al., 1993) and papers on groups now included in the Asteridae s.l. (Xiang et al., 1993; Morgan & Soltis, 1993; Kron & Chase, 1993), in addition to this one on the Asteridae s.l.

A detailed study examining which sequences belong in or out of a group as large as the Asteridae s.l. is a formidable task. Olmstead et al. (1992) established a series of goals for their molecular studies of the Asteridae and addressed the first two: (1) to evaluate the monophyly of the Asteridae and (2) to identify major lineages within the Asteridae. This study addresses the next two goals: (3) to circumscribe ordinal-level groups through greater sampling and (4) to determine relationships among them. We anticipate that this will bring us one step closer to the final goals of a revised classification of the Asteridae and of a better understanding of evolutionary patterns and trends within the group. By focusing on the Asteridae s.l., we examine in much greater detail the *rbc*L data for taxa suggested to belong to the group than is possible in the analyses of Chase et al. (1993, this issue). The coarse nature of the broad-scope analyses of Chase et al. (1993) weakens their utility as rigorous hypotheses of relationship, but they do serve a useful purpose by suggesting sets of taxa that merit inclusion in more detailed analyses such as this one.

The analysis and interpretation of large data sets are complicated by the probable existence of multiple islands of trees representing equally or nearly equally parsimonious solutions (Maddison, 1991). A single parsimony analysis, even one using a detailed search strategy, can identify only one island. Identifying and presenting separate islands of equal parsimony, or even within one or two steps of the shortest trees (especially when these trees may contain 2,000–4,000 steps), provide valuable insight into possible patterns of relationship and are essential when revised classifications or interpretations of character evolution are to be based on the outcome of a phylogenetic analysis. An inadequate analysis, in which a search for multiple islands is not carried out, may produce exaggerated resolution, lead to misleading conclusions, and deter potential lines of further research.

## Materials and Methods

The sequences included in the analyses reported here have been published previously (e.g., Olm-

stead et al., 1992), are from various researchers and included in the seed plant analysis of Chase et al. (1993), or are reported for the first time here. All sequences and their sources are listed in the Appendix at the end of this issue. Some of the sequences were obtained as described previously (Olmstead et al., 1992). The remaining sequences were determined by first PCR-amplifying the entire gene from a total DNA extract by use of primers described in Olmstead et al. (1992). Single-stranded DNA for dideoxy sequencing was then obtained by a second round of PCR using 0.01 μl of the original PCR product as template and a 1:100 primer ratio with the excess primer in the same concentration as in the initial PCR run.

Nucleotide positions 27–1428 were included in the cladistic analyses, but the actual number of nucleotides varied among species depending on whether sequences were complete for this region (see Appendix at end of issue). Positions 1–26 represent the PCR primer sequence for most sequences, and after position 1428 sequence alignment becomes problematic.

Several subsets of the entire data set were compiled to examine the entire Asteridae s.l. generally and several internal clades specifically, as well as to examine the question of sister group to the Asteridae s.l. In all cases, care was taken to include a number of outgroups, which were selected following examination of the results of an analysis of 475 *rbc*L sequences ("Search I" of Chase et al., 1993).

Parsimony analyses were conducted using PAUP 3.0s (Swofford, 1992) on a Mac IIfx. All analyses were conducted with equal weights assigned to all changes. The general search strategy proceeded as follows (variations are discussed in Results). First, two or more replicates of 200–1,000 searches each were carried out using a random-order, sequential entry with NNI branch swapping (nearest neighbor interchanges), STEEPEST DESCENT on, and with the MULPARS option off. The goal of this phase of the search was to increase the chance of locating the island or islands containing the shortest trees by finding a reasonably short tree to initiate a more detailed search. The shortest tree or trees from each replicate was entered separately as the starting point for the second phase search for all equal-length trees reachable from that starting point. The second phase of the search proceeded by using TBR swapping (tree bisection-reconnection) with MULPARS on. Searches on each individual data set, except for the one examining sister group relationships to the Asteridae s.l., were pursued until two or more islands of trees were discovered.

## Results

### Analysis of Asteridae s.l.

An analysis of 184 *rbc*L sequences is reported here, including 156 representatives of the Asteridae s.l. and 28 outgroup sequences. To examine the entire Asteridae s.l., a set of 105 sequences was compiled. To reduce the complexity of the data set while maintaining the best-possible distribution of taxa, several well-supported families with multiple representatives (e.g., Asteraceae, Acanthaceae, Cornaceae) were thinned from the number of representatives in the analyses of Chase et al. (1993, this issue). Choice of outgroup sequences was guided by the results of "Search I" of Chase et al. (1993). Five sequences (*Gunnera*, *Paeonia*, *Phoradendron*, *Schoepfia*, *Osyris*) comprising a clade identified as the sister group to the Asteridae s.l. in that search were included. Six progressively more remote outgroups, *Heuchera* and *Cercidiphyllum* ("rosid IV" clade of Chase et al., 1993), *Dianthus* ("rosid III"), *Tetracentron* ("hamamelid II"), *Platanus* ("hamamelid I"), and *Caltha* ("ranunculid"), were also included. All outgroups are "higher" dicots (sensu Donoghue & Doyle 1989), to minimize the problem of long outgroup branches (Swofford & Olsen, 1990), and fall outside the broadest possible circumscription of the Asteridae s.l. based on traditional or molecular evidence. Most of the outgroups belong to the closest sister groups (rosids and caryophyllids) to the Asteridae s.l. as identified by the subsequent and more complete "Search II" of Chase et al. (1993).

The search for the shortest trees connecting 105 sequences of the Asteridae s.l. and outgroups represents a major computational effort and resulted in the discovery of three islands of trees of equal parsimony. Considering the amount of time and effort expended in acquiring a data set of this size, the data deserve the substantial effort dedicated to their analysis. A more detailed description of the approach used will be described for this data set than for subsequent searches. As with any search where the number of taxa is above the limit of a branch-and-bound search algorithm (i.e., ca. 20 taxa), there is no way to guarantee finding the shortest tree or trees.

The search was initiated by performing 200 random-order-entry replicate searches using NNI swapping with MULPARS off (this search required approximately 5 hours and found one tree of length 3,609). The resulting tree was then used as a start for a search using TBR swapping with MULPARS off (26 min., length = 3,605), which was used, in turn, as the start for a search using NNI with

MULPARS on (2 hours, 432 trees of length 3,601). These trees were then used as the starting point for a search using TBR with MULPARS on. This search was terminated prematurely without swapping on all trees when the computer RAM buffer reached a limit of 4,600 trees (approximately 4 days, length = 3,600). An attempt to find shorter trees was then made by dividing the tree file into many smaller files containing subsets of the 4,600 trees. TBR swapping was initiated on several Mac II computers simultaneously with MAXTREES set to the number of trees in each subset plus one. This strategy enables TBR swapping to proceed on all 4,600 trees saved, but will not save any more trees. The search for shorter trees from the 4,600 trees of length 3,600 lasted several days with as many as eight computers operating simultaneously. Two separate trees of length 3,600 each led to the same island (Maddison, 1991) of 102 equal-length trees (length = 3,597).

The resulting strict consensus tree (Fig. 1A) for island-102 (terminology of Maddison, 1991) shows a basal split in the Asteridae s.l. with one branch consisting of the Lamiidae and the small *Garrya* clade and the other consisting of the ericalean clade, the Cornales (including the Hydrangeaceae), Apiales, Dipsacales, Asterales s.l., and the small *Ilex* clade. In addition to the basal split into two major lineages, this tree differs from the results of Chase et al. (1993) in showing the Cornales as a more derived branch than the ericalean clade.

While this search was in progress, a second search was initiated on the same set of 105 sequences by performing 1,000 random-order-entry replicate searches using NNI swapping with MULPARS off (26 hours, one tree, length = 3,605). This tree was then input directly into a search using TBR swapping with MULPARS on. This search required approximately 10–12 weeks computer time and resulted in the discovery of a second island of length 3,597 containing 2,784 trees (Figs. 1B, 2). During this search >6,300 trees were found at one step longer, of which >3,500 were swapped before a shorter tree was found. The topology of the strict consensus tree (Fig. 1B) for island-2,784 is dramatically different from that derived from island-102 with respect to the relationships among the primary groups identified within the Asteridae s.l. These results unite the Lamiidae with the Asterales s.l., thus forming a clade equivalent to the Asteridae of Cronquist except for the exclusion of the Dipsacales. The Dipsacales and Apiales together are sister group to the above-mentioned clade, with the small *Ilex* and *Garrya* clades each forming progressively more basal branches, and the Cornales and ericalean clade producing a basal trichotomy.

After the first two islands were discovered using the search strategy outlined above, another approach to finding initial trees, possibly representing separate islands, was tried (suggested by D. Maddison, pers. comm.). One hundred replicate random-order-entry searches were conducted using TBR swapping with MULPARS on, but with the option to save no more than two trees greater than, or equal to, length "X," where "X" is a number small enough to be certain to be shorter than the shortest tree found. This approach enables each random start to be searched much more completely than the approach outlined above. One replicate yielded two trees of length 3,597 and which were topologically distinct from any tree belonging to island-102 or island-2,784. A search for all most parsimonious trees yielded 5,568 trees at that length. The initial search required 11 days and the search for all parsimonious trees in the island required an additional seven weeks to complete. This island contains exactly twice as many trees as island-2,784 and can be accounted for by one additional polytomy (within the Gentianales). Topologically, this island is identical with island-2,784, except that the Boraginales are united with the Gentianales instead of with the Solanales and the relationships among the five sequences representing the Gentianales are different (hence this island is not illustrated). Figure 3 shows the strict consensus of all trees discovered in the three islands.

Another analysis was performed to explore more fully the putative sister group to the Asteridae s.l. "Search I" of Chase et al. (1993, this issue) identified the clade mentioned above as sister group, whereas their "Search II" (Chase et al., 1993) identified a small clade of two sequences (*Dillenia* and *Vitis*) as sister group to the Asteridae s.l. For this analysis, 40 sequences of the Asteridae s.l. were removed and 17 additional dicot sequences were included, giving a total of 82 sequences. This analysis found 30 equal-length trees of length 3,322 (Fig. 4). This search was initiated with 300 random-order-entry replicate searches and was not replicated to find alternate islands, but the search strategy was equivalent to that used to find one of the shortest islands in other analyses reported here. This result is congruent with that based on the previous analysis in suggesting that the Santalales, *Paeonia*, and *Gunnera* do not belong together or with the Asteridae s.l. and more likely belong in the large clade identified as Rosidae s.l. in the analyses of Chase et al. (1993). The results do not place the *Dillenia* and *Vitis* sequences as sister

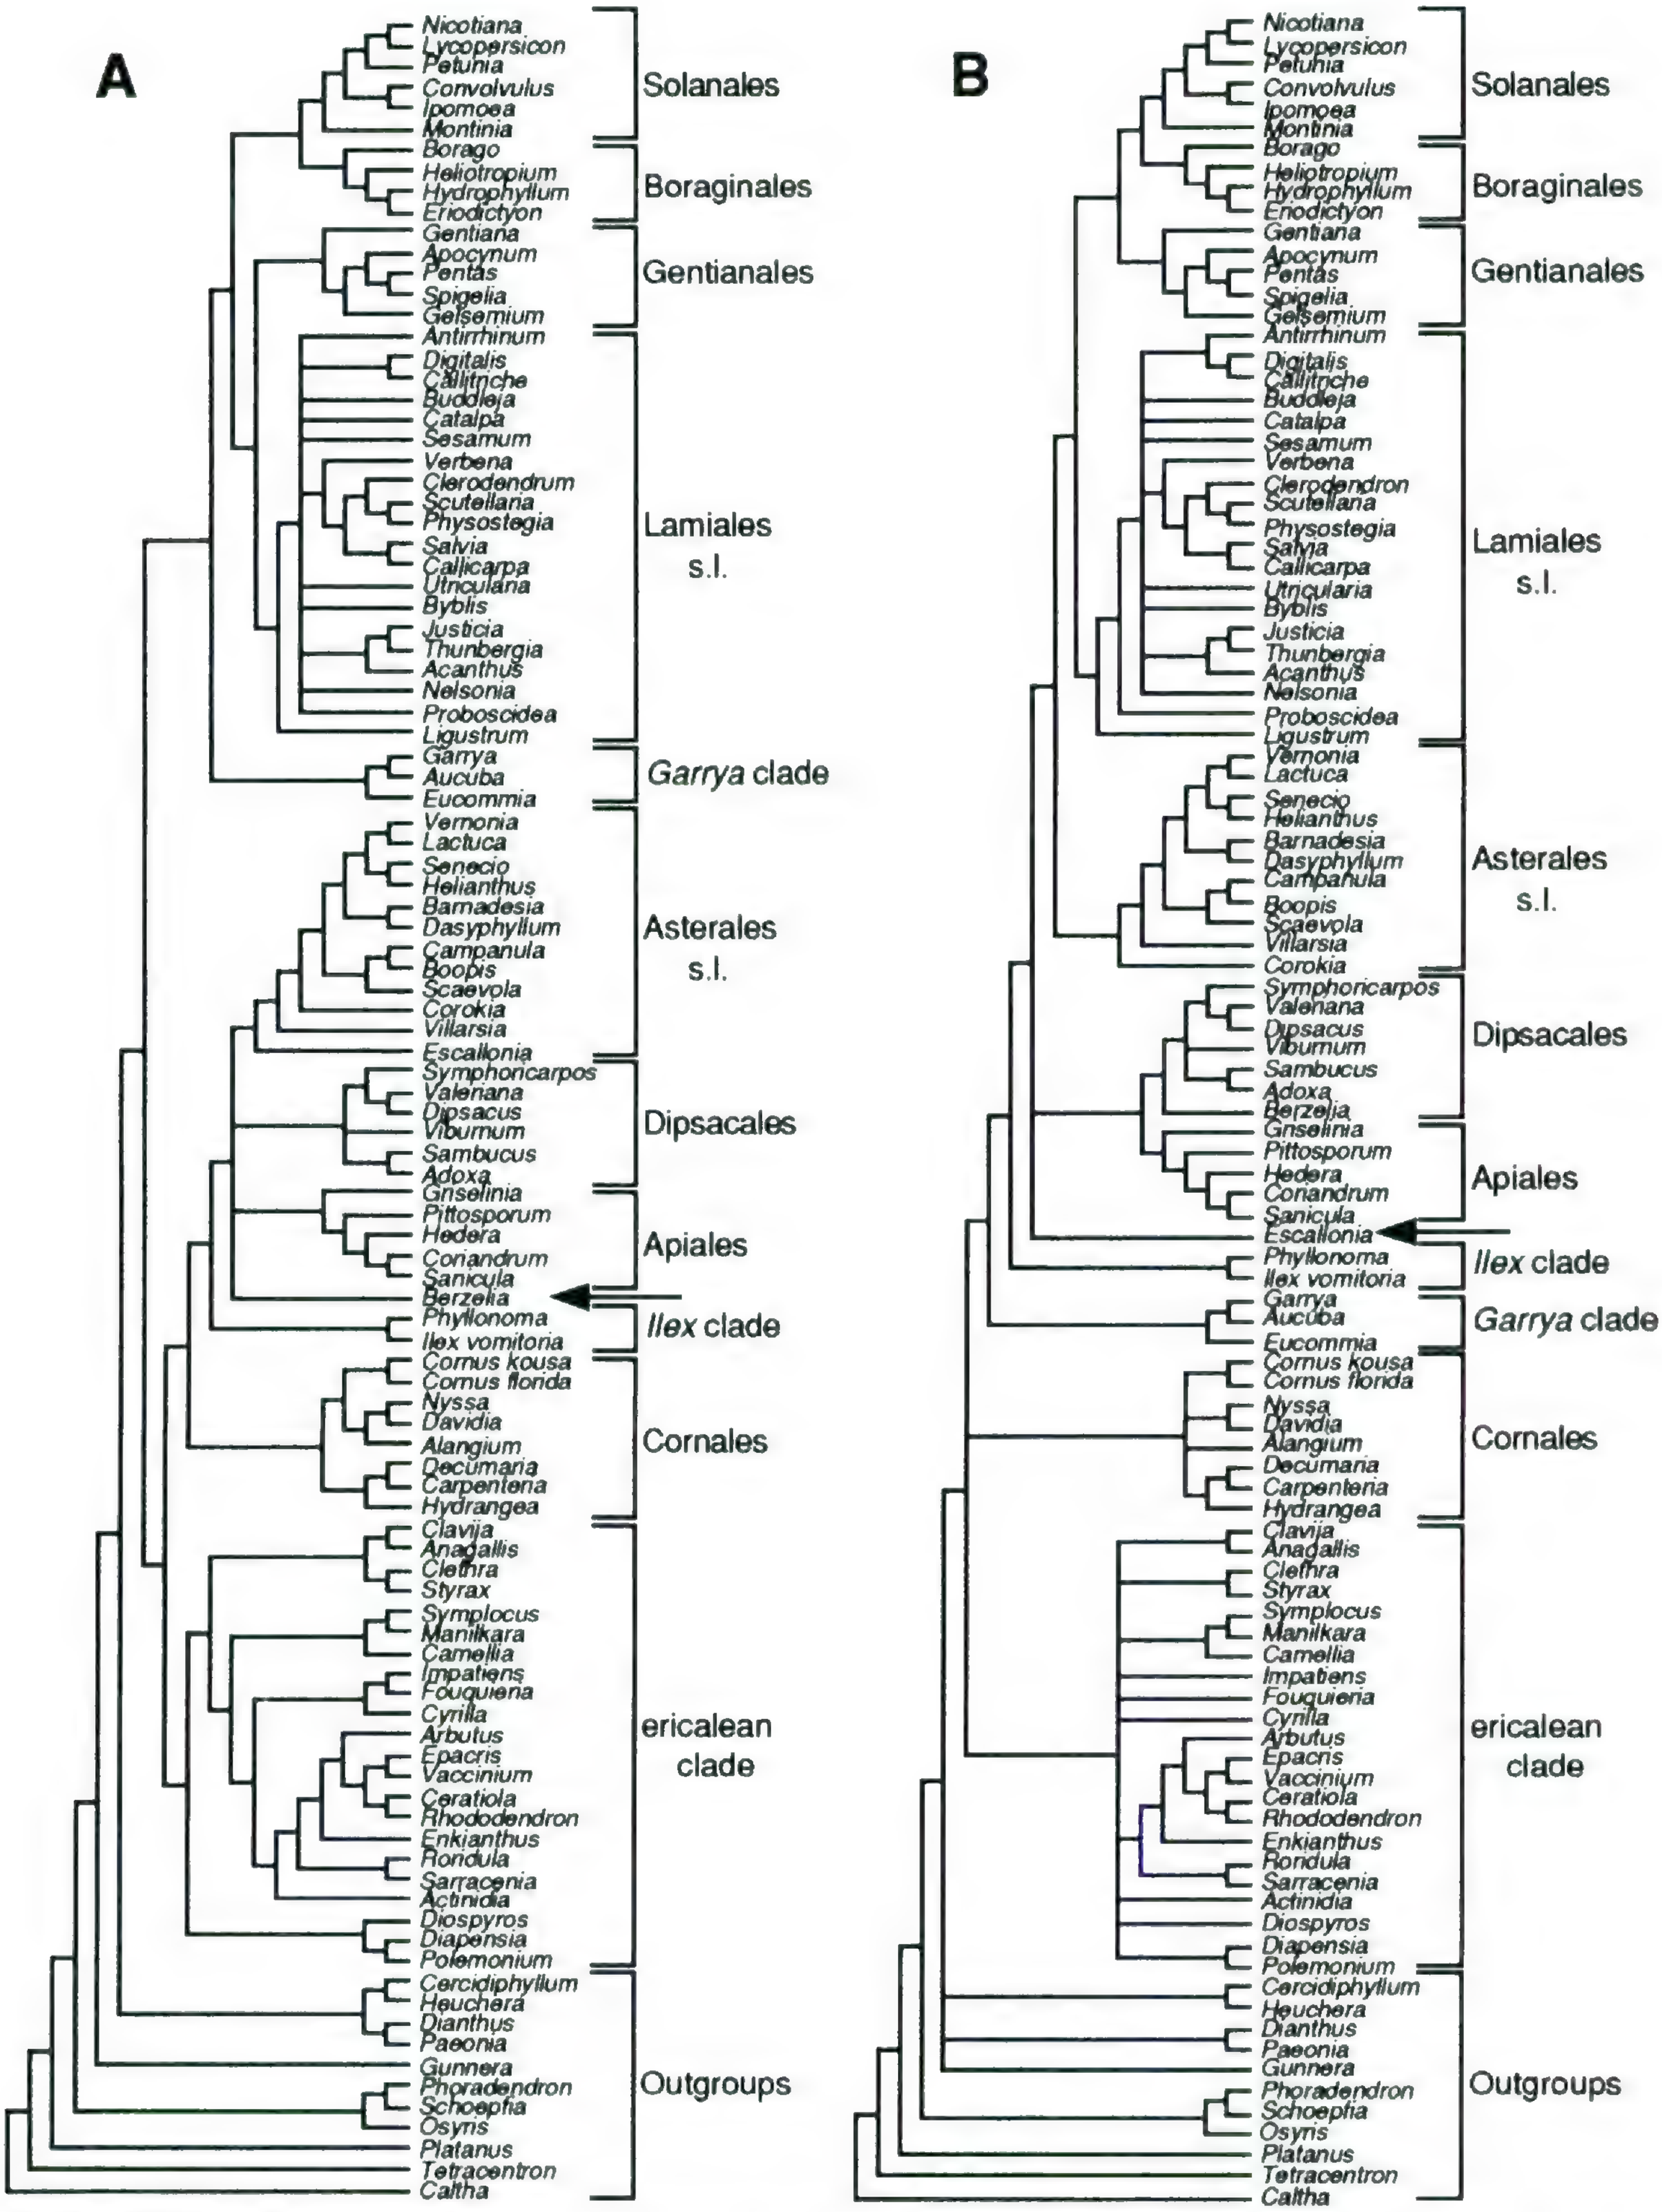

FIGURE 1. Strict consensus trees for two islands of equal parsimony in the Asteridae s.l. (105 *rbc*L sequences, including 11 outgroups; length = 3,597; C.I. = 0.25; R.I. = 0.51).—A. Island-102. Strict consensus of 102 trees.—B. Island-2,784. Strict consensus of 2,784 trees. Eleven clades that are congruent between the two islands and island-5,568 (not shown) are identified. Arrows identify sequences that resolve to a specific clade in one island, but not in the other.

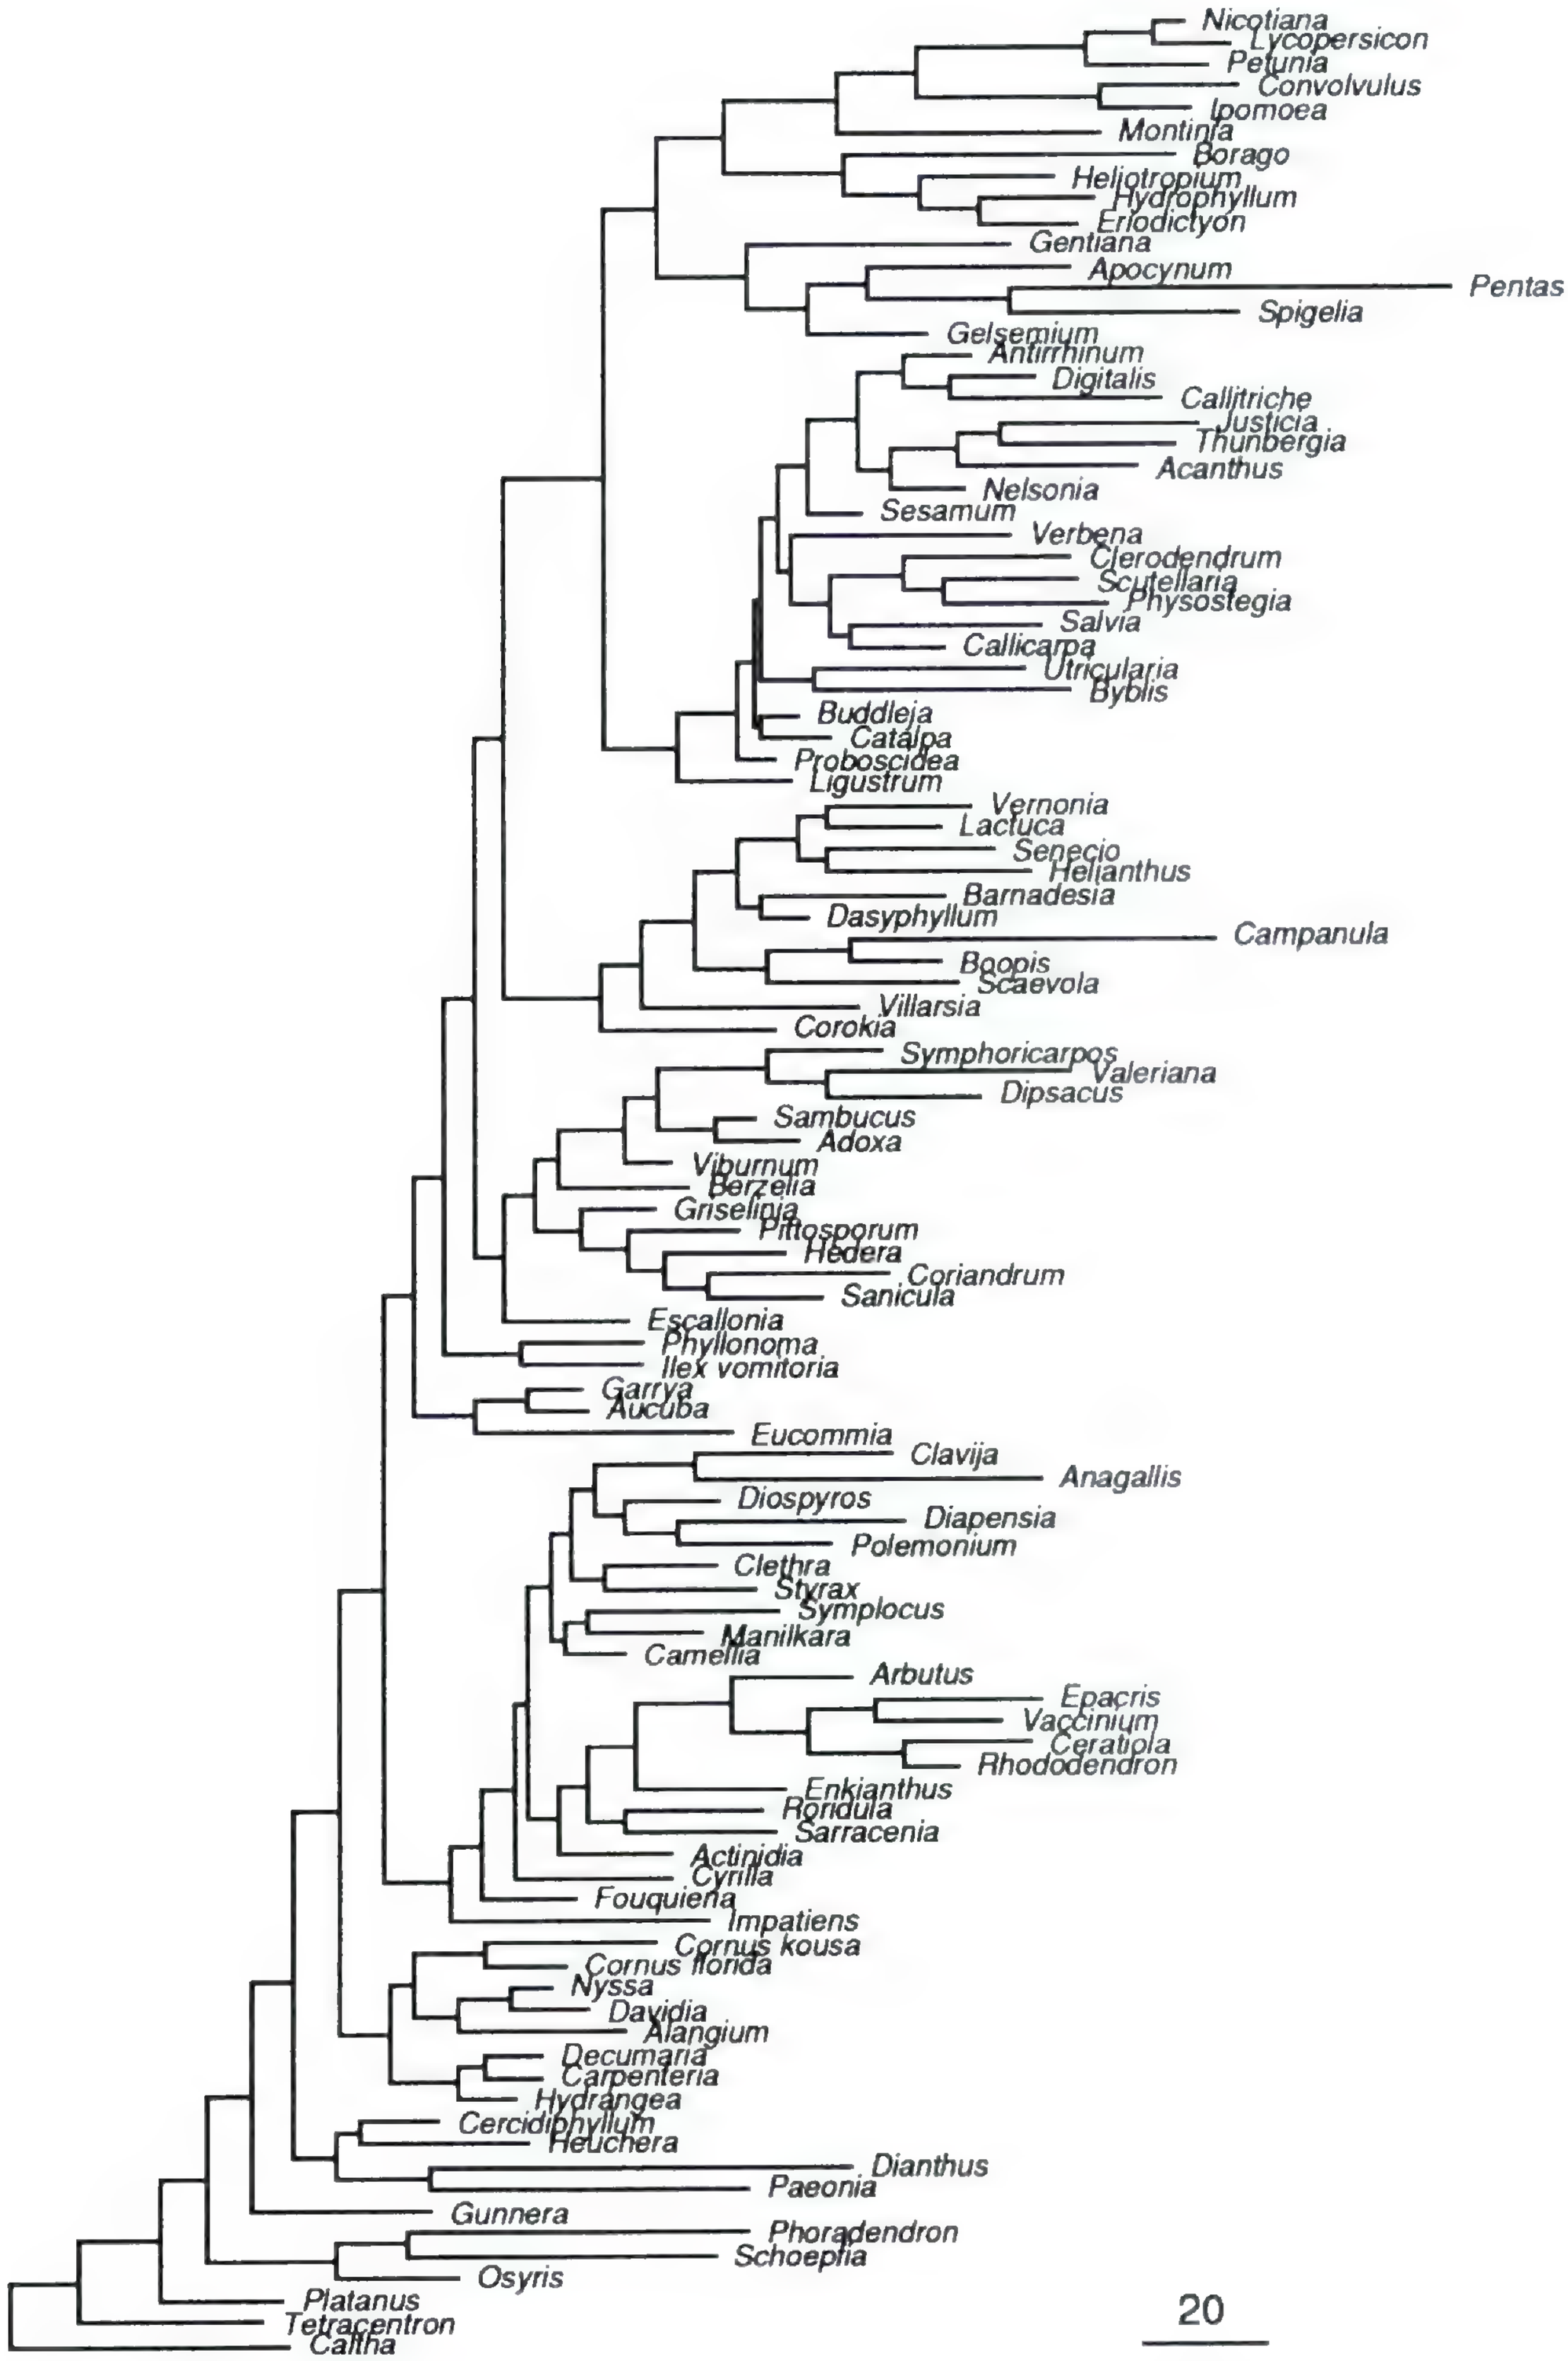

FIGURE 2. Majority rule consensus tree of island-2,784 selected as representative tree to illustrate branch lengths (ACCTRANS optimization). Particularly long branches are evident in *Pentas* (Rubiaceae) and *Campanula* (Campanulaceae); see discussion concerning incongruent results in different analyses containing these sequences (e.g., *Pentas* in Figs. 3 and 5). Note scale bar equal to 20 inferred nucleotide substitutions.

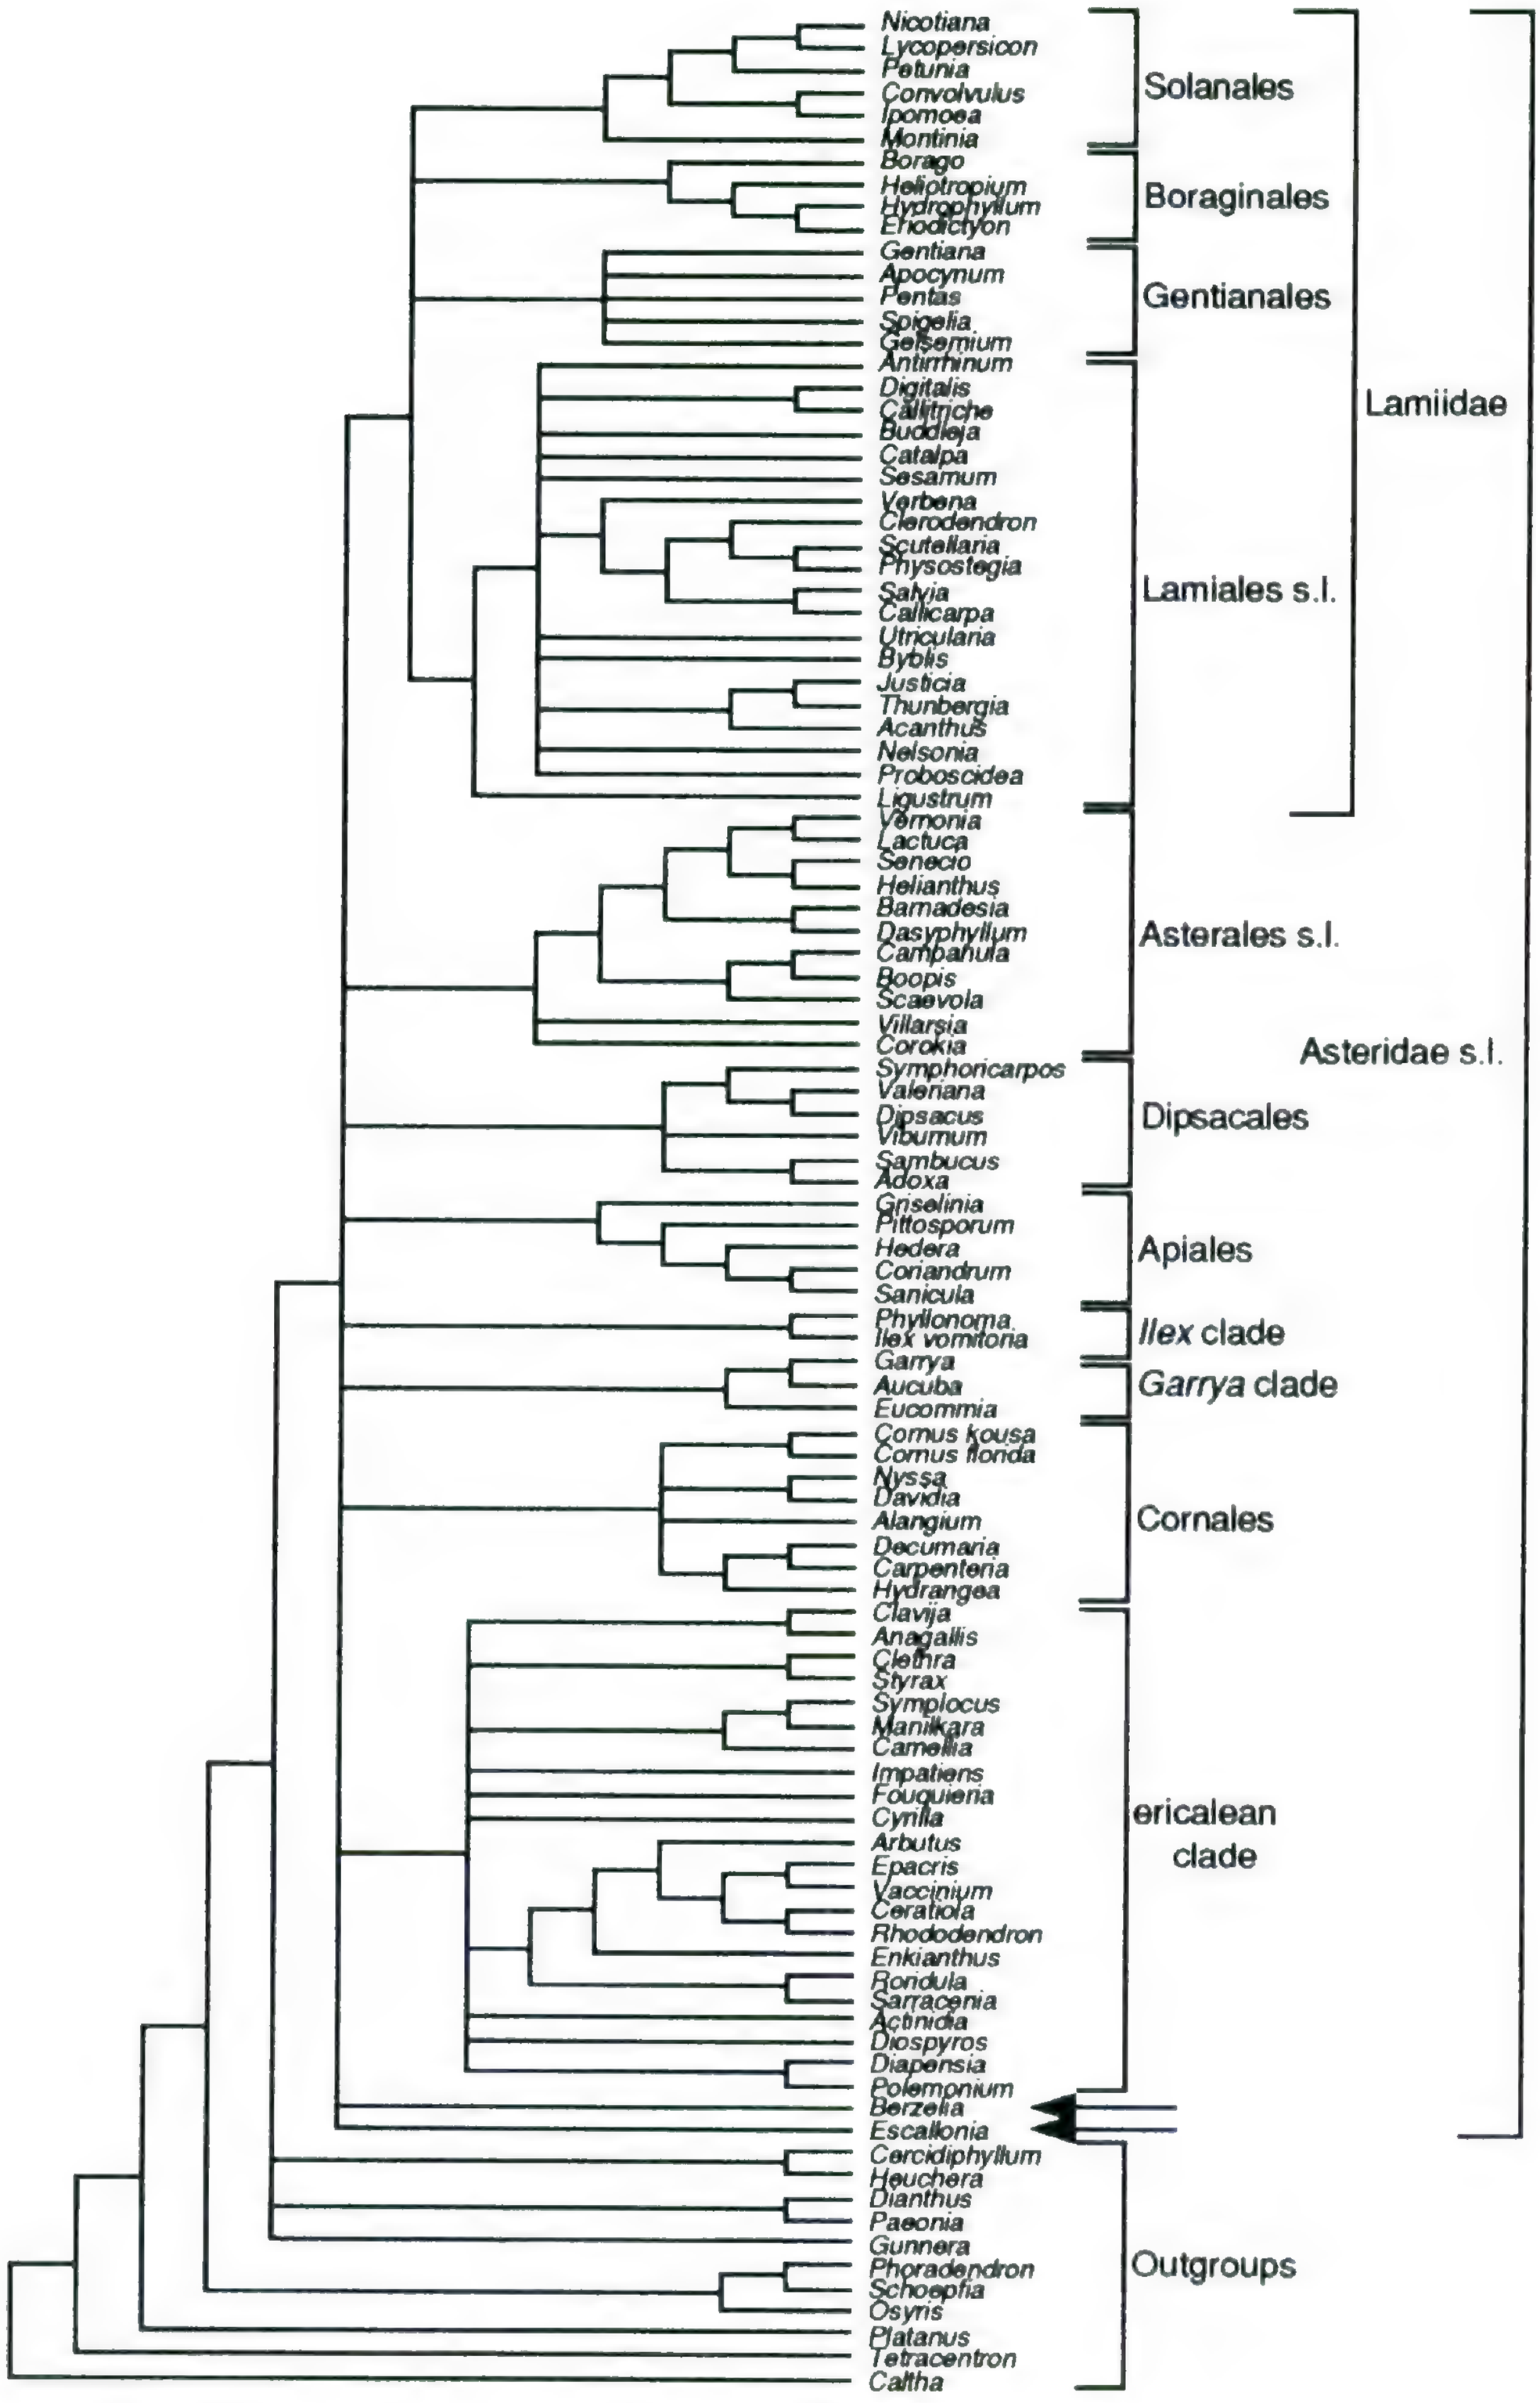

FIGURE 3. Strict consensus tree of 8,454 equal-length trees based on *rbc*L sequences. Trees from three islands (island-102, island-2,784, and island-5,568) are combined. Eleven terminal clades that are congruent among all three islands are identified. The Lamiidae sensu Takhtajan (1987) is the only group resolved between the level of the 11 congruent clades and the entire Asteridae s.l. *Berzelia* and *Escallonia* (indicated with arrows) are not resolved to any of the clades that are congruent between islands.

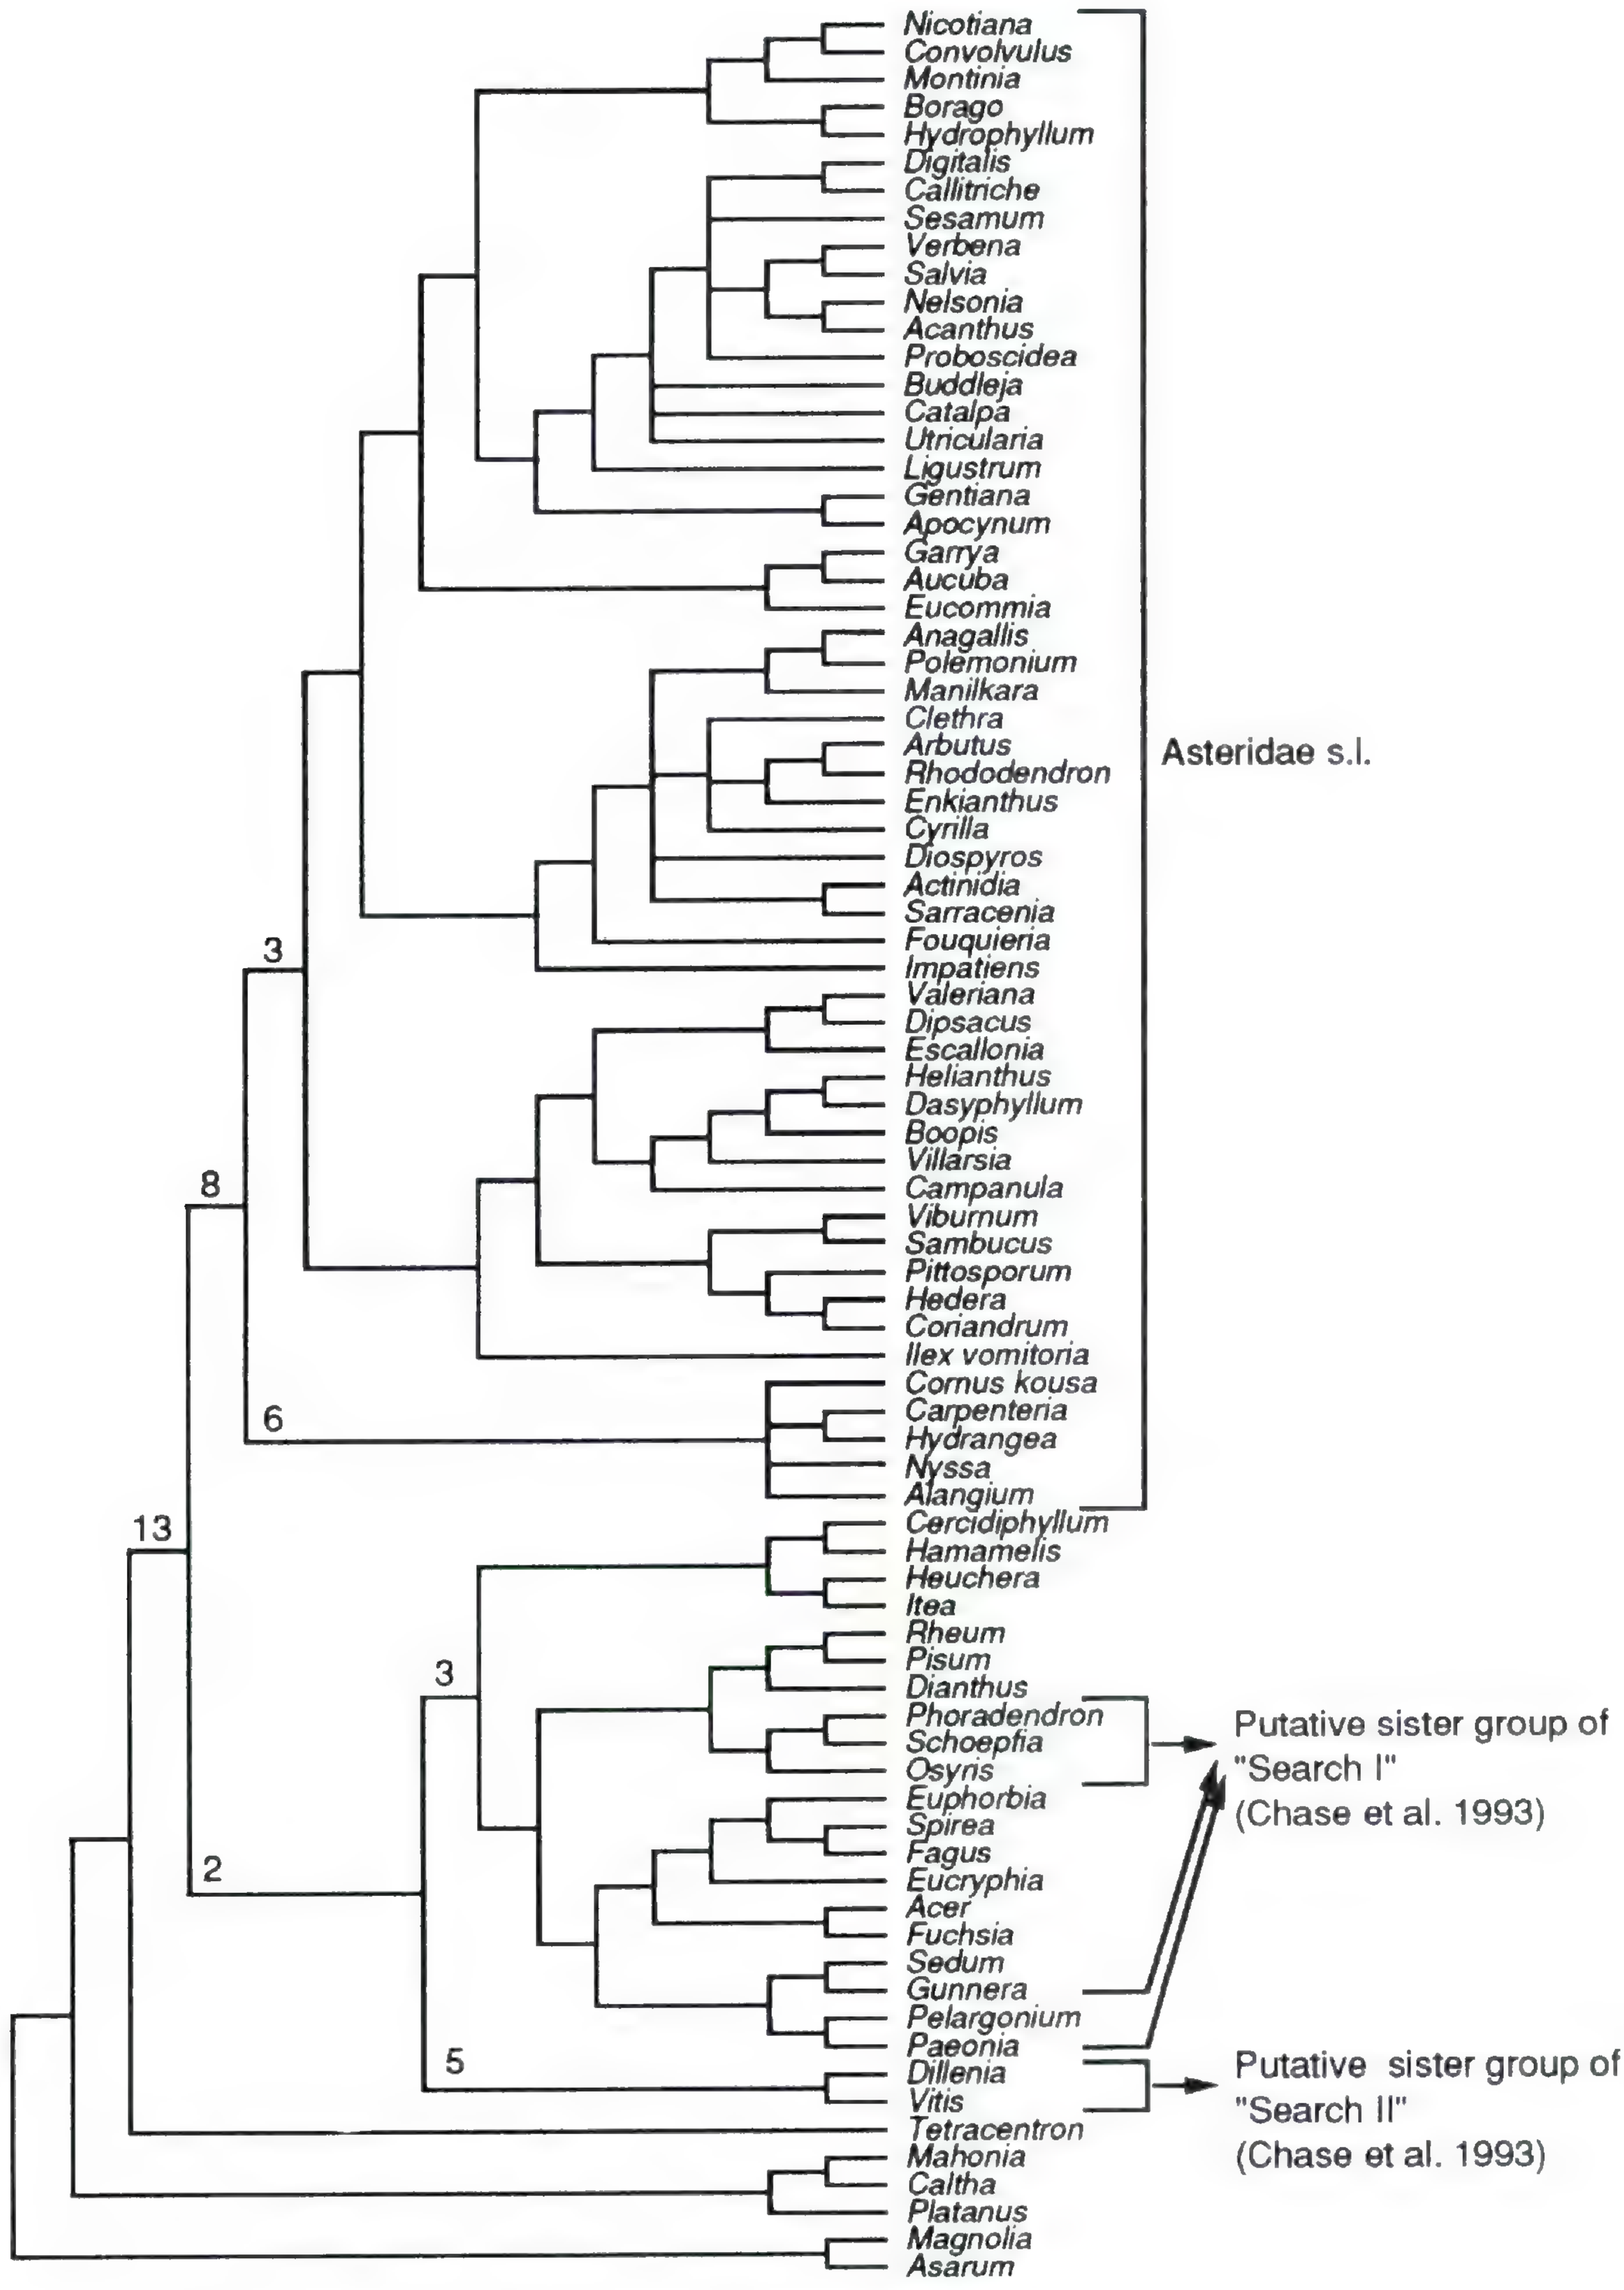

FIGURE 4. Strict consensus of 30 trees based on *rbc*L sequences resulting from the analysis designed to explore sister-group relationships to the Asteridae s.l. (length = 3,322, C.I. = 0.25, R.I. = 0.41). The sister group to the Asteridae s.l. indicated by this analysis is a large clade consisting of parts of the Rosidae and Dilleniidae sensu Cronquist (1981). Putative sister groups suggested by "Search I" and "Search II" of Chase et al. (1993) are indicated. Typical branch lengths in the vicinity of the node from which the Asteridae s.l. and their sister group diverge are indicated.

group to the Asteridae s.l. either. Instead, these sequences are placed at the base of the Rosidae s.l., suggesting that they represent a clade that diverged close to the divergence of the two larger clades. A search for multiple islands might find equal length trees congruent with the results of "Search II" of Chase et al. (1993) with respect to the placement of these two sequences.

ANALYSIS OF SUBCLADES

Detailed analyses were conducted on three subsets of the asterid *rbc*L data that were identified as clades by Olmstead et al. (1992) and in "Search I" of Chase et al. (1993). The primary purpose for the subclade analyses is to examine in detail more sequences within major clades than is possible in the more inclusive broad analysis of the Asteridae s.l. Thus, the subclade analyses are viewed in relationship to the Asteridae s.l. analysis as that analysis is to the seed plant analyses of Chase et al. (1993). Results from this nested hierarchical approach should be complementary; the local analyses better assess relationships within terminal clades and the broader analyses better assess relationships among those clades. Time considerations dictated that selection of these subsets of sequences precede the completion of "Search II" (Chase et al., 1993) and the search for multiple islands conducted on the 105-sequence Asteridae s.l. data set described above. The first subset analyzed is the Lamiidae sensu Takhtajan (1987). The second (hereafter referred to as the Asterales–Dipsacales–Apiales) contains the Asterales, Campanulales, Dipsacales, Apiales, and several taxa traditionally assigned to other orders in the Asteridae or Rosidae (sensu Cronquist, 1981). Both "Searches I & II" of Chase et al. (1993) identified a small clade containing *Garrya* (Garryaceae), *Aucuba* (Cornaceae), and *Eucommia* (Eucommiaceae) placed near the point of divergence of the two above-mentioned, larger clades. To examine the possible relationships of these three taxa, they were included in each analysis. The third clade examined in greater detail is one containing representatives of the Ericales, Ebenales, Primulales, and other taxa from the Rosidae, Dilleniidae, and Asteridae. The Cornales and Hydrangeaceae represent the only primary group within the Asteridae s.l. not included in a more detailed analysis here, because a detailed analysis of this group appears elsewhere (Xiang et al., 1993).

To examine the Lamiidae, a set of 72 sequences was compiled. This set included all of the sequences belonging to the group "Asteridae I" in "Search II" of Chase et al. (1993), except *Vahlia*, and included nine additional sequences from taxa traditionally assigned to the orders Gentianales (six) and Scrophulariales (three). Outgroup sequences included *Cornus* (Cornaceae), *Nyssa* (Nyssaceae), *Arbutus* (Ericaceae), *Polemonium* (Polemoniaceae), *Ilex* (Aquifoliaceae), *Escallonia* (Grossulariaceae), *Hedera* (Araliaceae), *Viburnum* (Caprifoliaceae), and *Dasyphyllum* (Asteraceae). The analysis of the Lamiidae data set (72 sequences) resulted in the discovery of four islands (although more may exist); two islands contain 135 (Fig. 5) and 1,350 trees (Fig. 6A), each of 2,189 steps, whereas the other two are one step longer (see below). Both islands identify as clades the Solanales (e.g., Solanaceae, Convolvulaceae, and *Montinia*), Boraginales (e.g., Boraginaceae, Hydrophyllaceae), Lamiales s.l. (e.g., Oleaceae, Bignoniaceae, Labiatae, Verbenaceae, Scrophulariaceae, Acanthaceae), and Gentianales (e.g., Rubiaceae, Gentianaceae, Apocynaceae, Loganiaceae), with a clade comprising the Solanales and Boraginales sister group to the others. The differences between the two islands fall entirely within the Lamiales s.l. clade, where several individual sequences or small groups of sequences occupy very different positions. Much resolution within the Lamiales s.l. is lost in the strict consensus of both islands combined (Fig. 6B). Both islands identify the *Garrya–Aucuba–Eucommia* clade as sister group to the Lamiidae. Two additional islands (not shown) containing 2,160 and 135 trees representing local optima were discovered at one step longer (2,190 steps). These trees are identical to the shorter islands with respect to the pattern of relationships among primary lineages within the Lamiidae, but differ in that the *Garrya* clade is not identified as their sister group.

To examine the Asterales–Dipsacales–Apiales, a set of 43 sequences was compiled. This set included all of the sequences belonging to the group "Asteridae II" in "Search II" of Chase et al. (1993), except that six representatives of the Asteraceae were included (rather than 14), and one additional sequence each of *Ilex* and of Apiaceae were added. *Garrya*, *Aucuba*, and *Eucommia* were included. Outgroup sequences included *Cornus*, *Nyssa*, *Arbutus*, *Polemonium*, *Nicotiana* (Solanaceae), *Gentiana* (Gentianaceae), and *Antirrhinum* (Scrophulariaceae). The analysis of this data set resulted in the discovery of two islands containing 80 (Fig. 7A) and 196 trees (Fig. 7B) each of 1,368 steps. The smaller island identifies a monophyletic Asterales–Dipsacales–Apiales, whereas the island of 196 trees (Fig. 7B) is unresolved with respect to these three orders and

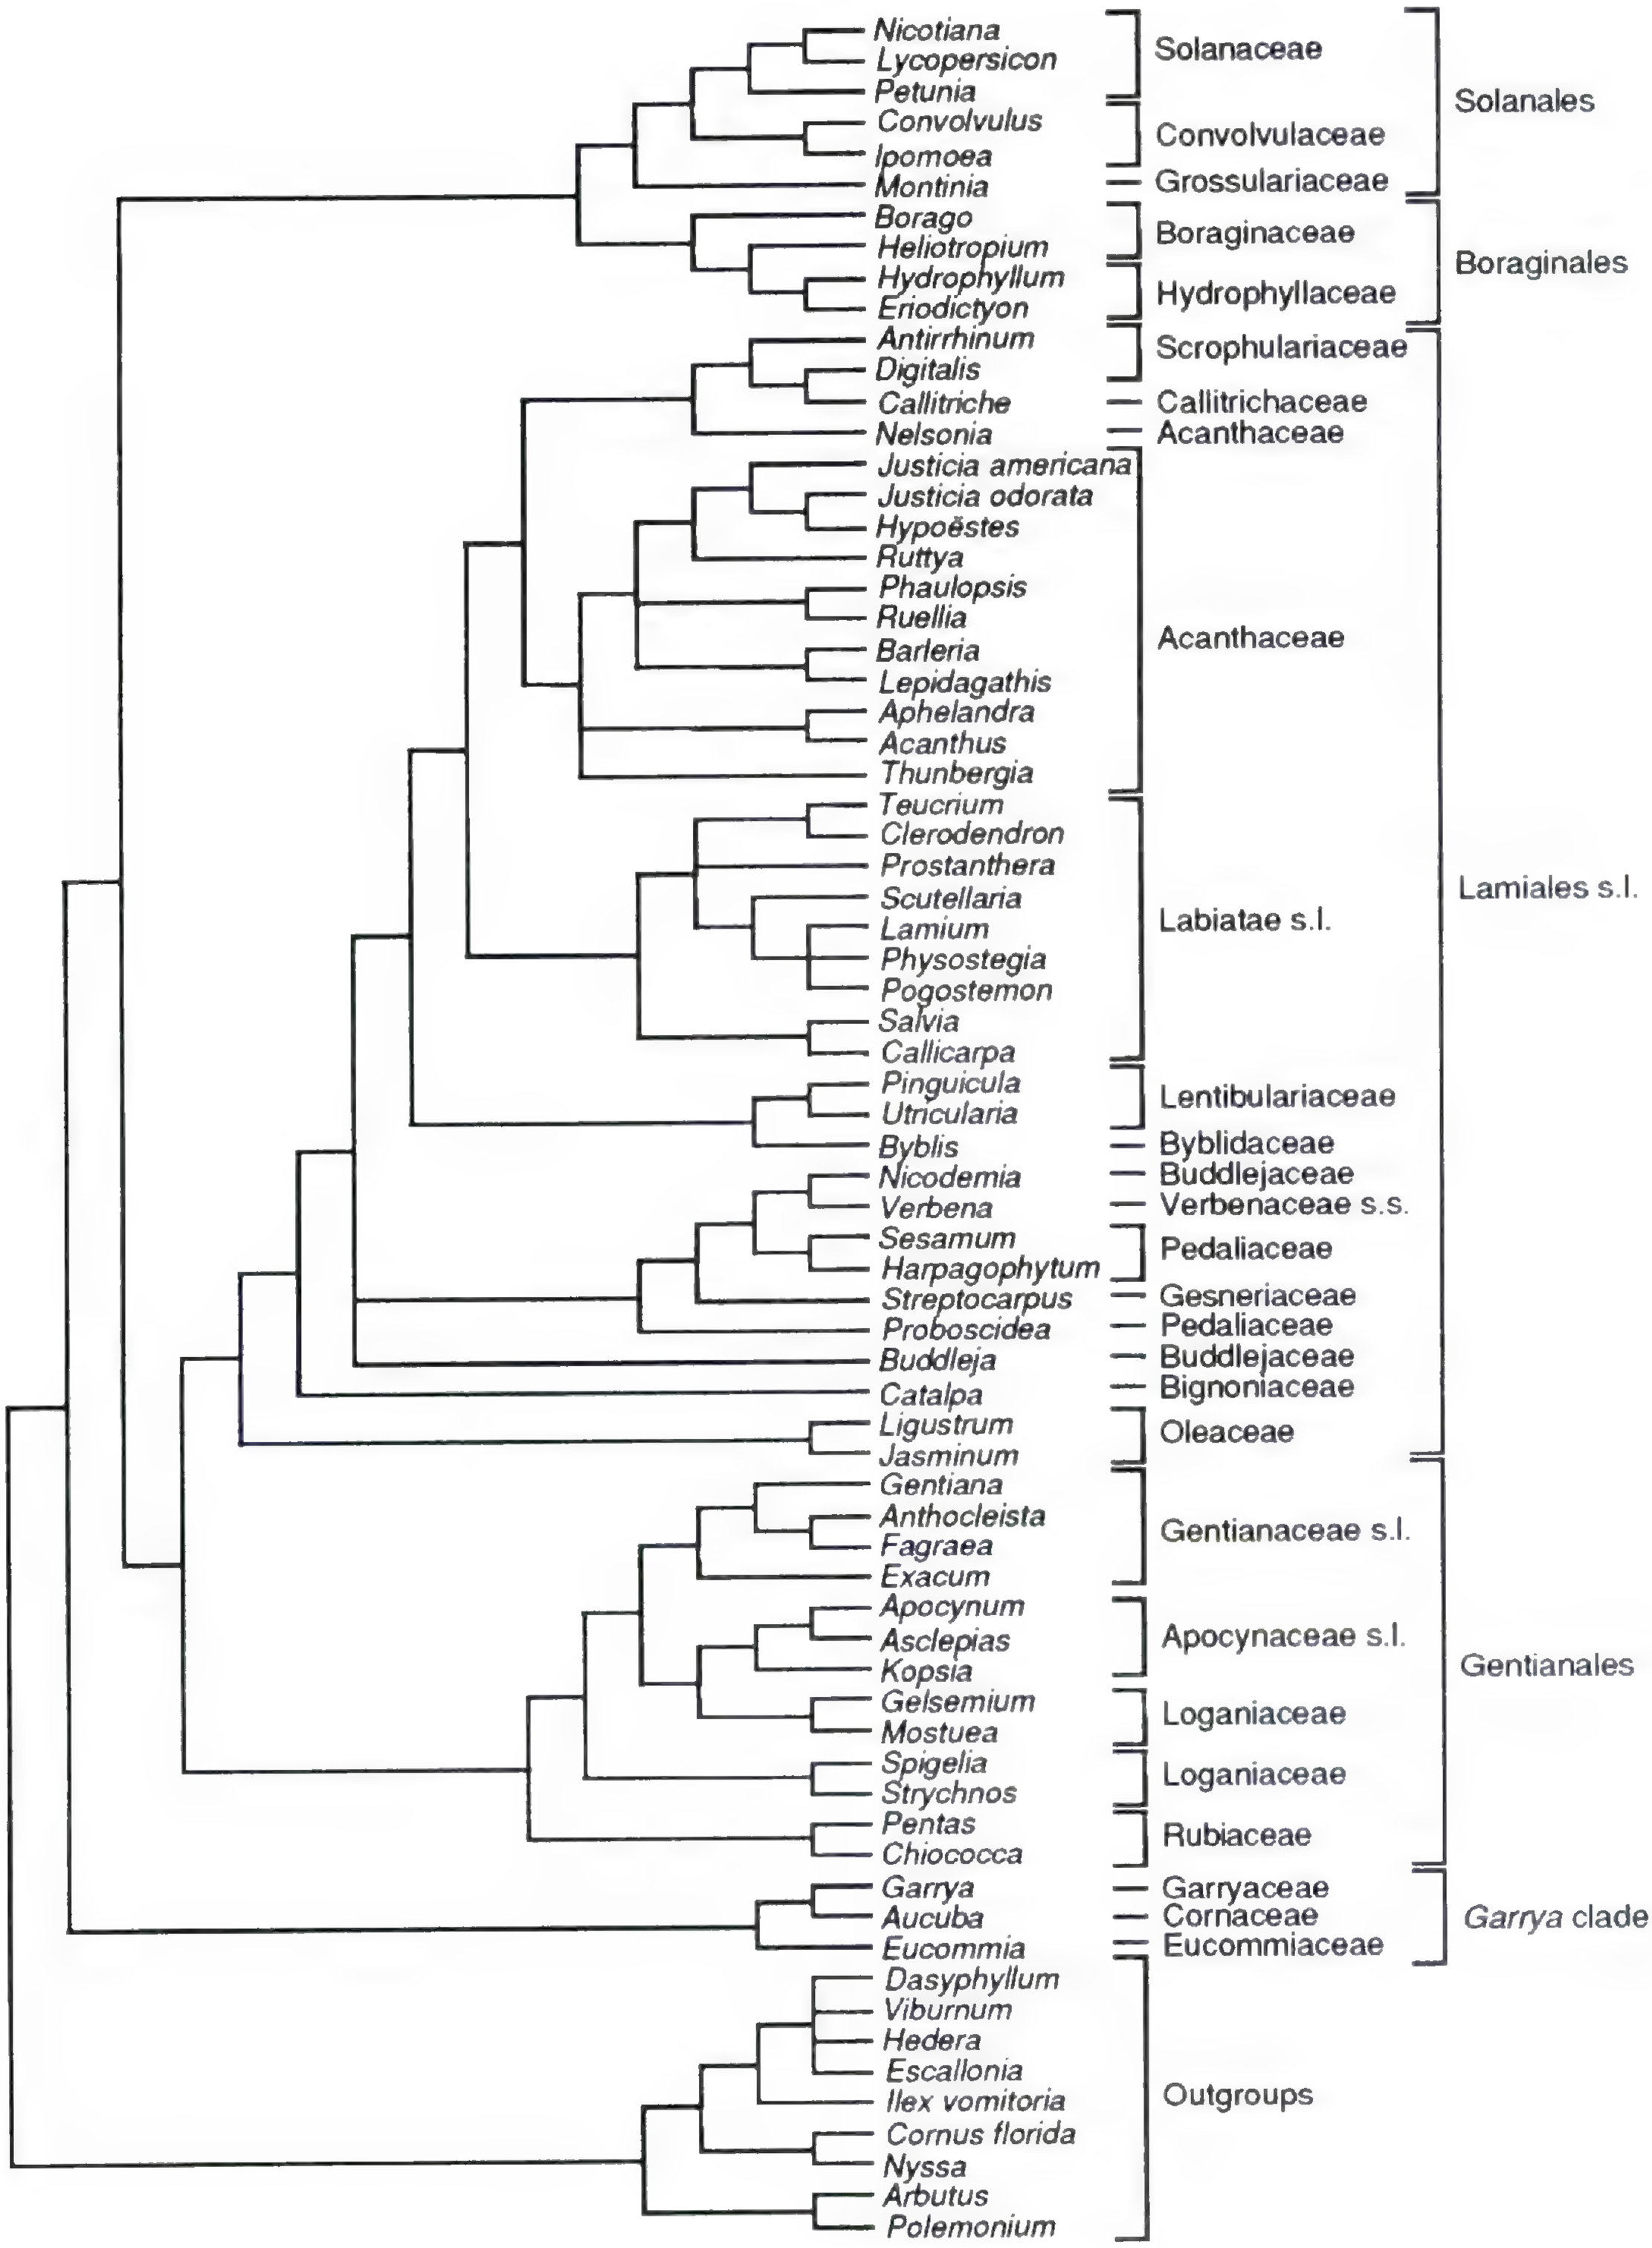

FIGURE 5. Lamiidae, island-135. Strict consensus of 135 trees based on *rbc*L sequences with increased taxon sampling in the Lamiidae (length = 2,189, C.I. = 0.31, R.I. = 0.57). Family designations follow Cronquist (1981), except for the Labiatae (Cantino et al., 1992), and do not imply necessarily that the entire family belongs where these representatives occur. Two additional islands each one step longer place the *Garrya* et al. clade among the other designated outgroups and not as sister group to the Lamiidae (not shown).

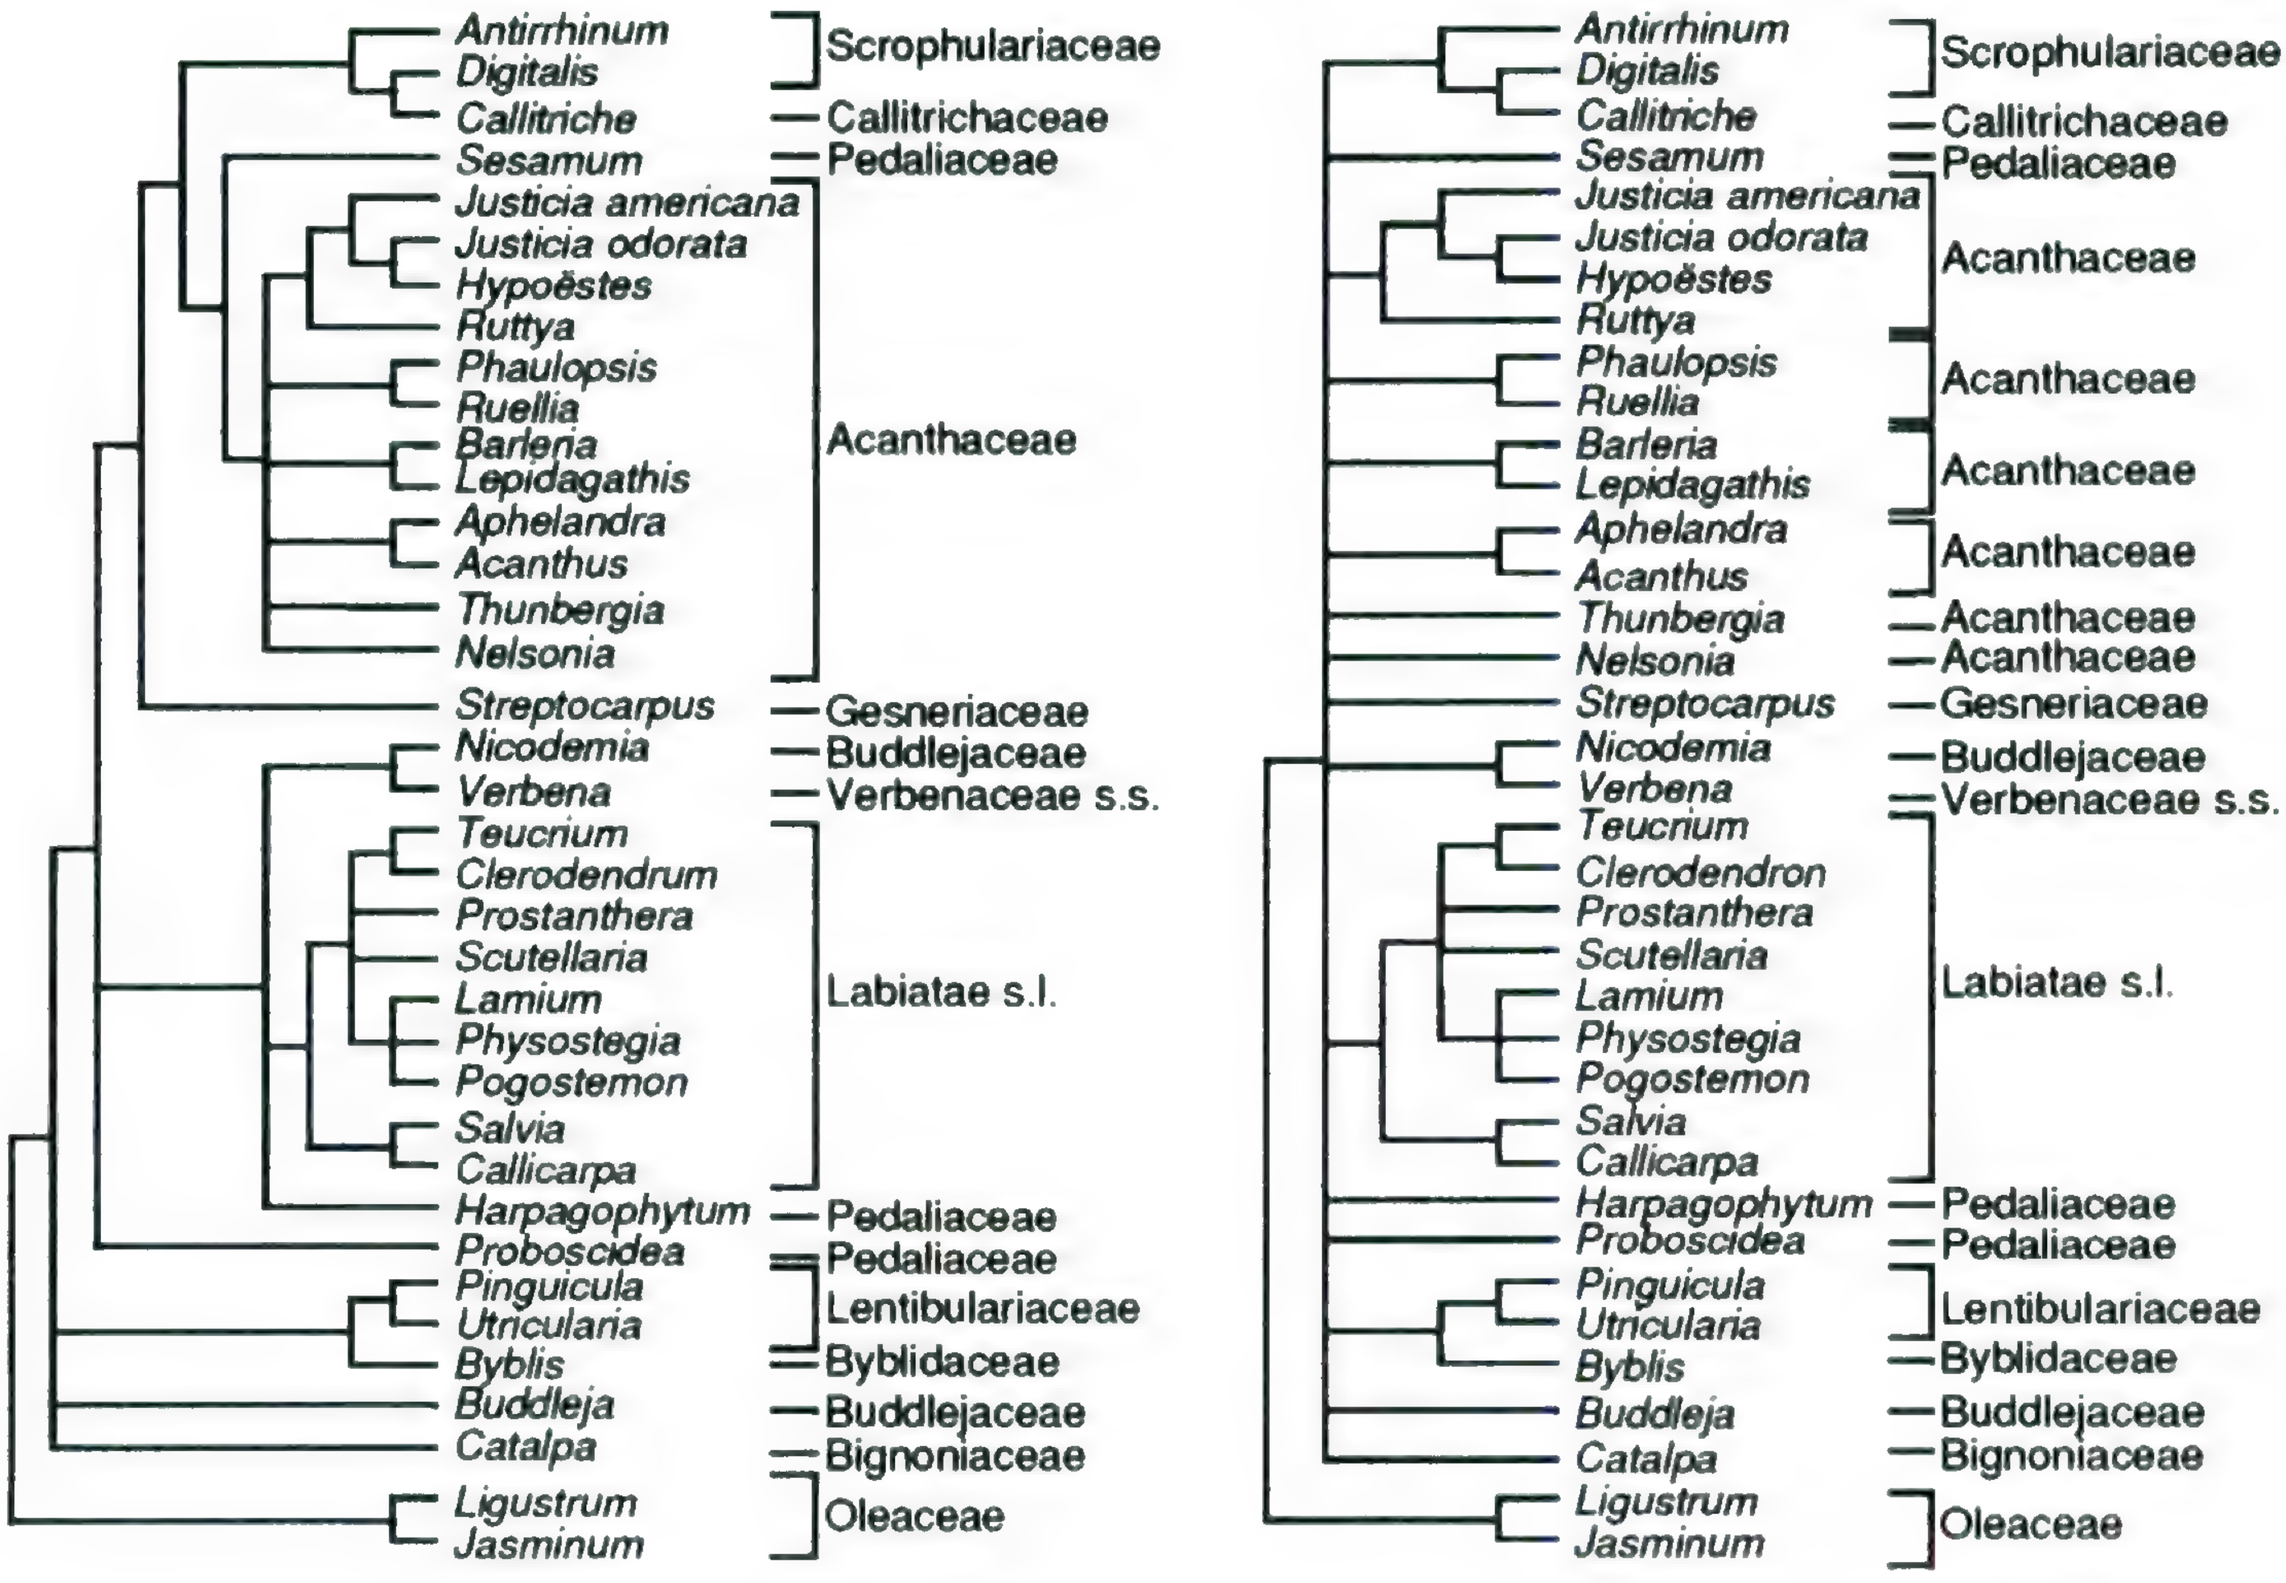

FIGURE 6. Strict consensus trees of the Lamiales s.l. based on *rbc*L sequences. These trees represent the portion of the Lamiidae analysis that is variable among islands; relationships among other members of the Lamiidae and outgroups are the same as in Figure 5.—A. Island-1,350. Strict consensus of 1,350 trees (length = 2,189, C.I. = 0.31, R.I. = 0.57).—B. Strict consensus of 1,485 equal-length trees from island-135 and island-1,350 combined. Family designations as in Figure 5.

several other groups (however, the Dipsacales and Apiales group with representatives of the Cornales in many trees). This is similar to the results of the Asteridae s.l. analysis, in which one island identifies this clade (Fig. 1A) and the other does not (Fig. 1B). Both islands identify the following clades: Dipsacales, Asterales s.l. (including Campanulales, Menyanthaceae, and *Corokia*), Apiales (including *Pittosporum* and *Griselinia*), and the group containing *Ilex*, *Phyllonoma*, and *Helwingia*.

To examine the ericalean clade, a set of 60 sequences was compiled, including all of the sequences belonging to the group "Asteridae III" in "Search II" of Chase et al. (1993) except *Heliamphora*. Eight additional sequences representing the Ericaceae were included (see Kron & Chase, 1993). Nineteen representatives of other clades in the Asteridae s.l. were included as outgroups. The analysis of this data set resulted in the discovery of two islands of trees, one containing 612 trees (Fig. 8B) of 1,889 steps and the other containing 357 trees (Fig. 8C) of 1,890 steps. Both islands identify a monophyletic Ericaceae s.l. (including the Epacridaceae, Empetraceae, and Pyrolaceae), in agreement with Kron & Chase (1993). All members of this clade belong to Cronquist's Dilleniidae, except *Impatiens*, *Roridula*, and *Polemonium* (see discussion below). The largest clade that is congruent between the two islands is the Ericaceae. The shorter island is congruent in most respects with the results of Kron & Chase (1993). The strict consensus tree of both islands combined indicates very little resolution outside the Ericaceae (Fig. 8A).

## DISCUSSION

The goals of a study of this nature (i.e., reconstructing the phylogeny of the Asteridae) are lofty, but accomplishing them is problematic. A major problem with analyzing this and any other large and complex systematic data set is assessing the

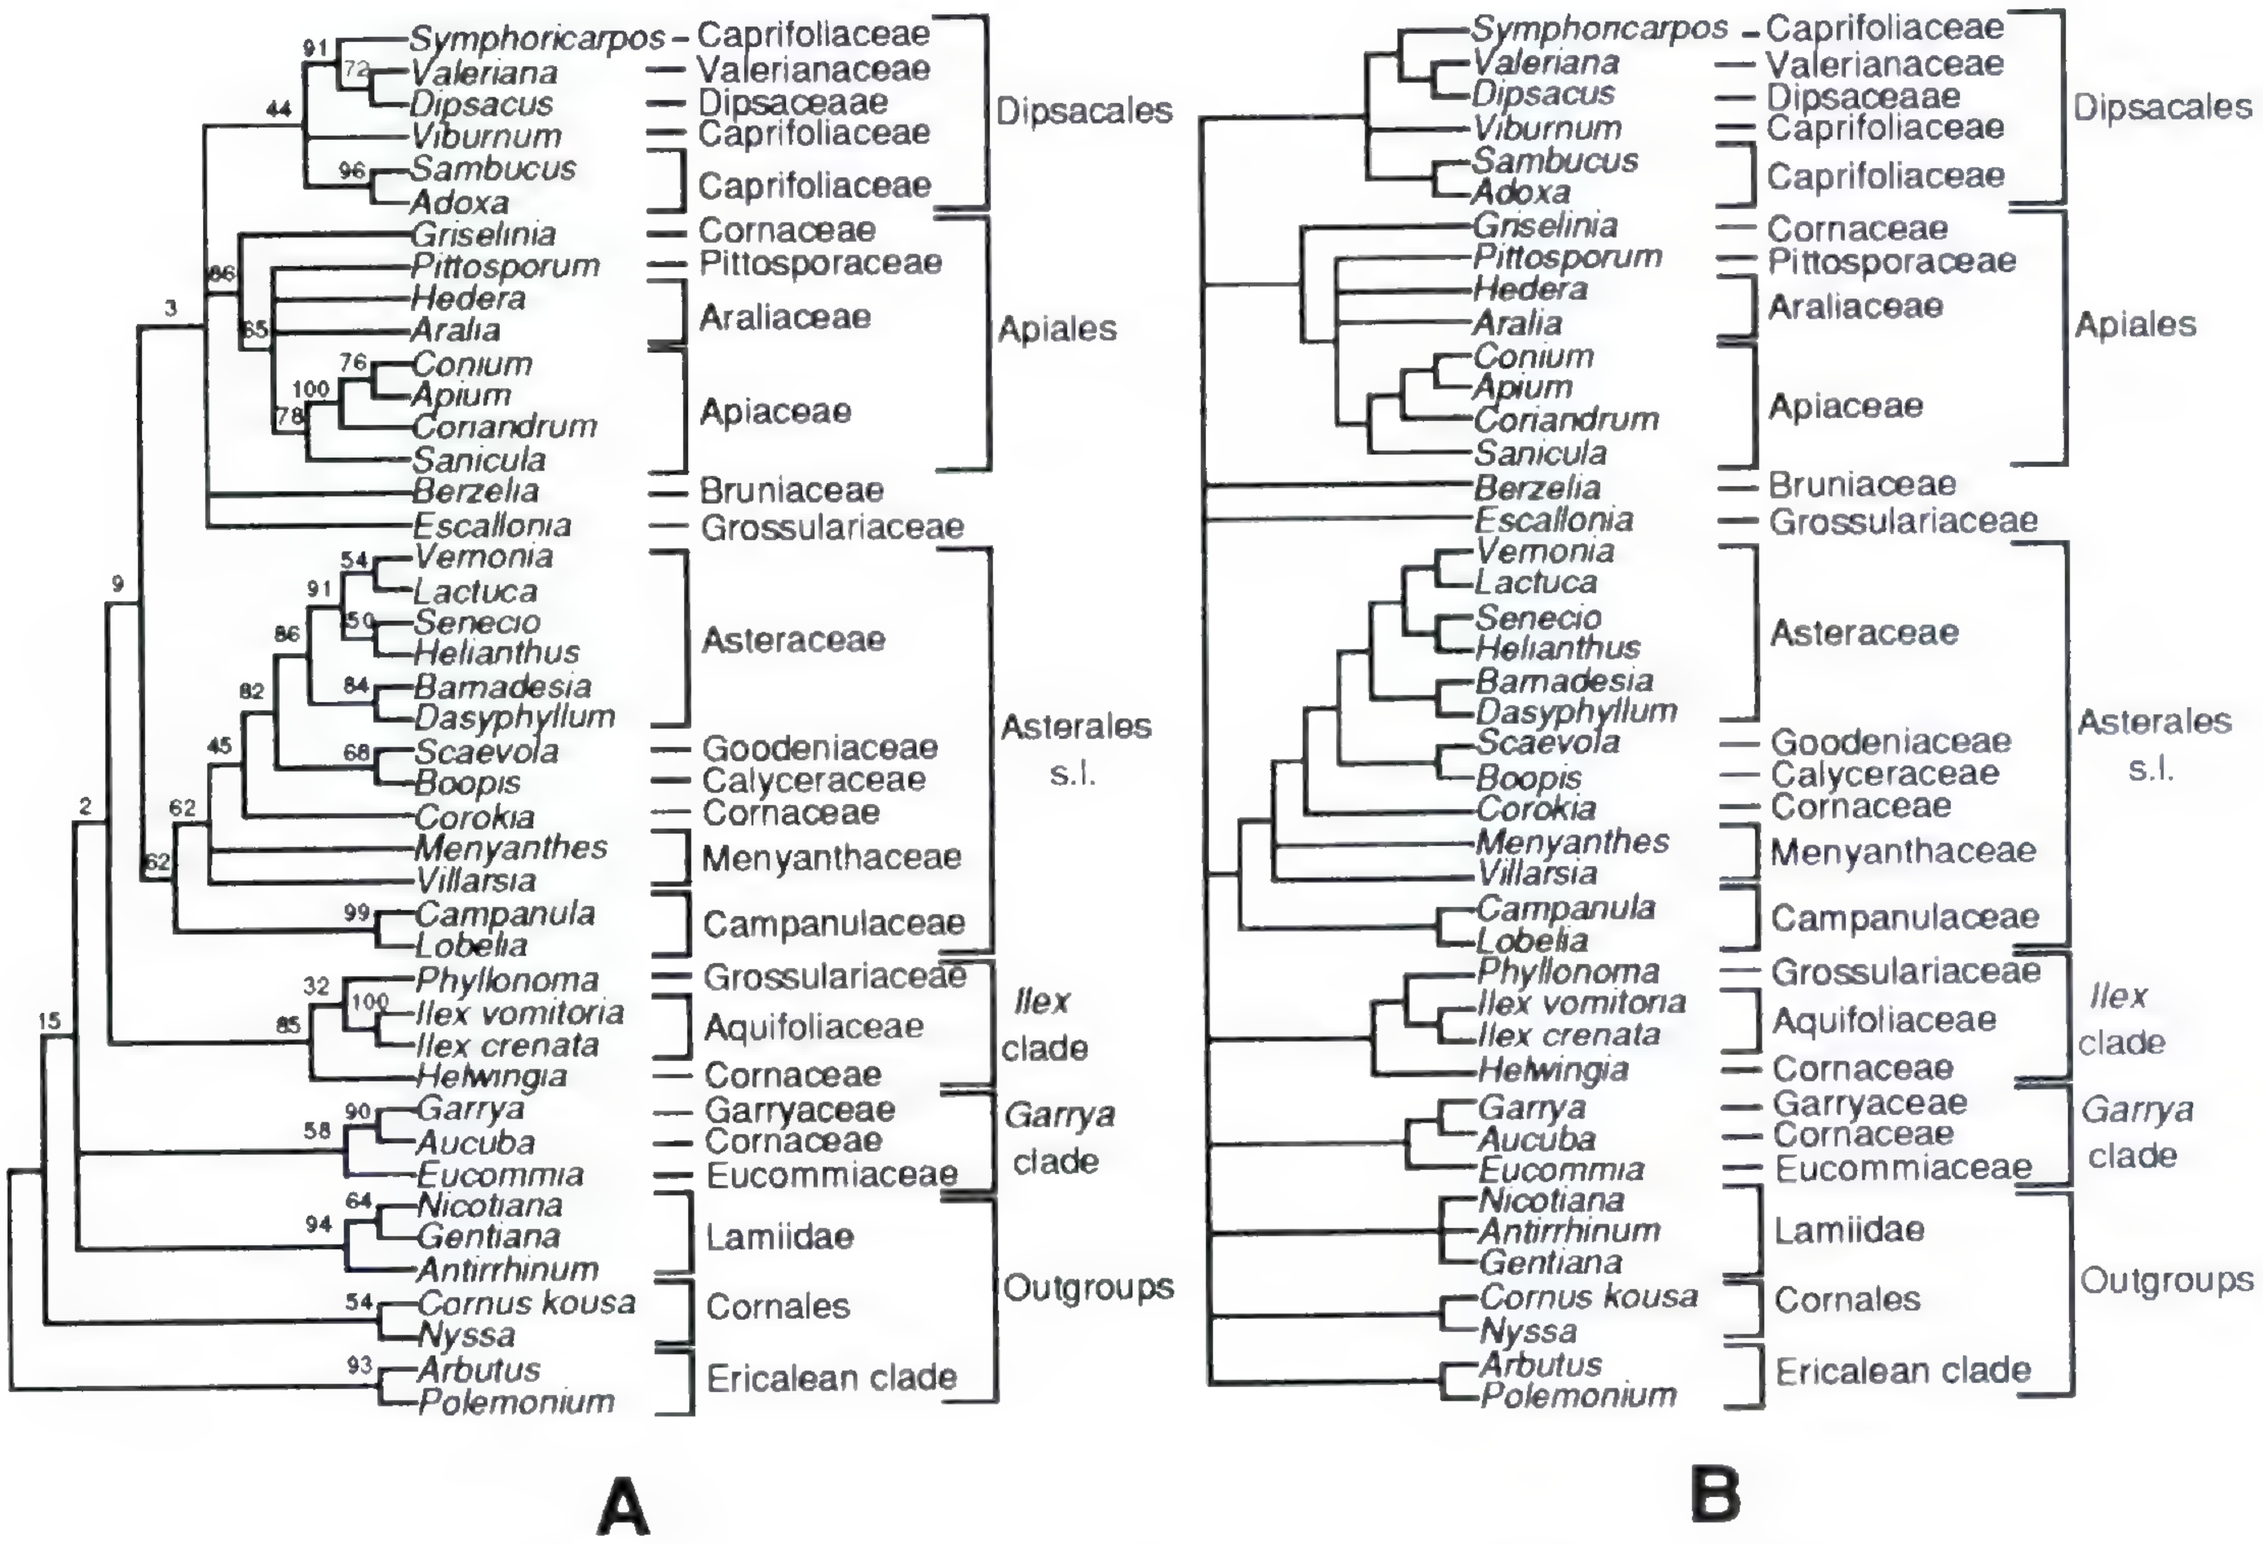

FIGURE 7.—Strict consensus trees for *rbc*L sequences representing the Asterales s.l., Apiales, and Dipsacales.—A. Island-80. Strict consensus of 80 trees (length = 1,368, C.I. = 0.39, R.I. = 0.51). Numbers above branches indicate percent occurrence of subtended clade in 100 bootstrap replicates.—B. Island-196. Strict consensus of 196 trees (length = 1,368, C.I. = 0.39, R.I. = 0.51). This consensus tree is the same as for the combined consensus of island-80 and island-196. Family designations follow Cronquist (1981) and do not imply necessarily that the entire family belongs where these representatives occur.

reliability of the results. How can one be sure that the results found represent the optimal solution for the data? How can one resolve incongruence between separate analyses conducted on similar data sets (e.g., differences between the analyses of Chase et al., 1993, this issue, and analyses presented here)? Will sampling more taxa, sampling more characters (e.g., nucleotides), or more detailed analyses of a subset of the data provide better results? It is not clear that there is a single best answer to any of these questions and when data of this nature are compiled for the first time for a group of organisms, as these are for the Asteridae (and angiosperms), there is no independent, external means for evaluating the results. Internal methods for evaluating trees (e.g., bootstrap or decay analysis) are extremely difficult to implement on a large data set. Bearing in mind that there is little in the way of rigorous, quantitative, phylogenetic hypotheses against which to evaluate these results, they should be considered preliminary, awaiting the availability of a substantially greater amount of data derived from other sources.

For the results of a cladistic analysis to provide strong support for a hypothesis, alternative hypotheses must be examined. This requires searching for multiple islands with sufficient diligence to reach other islands, if they exist. For one well-known data set of human mitochondrial DNA sequences (Vigilant et al., 1991), a reanalysis of the data yielded separate islands each having different implications with respect to the geographic origin of modern humans (Maddison et al., 1992). The initial analysis (Vigilant et al., 1991) was unable, by design, to find more than one island and, therefore, was predestined to yield one conclusion.

A total of approximately eight to ten months of computer time was spent on the several analyses reported here. Multiple islands were found whenever the appropriate search strategy was employed for each data set examined in this study. In all cases only two or three separate initial searches each of 200–2,000 random-order-entry starting points were required to find multiple islands, leaving open the possibility that additional islands, some perhaps shorter, remain to be found. Whereas it

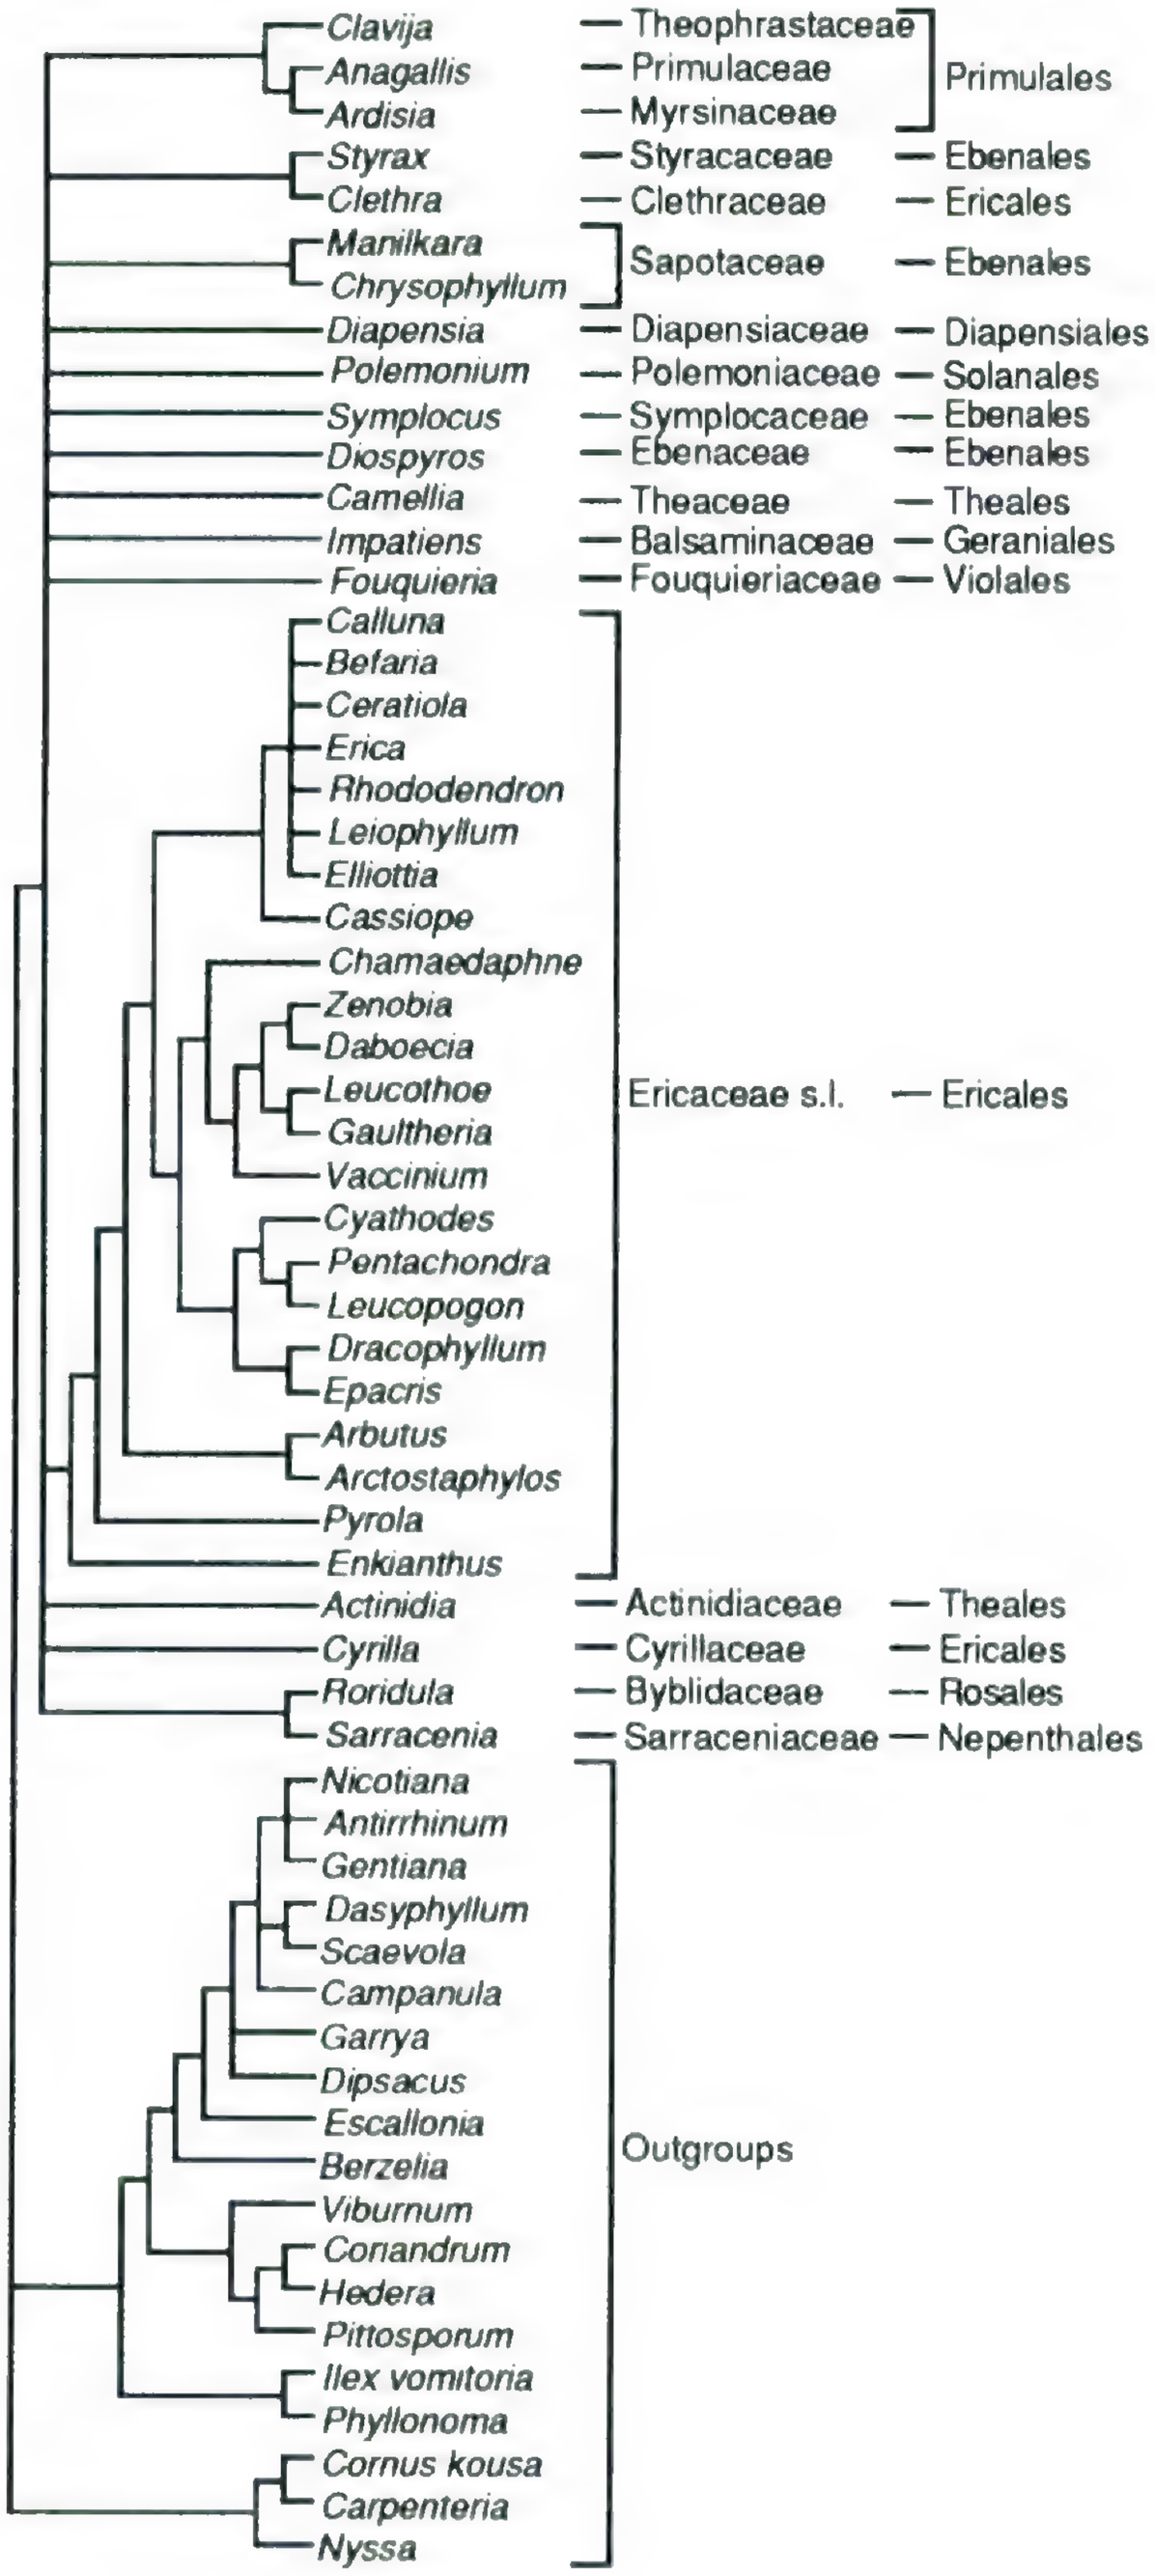

FIGURE 8. Strict consensus trees for the ericalean clade based on *rbc*L sequences.—A. Strict consensus of 969 trees combining island-612 and island-357. Resolution resides almost exclusively within the Ericaceae s.l.—B. Strict consensus of island-612 (612 trees length = 1,889, C.I. = 0.33, R.I. = 0.55).—C. Strict consensus of island-357 (357 trees length = 1,890, C.I. = 0.33, R.I. = 0.55). Relationships among outgroups and within Ericaceae s.l. are the same for both islands, thus are only indicated in A. Family designations follow Cronquist (1981) and do not imply necessarily that the entire family belongs where these representatives occur.

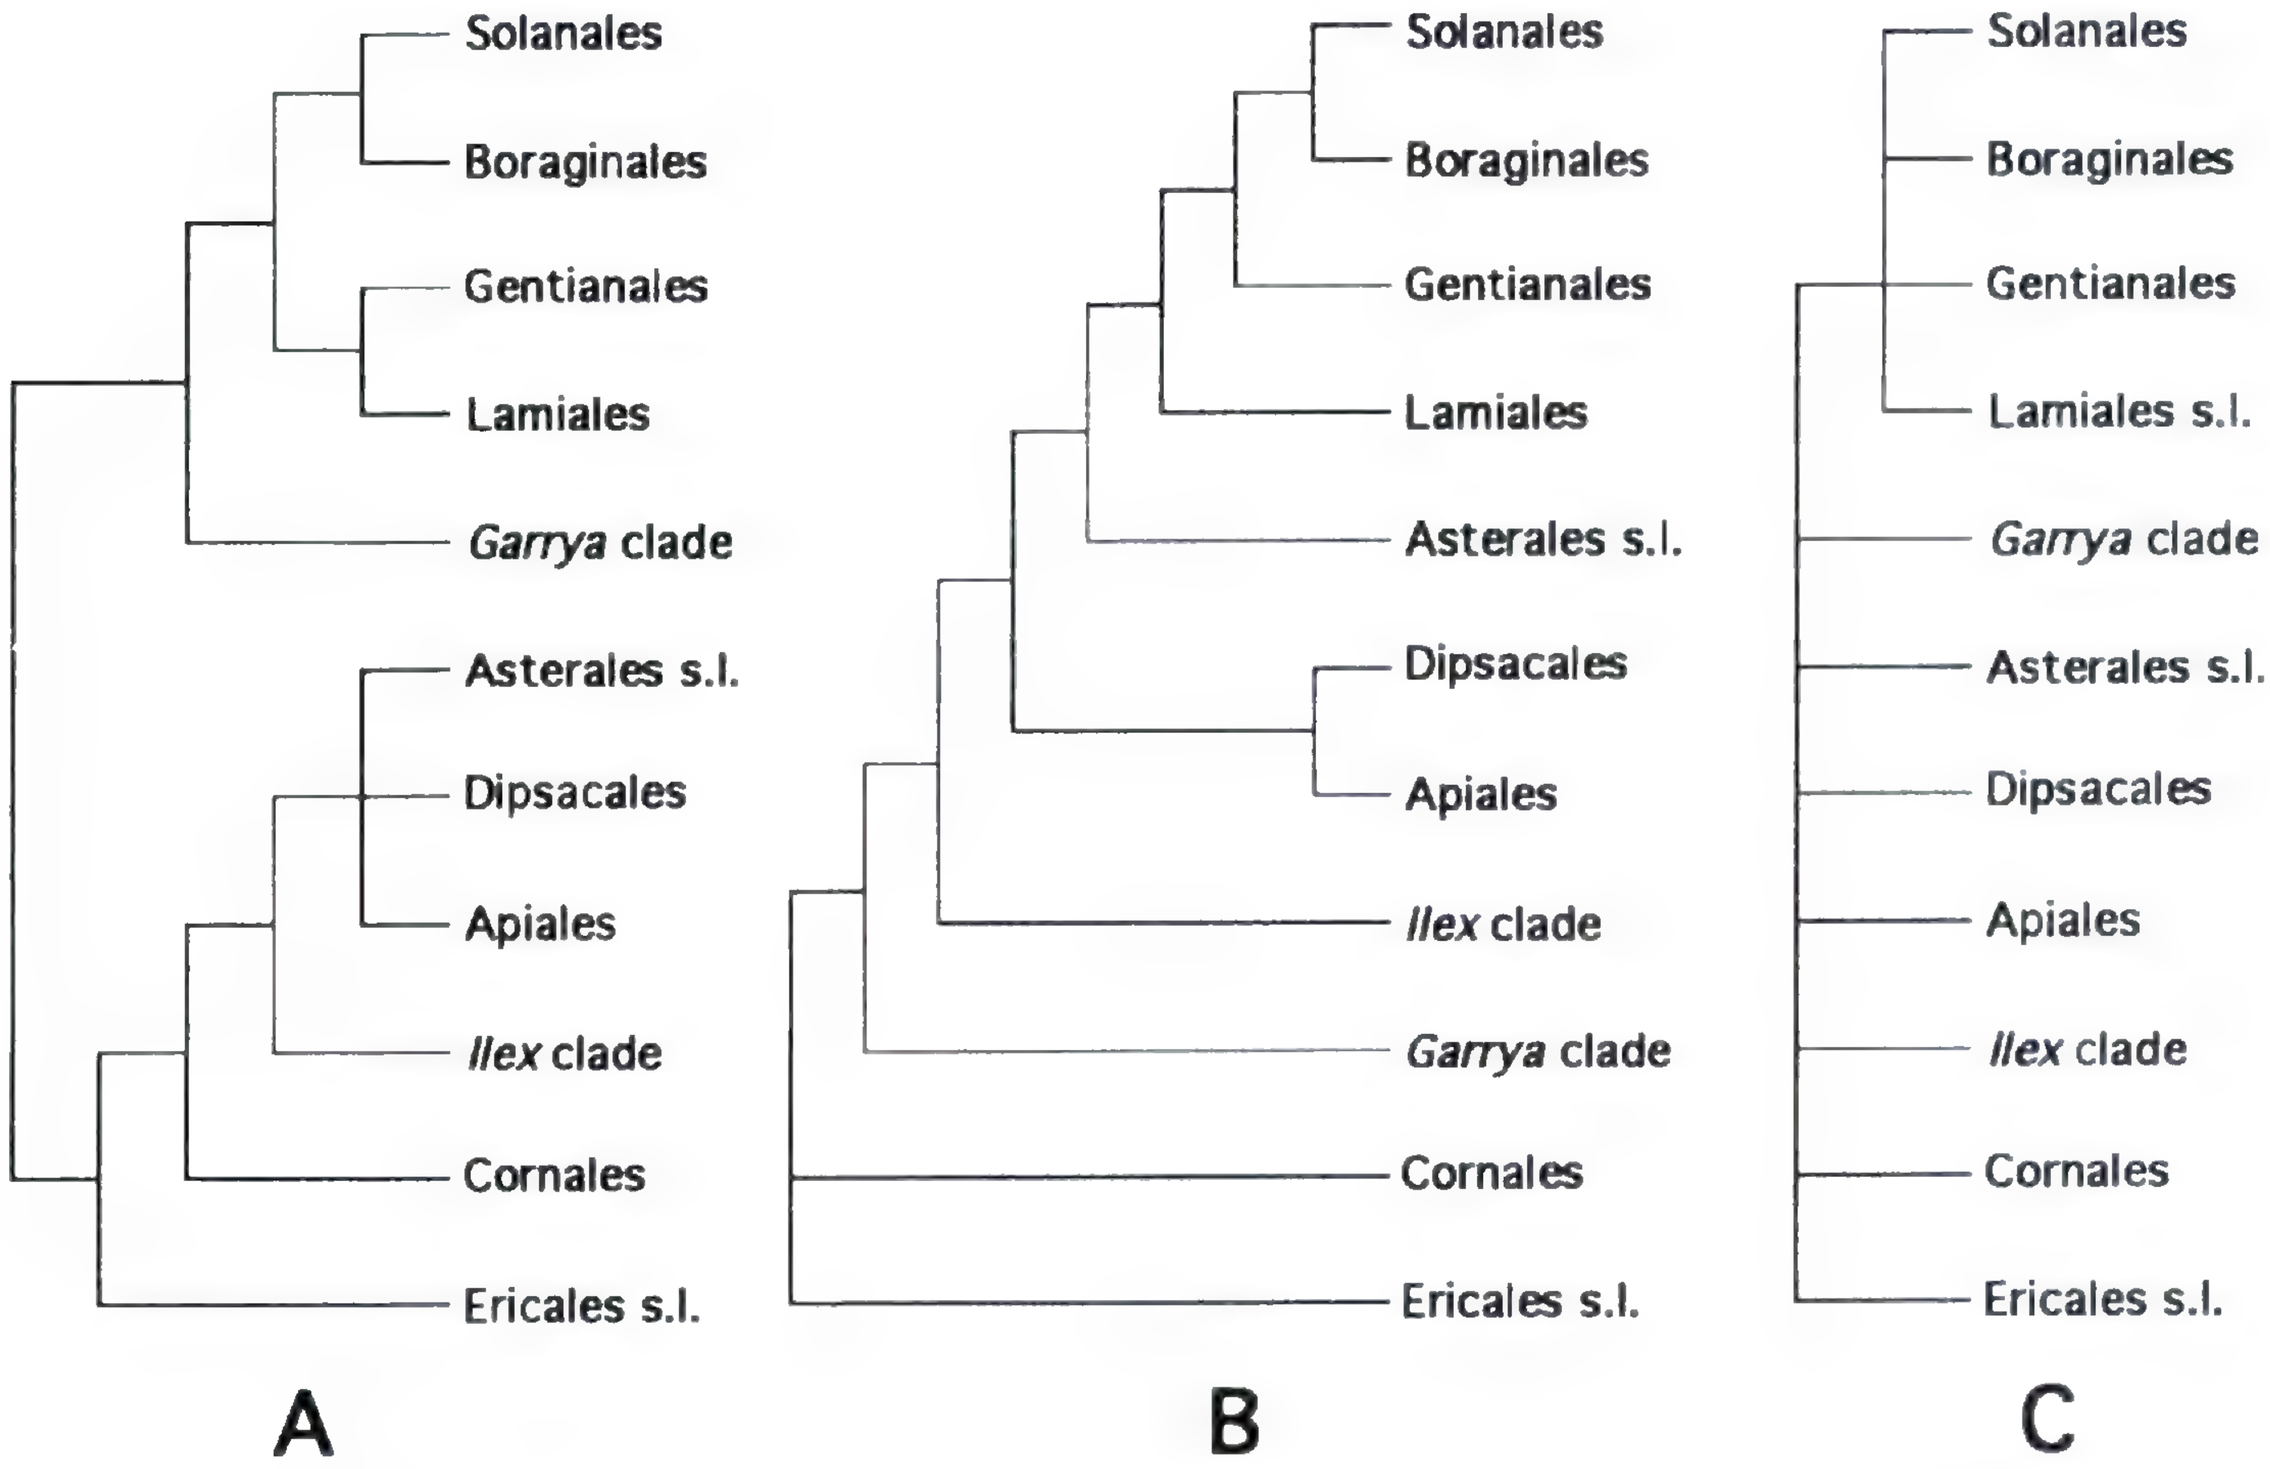

Figure 9.—Condensed cladograms representing the relationships among primary groups in the Asteridae s.l. based on *rbc*L sequences.—A. Island-102.—B. Island-2,784.—C. Combined consensus of island-102, island-2,784, and island-5,568.

is not possible to know if all islands within the Asteridae s.l. have been discovered, finding at least two islands provides a cautionary note with respect to the extent to which the findings can be used for evolutionary and systematic interpretations.

The discovery of multiple islands of trees of equal, or near-equal, length implies that there are regions of conflict in the hypotheses of relationship that derive from them. The conclusions in which we can have the most confidence are those that are shared between islands. The analysis of 105 sequences (designed to examine overall relationships within the Asteridae s.l.) and the analysis of 82 sequences (which includes numerous additional outgroup sequences, but reduced sampling within the Asteridae s.l.) both agree with the conclusions of Olmstead et al. (1992) and Chase et al. (1993) in the circumscription of a monophyletic Asteridae s.l. Within the Asteridae s.l., the three islands of trees discovered in the analysis of 105 sequences are congruent in the composition of 11 terminal groups (Fig. 9) and in the monophyly of one group comprising four of the terminal groups (Lamiidae sensu Takhtajan, 1987). Differences among islands exist both within and among these 11 groups, indicating that different cladistic patterns within monophyletic groups can influence the most parsimonious patterns among those groups. Two sequences (*Berzelia* and *Escallonia*) each fall into a specific clade in one island, but remain unresolved in the other island. Interestingly, these two sequences represent families that Hufford (1992) identified as individual branches at the base of the entire Asteridae s.l. They will be included in the discussion below with the clade to which they belong in at least one island.

The names used for groups identified here were chosen to reflect formally described taxonomic groups to which they are most closely similar. However, we consider these to be provisional names at this time, and they should not be viewed as constituting a formal classification. The 11 putatively monophyletic groups identified within the Asteridae s.l. are as follows (family, order, and subclass designations for included representatives follow Cronquist, 1981, unless otherwise noted):

(1) **Cornales.** This clade contains representatives of the Cornaceae, Hydrangeaceae, and Nyssaceae, all formerly placed in the subclass Rosidae. Several representatives placed within or near one or the other of these families in most angiosperm classification schemes are found elsewhere in the

*rbc*L tree of the Asteridae s.l. Three subgroups are identified within this clade: the Hydrangeaceae, *Cornus* (representing the Cornaceae s.s.), and the Nyssaceae. *Alangium* remains unresolved with respect to placement in either the Cornaceae s.s. or Nyssaceae (but see Xiang et al., 1993). Both Anderberg (1992) and Hufford (1992) identified this clade (including Loasaceae and Sarraceniaceae in Hufford, 1992) in their morphology-based cladistic analyses. Greater sampling and more detailed analysis of this clade shows substantial resolution based on *rbc*L sequences; see Xiang et al. (1993) and Morgan & Soltis (1993) for further discussion.

(2) **Ericalean clade.** This clade is mostly composed of former representatives of the Dilleniidae, including the orders Diapensiales, Ebenales, Ericales, Nepenthales, Primulales, Theales, and Violales (*Fouquieria*). The only non-dilleniid representatives in this clade are *Polemonium* (Polemoniaceae, Asteridae), *Roridula* (Byblidaceae, Rosidae), and *Impatiens* (Balsaminaceae, Rosidae). The clade identified here (see also Chase et al., 1993; Kron & Chase, 1993) has not been recognized in any formal classification. Within this group (Fig. 8A) representatives of the Ericaceae s.l. form a clade (Kron & Chase, 1993), as do a few pairs or triplets of sequences: *Clavija*, *Anagallis*, *Ardisia* (Primulales), *Styrax* (Styracaceae, Ebenales) with *Clethra* (Clethraceae, Ericales), *Manilkara* with *Chrysophyllum* (Sapotaceae, Ebenales), and *Sarracenia* (Sarraceniaceae, Nepenthales) with *Roridula* (Byblidaceae, Rosales). Most of the rest of the sequences in this clade are single representatives of families. This clade is noteworthy for the lack of resolution even within islands at the level of sampling represented here (Fig. 8B, C). *Actinidia* and *Roridula*–*Sarracenia* consistently occur with the Ericaceae (Fig. 8), each as sister group in one island, but do not appear as part of the clade in the consensus tree, because *Cyrilla* occurs in that clade in one island and not in the other. Considerably more work is needed before the picture of relationships within this clade can be brought into focus. See Kron & Chase (1993) for further discussion.

(3) ***Garrya* clade.** This small clade is represented by three sequences: *Garrya* (Garryaceae, Cornales), *Aucuba* (Cornaceae), and *Eucommia* (Eucommiaceae, Eucommiales, Hamamelidae). This represents a previously unrecognized group and includes species not formerly placed in the Asteridae. However, morphological and chemical features uniting these taxa and supporting their association with the Asteridae s.l. can be recognized (see below and Xiang et al., 1993).

(4) ***Ilex* clade.** This small clade is represented by four sequences: *Ilex crenata* Thunberg and *I. vomitoria* Aiton (Aquifoliaceae, Celastrales, Rosidae), *Helwingia* (Cornaceae), and *Phyllonoma* (Grossulariaceae, Rosales). This is another previously unrecognized clade, which does, nonetheless, have putative morphological synapomorphies (Morgan & Soltis, 1993) and is united with the Asteridae s.l. by the presence of unitegmic and tenuinucellate ovules. Our results, with greater sampling within the Asteridae s.l., differ from those of Morgan & Soltis (1993) in identifying *Ilex* and *Phyllonoma* as sister taxa (Fig. 7A, B). However, Morgan & Soltis (1993) emphasize that *Helwingia* and *Phyllonoma* share the unusual feature of epiphyllous inflorescences, suggesting that they may be more closely related than either is to *Ilex*.

(5) **Apiales.** This clade comprises representatives of the families Pittosporaceae, Araliaceae, Apiaceae, and *Griselinia* (Cornaceae), all formerly placed in the Rosidae. The Araliaceae and Apiaceae long have been recognized as closely related, and Dahlgren (1980) recognized the association of Pittosporaceae with the Apiales. Anderberg (1992) identified a monophyletic Apiales–Pittosporaceae in his morphology-based analysis of the Ericales and related families, whereas Hufford (1992) found no support for this union in his morphology-based analysis. The representatives of the Apiaceae included here form a monophyletic group (but see Plunkett et al., 1992), whereas *Pittosporum* and the representatives of the Araliaceae form an unresolved polychotomy with the Apiaceae. *Griselinia* is basal within this clade and represents one of several taxa formerly associated with the Cornaceae, but here found associated with various groups of Asteridae (see below and Morgan & Soltis, 1993).

(6) **Dipsacales.** This clade matches the order as circumscribed by Cronquist (1981). Within the order, *Sambucus* and *Adoxa* form a clade and *Dipsacus*, *Valeriana*, and *Symphoricarpos* form a clade. *Viburnum* forms a trichotomy with the other two clades. The Caprifoliaceae, as classically circumscribed (represented here by *Symphoricarpos*, *Viburnum*, and *Sambucus*), appear to be a paraphyletic, ancestral grade within the Dipsacales. Downie & Palmer (1992) did not identify a monophyletic Dipsacales; *Viburnum* and *Sambucus* occurred with the Asterales s.l. and the rest of the order with the Apiales (*Adoxa* was not included in their study). *Berzelia* (Bruniaceae, Rosales) occurs as the basal branch of this clade in island-2,784 (Figs. 1B, 2), but is unresolved at the base of a clade comprising the Dipsacales, Asterales s.l., and Apiales in island-102 (Fig. 1A) and in the Astera-

les–Dipsacales–Apiales analysis (Fig. 7). See Donoghue et al. (1992) for further discussion.

(7) **Asterales s.l.** This clade comprises the orders Asterales, Campanulales, and Calycerales, as well as the Menyanthaceae (Solanales), and *Corokia* (Cornaceae). In the analysis of 105 sequences of the Asteridae s.l., the Campanulaceae, Goodeniaceae, and Calyceraceae together form the sister group to the Asteraceae, whereas with greater sampling in the Asterales s.l., only the Goodeniaceae and Calyceraceae form the sister group (in agreement with "Search II" of Chase et al., 1993, and Michaels et al., 1993) with the Campanulaceae forming the basal lineage within the clade (Fig. 7). The very long terminal branch of *Campanula* (Fig. 2), when included in an analysis without the closely related sequence *Lobelia* (e.g., Fig. 1), raises the possibility of artifactual placement due to long-branch attraction (Felsenstein, 1978). When *Lobelia* also is included (Fig. 7), the long-branch problem is lessened. The Asterales s.l. have been the subject of extensive *rbc*L sequence analysis (Kim et al., 1992; Michaels et al., 1993). Michaels et al. (1993) report a detailed analysis of this group in which the Campanulaceae are excluded from both the sister clade of the Asteraceae (bootstrap value—86% and decay index—four steps) and from the clade comprising the Asteraceae and its sister group (84%, four steps). A bootstrap analysis was performed on the 43-sequence data set used in this study with similar results (Fig. 7A). The fact that "Search I" of Chase et al. (1993) included both *Campanula* and *Lobelia* in the sister group to the Asteraceae indicates that "Search I" probably did not reach maximum parsimony for this clade. Anderberg's (1992) morphological analysis identified the Campanulaceae as sister group to the Asteraceae, with the Goodeniaceae–Calyceraceae as the next branch. The association of the Menyanthaceae with the Asterales was not predicted by conventional classifications, but was identified by Olmstead et al. (1992) based on *rbc*L sequences and by Downie & Palmer (1992) based on analysis of cpDNA inverted repeat restriction sites, and has now been accepted by Thorne (1992). See Michaels et al. (1993) for further discussion. *Escallonia* (Grossulariaceae, Rosales) occurs as the basal branch of this clade in island-102 (Fig. 1A), but is unresolved at the base of a large clade comprising the Asterales s.l., Apiales, Dipsacales, and Lamiidae (sensu Takhtajan, 1987) in island-2,784 (Figs. 1B, 2) and island-5,568 (not shown).

(8) **Gentianales.** This clade comprises the Apocynaceae, Asclepiadaceae, Gentianaceae, Loganiaceae, and Rubiaceae. Of recent classifications, Thorne's (1992) is the only one fully in accord with this circumscription. Others have included Oleaceae and Menyanthaceae (in superorder Gentiananae; Dahlgren, 1980; Takhtajan, 1987), or excluded Rubiaceae (Cronquist, 1981). The monophyly of this group is supported by the analysis of restriction site variation in the cpDNA inverted repeat (Downie & Palmer, 1992). Within the clade, the representatives of the Rubiaceae and Apocynaceae s.l. (including the Asclepiadaceae) each form monophyletic groups, as does a group containing representatives of the Gentianaceae and two members of the Loganiaceae (*Anthocleista* and *Fagraea*). The Loganiaceae represent a heterogeneous assemblage, with members in several lineages of the Gentianales (Bremer & Struwe, 1992).

A comparison of the results of the analysis of the Asteridae s.l. data set with those of the Lamiidae data set reveals an interesting and possibly common artifact of analysis when a sequence generating a long terminal branch is included (as with *Campanula* above). In the analysis with fewer Gentianales (Figs. 1, 2), *Gentiana* is basal, with *Gelsemium* next, then *Apocynum*, and *Pentas* and *Spigelia* are terminal. *Pentas* (Rubiaceae) has a very long terminal branch (Figs. 2, 10). In the analysis with 13 Gentianales included (Figs. 5, 6), almost the exact reverse order is obtained with Rubiaceae basal (Rubiaceae is also basal in Downie & Palmer, 1992). A possible explanation for this difference is that in the analysis with fewer sequences, spurious similarity between one of the terminal taxa (*Gentiana*) and the sister group "pulled" that sequence to the base of the clade. Homologous similarity within the clade then resulted in a reverse branching order. In other words, the branching topology within the clade remains essentially the same, but the clade attaches to the rest of the tree at a different point. Adding more sequences along each lineage in the clade (e.g., including *Chiococca* in the Rubiaceae) increases the probability that parsimony analysis will correctly interpret homology, resulting in the correct attachment of the clade to the tree. A local analysis of the Gentianales was conducted to examine internal support within the clade. The 13 representatives of the Gentianales were included with seven outgroups (*Garrya*, *Eucommia*, *Nicotiana*, *Heliotropium*, *Antirrhinum*, *Catalpa*, and *Ligustrum*) and bootstrap and decay analyses were conducted. Seven equally parsimonious trees were found (Fig. 10), with the majority rule consensus tree and bootstrap majority rule consensus trees having the same topology as in Figures 5 and 6. The results support groups representing the Gentianaceae,

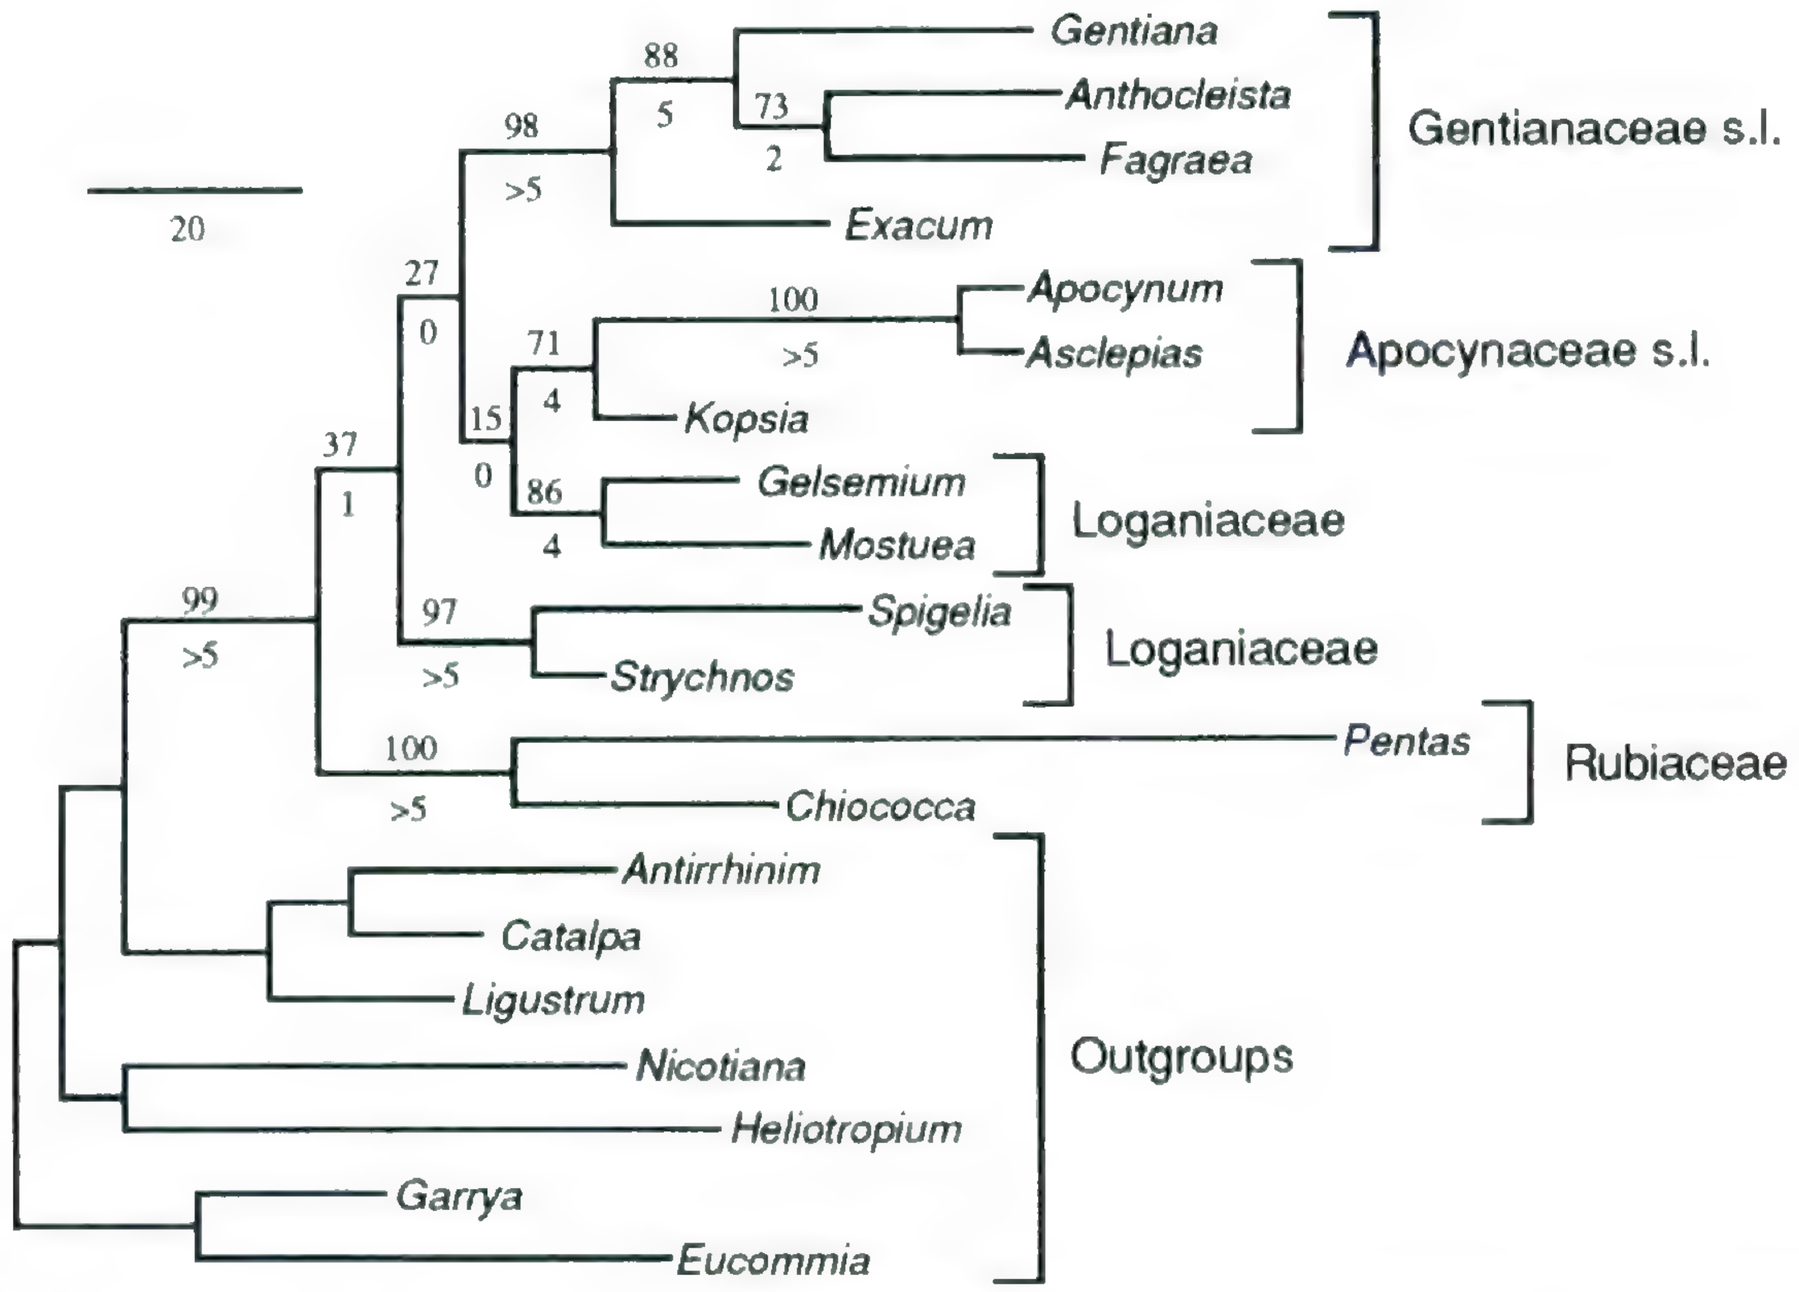

FIGURE 10. Majority-rule consensus of seven equal-length trees of the Gentianales based on *rbc*L sequences and rooted using seven outgroups from the Solanales, Boraginales, Lamiales s.l., and the *Garrya* clade. This tree is equivalent to the topology found in the analysis of the entire Lamiidae data set (Fig. 5) and represents the bootstrap majority-rule consensus. Internal support for groups within the Gentianales is indicated by branch lengths proportional to the scale bar in the upper left and by bootstrap values above and decay indices below internodes subtending clades. A decay index of zero indicates the node collapses in the strict consensus of the seven trees.

Apocynaceae s.l., Rubiaceae, and two separate groups of Loganiaceae (*Gelsemium–Mostuea* and *Spigelia–Strychnos*), but provide little support for any internal groupings.

(9) **Solanales.** This clade is comprised of the Convolvulaceae, Solanaceae, and *Montinia* (Grossulariaceae). Comparable groups exist in the classifications of Dahlgren (1980) and Thorne (1992), except for the inclusion of the Polemoniaceae by Dahlgren (1980). Both Takhtajan (1987) and Thorne (1992) included the Polemoniaceae in a more inclusive group with the Solanales and Boraginales. *Montinia*, not previously suggested to belong to this group on the basis of conventional characters, is basal to the Solanaceae and Convolvulaceae (see below and Morgan & Soltis, 1993). The Solanales and Boraginales form a clade in most analyses, but in island-5,568 (not shown) the Solanales are sister to a clade comprising the Boraginales and Gentianales.

(10) **Boraginales.** This clade comprises the Hydrophyllaceae and Boraginaceae. Groups comparable to this exist in most recent angiosperm treatments (Dahlgren, 1980; Takhtajan, 1987; Thorne, 1992; but not Cronquist, 1981). With the limited sampling currently available, the Boraginaceae appear paraphyletic and the Hydrophyllaceae a monophyletic derivative from them. However, the putatively primitive borages in the woody subfamilies Ehretioideae and Cordioideae have not been sampled for *rbc*L sequences. The Boraginales are sister group to the Solanales in most analyses reported here and in the analyses of Olmstead et al. (1992) and Chase et al. (1993), but are sister group to the Gentianales in island-5,568 (not shown).

(11) **Lamiales s.l.** This clade is comprised of the orders Scrophulariales, Lamiales, and Callitrichales, as well as *Byblis* (Byblidaceae, Rosales) and was recognized by Olmstead et al. (1992) and Downie & Palmer (1992) as monophyletic. This group is recognized by Dahlgren (1980), Takhtajan (1987), and Thorne (1992), but all three treatments maintain a distinction between the Lamiales s.s. and the Scrophulariales. As was pointed out previously (Olmstead et al., 1992), the Scrophulariales are not a monophyletic group. In addition, results presented here (Fig. 5) and results of current work (Wagstaff & Olmstead, unpublished data) suggest that the Lamiales s.s. also may not be monophyletic. Therefore, it seems appropriate not to subdivide this group at present. *Buddleja* and *Nicodemia* have been considered congeneric and placed either in the Buddlejaceae (e.g., Cronquist, 1981) or Loganiaceae (e.g., Mabberley, 1987). In

this analysis, they both clearly belong in the Lamiales s.l. rather than the Gentianales, but the two sequences do not appear to be closely related. Likewise, the Oleaceae have been placed either in the Scrophulariales (e.g., Cronquist, 1981), Gentianales (e.g., Stebbins, 1974), or in their own order, Oleales, allied with the Gentianales (Dahlgren, 1980; Takhtajan, 1987). Based on this *rbc*L analysis the Oleaceae appear to be the basal branch of the Lamiales s.l.

As with the ericalean clade, the strict consensus of the two islands discovered in the analysis of the Lamiidae reveals little resolution within the Lamiales s.l. However, unlike the ericalean clade, where there is little resolution within either island, in this group each island exhibits substantial resolution with particular sequences or small groups occurring in very different places in the two islands. This clade is more densely sampled than most other clades in the Asteridae s.l. Most of the groups that are congruent between islands consist of multiple representatives of large families, including the Acanthaceae, Scrophulariaceae, and Labiatae s.l. The Lamiales s.s. (Labiatae and Verbenaceae) may not be a monophyletic group, as was suggested previously based on a more limited sampling of *rbc*L sequences (Olmstead et al., 1992). Most of the representatives of the Lamiales s.s. form a monophyletic group with no clear distinction between the traditional Labiatae and Verbenaceae. In this respect the clade closely fits the circumscription of the family first suggested by Junell (1934) and recently revived by Cantino et al. (1992). However, *Verbena*, the sole representative of subfamily Verbenoideae in this analysis, is placed closest to *Nicodemia* in a position removed from the rest of the Lamiales in island-135 (Fig. 5) and basal to them in island-1,350 (Fig. 6A). The Lamiales s.l. are the subject of continuing research (Hedrén et al., in prep.; Scotland & Olmstead, in prep.; Wagstaff & Olmstead, unpublished).

These results are fully congruent with those of Olmstead et al. (1992) for relationships among clades within the Asteridae s.l. However, in that study the Dipsacales and Apiales form a clade and together with the Asterales s.l. form another, more inclusive, clade, whereas in this study relationships among the three groups remain unresolved. A bootstrap analysis (Olmstead et al., 1992) suggested moderately strong support (79%) for the Dipsacales–Apiales clade and weaker support for the Asterales–Dipsacales–Apiales (61%). The results of a bootstrap analysis conducted here (Fig. 7) indicate 11% (not indicated on Fig. 7) and 9% values, respectively, for the same two groups. These much lower values reflect the much greater taxon sampling density of this study (see Olmstead et al., 1992, for discussion of this effect). The Asterales–Dipsacales–Apiales clade also is found in both analyses of Chase et al. (1993). Differences in sampling and search strategies may account for the different results obtained in the three studies. A clade comprising the Dipsacales and Apiales minus *Viburnum* and *Sambucus* was found by Downie & Palmer (1992), but their study did not support a united Asterales–Dipsacales–Apiales. No clade comprising any combination of these groups was found by Hufford (1992).

The last four clades, Gentianales, Solanales, Boraginales, and Lamiales s.l., together form the only higher-order clade that is congruent between all three islands. These orders form Takhtajan's (1987) subclass Lamiidae. This group is one of the most strongly supported clades in bootstrap analyses of *rbc*L data (94%—Olmstead et al., 1992; 94%—Morgan & Soltis, 1993) and also was identified in the cpDNA inverted repeat restriction site analysis of Downie & Palmer (1992). Relationships among the four primary clades within the Lamiidae remain unresolved in Olmstead et al. (1992), Downie & Palmer (1992), and in the strict consensus of the 3,900 trees found in "Search II" of Chase et al. (1993). In the analysis of the Asteridae s.l., the Lamiales s.l. are basal in island-2,784 (Figs. 1B, 2) and island-5,568 (not shown), whereas a clade comprising the Solanales and Boraginales is basal in island-102 (Fig. 1A). In the Lamiidae analysis, with greater sampling within the group, the Solanales–Boraginales appear basal in both islands found. However, the strength of the latter conclusion is weakened by the reduced outgroup sampling in that analysis. Morgan & Soltis (1993), including a sequence for the saxifragaceous genus *Vahlia* at the base of the Lamiales s.l., identify the Gentianales as the basal branch within the Lamiidae.

The analyses of Chase et al. (1993) and the inverted repeat restriction site analysis of Downie & Palmer (1992) identify the *Garrya* clade as the sister group to the Lamiidae. That result also was obtained in island-102 and both of the shortest islands resulting from the analysis of the Lamiidae data set. However, island-2,784, island-5,568, and both of the islands one step longer than the shortest in the Lamiidae analysis do not support the sister group relationship between the Lamiidae and the *Garrya* clade.

"Search II" of Chase et al. (1993) identified the small clade of *Dillenia* and *Vitis* as sister group to the Asteridae s.l., but our results suggest that the sister group is a large clade comprising most

of the Rosidae and Dilleniidae (including *Dillenia* and *Vitis*). That this relationship remains uncertain is indicated by the short internode length between the divergence of this small branch from the main lineage of the Rosidae and in adjacent internodes (Fig. 4). Thus, the question of the sister group to the Asteridae s.l. remains unresolved, but the conclusion that this clade originated relatively early in the diversification of the higher dicots (Olmstead et al., 1992) is supported here and in the analyses of Chase et al. (1993).

These results and those of Olmstead et al. (1992) both leave the base of the Asteridae s.l. unresolved. Island-102 in this study identified the Lamiidae and *Garrya* clades as the basal branch, whereas island-2,784 and island-5,568 were unresolved at the base, with either the Cornales or the Cornales–ericalean groups as possible basal branches. The analyses of Chase et al. (1993) identify the Cornales as basal within the Asteridae s.l. and the ericalean clade the next branch. The cpDNA inverted repeat restriction site study of Downie & Palmer (1992) identified the ericalean group as basal, then the Dipsacales–Apiales, Asterales s.l., Cornales, and Lamiidae, but their study had few representatives of the ericalean group (Polemoniaceae and Fouquieriaceae) and fewer outgroups. Hufford (1992) identified three solitary families as individual basal branches (Bruniaceae, Alseuosmiaceae—not included in *rbc*L analyses, and Escalloniaceae), then the Cornales, ericalean group, and the traditional Asteridae. Anderberg (1992) identified the ericalean group as basal, with no resolution among the remaining groups, but his study also suffered from extremely limited outgroup sampling, which compromises any conclusions at this level.

These results represent a detailed, but by no means exhaustive, search for optimal solutions to the *rbc*L phylogeny of the Asteridae s.l. Our two-tiered approach of broadly sampling the entire Asteridae s.l. and sampling more densely within recognized clades offers opportunities to explore patterns of relationship in greater detail at various levels. The discovery of multiple islands in each of the subsets of the data in which a search for islands was conducted indicates that analysis of *rbc*L data (and probably most large complex DNA sequence data sets) must include an appropriate search strategy for finding multiple islands. The presence of multiple islands, which, by their nature, imply different patterns of relationship, indicates that the *rbc*L data by themselves cannot resolve relationships at all levels within the Asteridae s.l. Congruence between analyses at different hierarchical levels is encouraging, although it does not in any sense constitute a test of the results found in one analysis, because the same data form the basis for all analyses. In contrast, incongruence between analyses at different levels (e.g., the inverted topology of the Gentianales in one analysis relative to another) demands an explanation.

In addition to the two-tiered hierarchical analyses reported here for the Asteridae s.l., the analyses of Chase et al. (1993) present a third tier available for comparison (i.e., angiosperms and seed plants). The same 11 primary clades identified here in the Asteridae s.l. are identified in that analysis. However, the pattern of relationships among primary lineages within the Asteridae s.l. implied by the analyses of Chase et al. (1993) is incongruent with each island found in the analysis of the Asteridae s.l. data set. Two important differences exist between these analyses: (1) the analyses of Chase et al. (1993) have greater sampling of ingroup and outgroup sequences in a single analysis, and (2) the smaller data sets used in this study were analyzed more fully for shortest trees and multiple islands. During the search for multiple islands in the Asteridae s.l., each search became "stuck" for a long time on a plateau of trees longer than was ultimately found by that search. In one search, a plateau three steps longer was searched with over 4,600 trees found at that length; the consensus tree was congruent with the results reported by Chase et al. (1993) for the Asteridae s.l. The seed plant analysis was conducted with NNI swapping and a ceiling of 3,900 trees, of which only three were examined with TBR swapping and with MULPARS off. This search strategy is unlikely to enable one to get off a plateau such as those encountered in our searches. This suggests that, as was explicitly admitted in Chase et al. (1993) for their broad analyses in general, their results may represent a suboptimal plateau with respect to the Asteridae s.l.

## CONGRUENCE WITH CONVENTIONAL CHARACTERS

The identification of biological traits, other than nucleic acid bases at particular positions in a DNA sequence, which are congruent with the results of a DNA sequencing study, provides potential synapomorphies and important validation for groupings suggested by the molecular analysis. The *rbc*L analysis of the Asteridae offers the opportunity to examine some of the critical characters that have been used in traditional classifications.

The most visible feature commonly associated with the Asteridae is the sympetalous corolla. It

formed the basis for a major group of dicots, the Gamopetalae (de Candolle, 1813), in early classifications. Many families characterized by sympetaly, which have been segregated into different subclasses in many recent classifications (e.g., Cronquist, 1981), are reunited in the *rbc*L tree in the clade designated Asteridae s.l. The *rbc*L tree, however, includes several polypetalous groups, including the Cornales (as broadly defined by Cronquist, with representatives found in several clades), Apiales, Grossulariaceae (*Escallonia* and *Phyllonoma*), Hydrangeaceae, and Pittosporaceae (*Pittosporum*). The distribution of these polypetalous taxa on the *rbc*L tree makes problematic the interpretation of the origin of sympetaly. The Cornales and the *Garrya* clade are the only groups of the 11 discussed above that are consistently polypetalous. Polypetalous groups are basal to otherwise predominantly sympetalous groups in many important clades. For examples of this pattern note *Corokia* with the Asterales s.l., *Vahlia* with the Lamiales s.l. (see Morgan & Soltis, 1993), and *Berzelia* with the Dipsacales. A few sequences represent families in which both sympetaly and polypetaly occur (e.g., *Camellia*—Theaceae, *Berzelia*—Bruniaceae). Some polypetalous taxa (e.g., *Sarracenia* and *Montinia*) are embedded within sympetalous clades (e.g., Ericales and Solanales, respectively). Hufford (1992) considered sympetaly to be a synapomorphy for his Cornifloraeasterid group (comparable to our Asteridae s.l.) exclusive of Bruniaceae (*Berzelia* in our study).

One possible explanation for the observed pattern of corolla fusion is that the Asteridae s.l. originally diversified as a polypetalous clade with subsequent evolution of sympetaly in several lineages. In this scenario, the polypetalous taxa near the base of many clades represent plesiomorphic relicts. However, an alternative hypothesis may be that sympetaly evolved early in the Asteridae s.l. and, during the early diversification of the clade, corolla fusion remained a developmentally labile trait before becoming rigidly canalized (Donoghue, 1989; Olmstead et al., 1992). In this scenario, polypetalous taxa represent the occasional reversion to polypetaly and would be expected to be found primarily near the base of clades. The pattern of corolla development in some groups (e.g., Apiales, Erbar, 1991) suggests that reversal from sympetaly to polypetaly has occurred (Olmstead et al., 1992). This is an example of an area in which morphology deserves renewed investigation as a result of hypotheses derived from a molecular cladogram. The distribution of corolla fusion among the groups and the existence of tree islands make difficult any assessment of corolla evolution. It appears that multiple origins are likely, but that some reversals may have occurred as well.

The presence of tenuinucellate ovules with a single integument has been associated with the Asteridae s.s. (e.g., Cronquist, 1981), but has many exceptions outside the narrow circumscription of the Asteridae. However, the broadly circumscribed Asteridae s.l. encompass the large majority of those exceptions. A single integument (the result of fusion or loss of one integument) characterizes nearly all groups in the Asteridae s.l., except some members of the ericalean clade (e.g., Primulales and some Ebenales). The tenuinucellate condition generally is considered to be derived from the crassinucellate condition in angiosperms and also characterizes most members of the Asteridae s.l.; exceptions include the *Garrya* clade and the Cornaceae and relatives (but not the Hydrangeaceae). The trait "crassinucellate ovule" encompasses a wide range of expression (Davis, 1966; Young & Watson, 1970) and is apparently derived from tenuinucellate ancestors where it occurs in the Asteridae s.l. Hufford (1992) identified single integument as a synapomorphy for his Cornifloraeasterid group and tenuinucellate ovules as a synapomorphy to the same group exclusive of the Bruniaceae.

The distribution of iridoid compounds has influenced heavily the classification of Dahlgren (1980), and the presence/absence of iridoids led Jensen et al. (1975) to reject the traditional Asteridae "as a natural group." Most discussions of the systematic significance of iridoids rely on their evolutionarily derived condition and the implication that the iridoids identify a monophyletic group (e.g., Jensen, 1992). This leads to conflicts with groupings based on other characters. The distribution of iridoids in the Asteridae s.l. suggests that iridoids form a synapomorphy for the entire clade comprising the Asteridae s.l. The distribution of iridoids in the ericalean clade combined with the lack of resolution in that clade makes it difficult to assess the basal state for the clade with respect to iridoids. The pattern of relationships depicted in island-2,784 (Figs. 1B, 2) includes the possibility that the ericalean clade is basal within the Asteridae, thereby leaving open the possibility that if that clade is non-iridoid-containing at its base then iridoids may have evolved twice in the Asteridae s.l. However, it seems that the presence of iridoids is the basal condition in the Asteridae s.l. and the absence of iridoids is best interpreted as losses in several lineages, including the Primulales, Ebenales and relatives (within the ericalean clade), the Apiales, the Campanulaceae (Asterales s.l.), the Asteraceae, and

the Solanales. Additional losses within the Asteridae s.l. are known (e.g., within the Gesneriaceae and Labiatae subfam. Nepetoideae). The presence of simple iridoids in some members of the Hamamelidae (e.g., *Liquidambar*, *Daphniphyllum*), which exhibit morphological, embryological, and *rbc*L evidence incongruent with a placement in the Asteridae s.l., suggests that iridoids have evolved more than once.

The distribution of iridoids in plants has proven to be problematic for systematics, but as phylogenetic hypotheses become more refined, the distribution of iridoids and other secondary compounds may make more sense. For example, Jensen (1992) presented an apparent contradiction in the Oleaceae, which contain both seco-iridoids (grouping them with the Gentianales) and verbascosides (grouping them with the Lamiales s.l.). The *rbc*L tree places the Oleaceae at the base of the Lamiales s.l. clade, suggesting that the seco-iridoids are a plesiomorphic trait shared with the Gentianales, whereas the verbascosides are a synapomorphy uniting them with the Scrophulariales and Lamiales.

### PROBLEMS MERITING FURTHER INVESTIGATION

The *rbc*L tree of the Asteridae s.l. suggests several unexpected groups that merit further investigation. For example, *Polemonium* (Polemoniaceae, Asteridae) is grouped (e.g., Fig. 1A) with *Diapensia* (Diapensiaceae, Dilleniidae). These two taxa share many characters, including fused, pentamerous perianths, three fused carpels with numerous ovules, axile placentation, ovules that are unitegmic and tenuicellate, an annular disk at the base of the ovary, and tetrasporangiate anthers opening by longitudinal slits. There are some differences in the secondary compounds reported for the two families, but both are congruent in the absence of iridoids and the presence of calcium oxylate crystals. *Diapensia* differs from *Polemonium* in having a second staminal whorl, a character shared with many members of the Dilleniidae, but in *Diapensia* the whorl opposite the petals is reduced to staminodia. The loss of staminodia in the Diapensiaceae would result in flowers indistinguishable from Polemoniaceae and, based on traditional criteria, assignable to the Asteridae rather than the Dilleniidae (e.g., in the system of Cronquist, 1981). The distribution of the Diapensiaceae is circumboreal at high latitudes, extending into temperate Asia. This suggests that the Polemoniaceae may represent the temperate North American derivatives of the Diapensiaceae.

The clade composed of *Garrya*, *Aucuba*, and *Eucommia* is an unanticipated grouping. However, all three taxa are dioecious and produce the iridoid aucubin. *Garrya* and *Aucuba* have similar pollen and are alike in producing petroselinic acid and in having a single whorl of stamens alternate with the petals (a character shared with the Asteridae s.s. and relatives (e.g., Apiales)). *Eucommia* lacks a corolla, but contains iridoids, has a single integument, and has a gynoecial structure that is virtually identical to that of *Garrya*, a unilocular ovary with two pendulous ovules and two style branches (*Aucuba* also has a unilocular ovule).

In several clades, a single taxon stands apart from the others, with respect to many conventional characters. Two examples are illustrative. *Griselinia* (Cornaceae) is united with the Apiales, but differs in having crassinucellate ovules, iridoids, and a single ovule. *Montinia* is perhaps the most unusual anomaly in this respect. It falls out in the Solanales, from which it differs in many respects (see Morgan & Soltis, 1993). *Griselinia* is basal within its clade, suggesting that its distinctive characters may be either plesiomorphic or autapomorphies not shared with the rest of the clade. *Montinia* appears basal within the Solanales, but embedded well within the Lamiidae, thereby making the case for plesiomorphy more difficult. Cases of anomalous results such as these demand further study, both molecular and morphological, to confirm or reject the placements suggested by these results.

## CONCLUSIONS

The results presented here and elsewhere in this issue (e.g., Xiang et al., 1993) represent another step toward a molecular-based phylogeny for the Asteridae s.l. It is clear from the existence of multiple equally parsimonious solutions, some different enough to belong to different islands using a TBR-swapping, heuristic search strategy, that we still have a long way to go to resolve many important questions. Conclusions that appear to be strong, based on the common occurrence of groups in different islands and in results of analyses at different hierarchical levels or of different data sets (Downie & Palmer, 1992; Hufford, 1992; Anderberg, 1992), include the following. (1) There exists a monophyletic Asteridae s.l. containing some elements not formerly assigned to the Asteridae. (2) The Lamiidae (sensu Takhtajan, 1987) are a monophyletic group comprising four separate clades, the Gentianales, Solanales, Boraginales, and Lamiales s.l. (including the Scrophulariales). (3) Eleven ter-

minal clades are congruent among all trees and all islands, including the four comprising the Lamiidae, the Asterales s.l., Dipsacales, Apiales, Cornales, an ericalean clade (including representatives of the Ebenales, Primulales, etc.), and two small clades herein referred to as the *Garrya* clade and *Ilex* clade. (4) With the exception of the Lamiidae, relationships among these primary lineages remain unresolved. (5) There is substantial resolution within many of these 10 clades (e.g., Apiales, Asterales s.l., Cornales, Dipsacales, Solanales), but not for others (e.g., ericalean clade, Gentianales, Lamiales s.l.). (6) Unitegmic and tenuinucellate ovules appear to be synapomorphies for the Asteridae s.l. (7) Sympetaly and the presence of iridoids also may be basal traits for the Asteridae s.l., but additional resolution is needed to distinguish multiple origins from a single origin with subsequent reversals.

# PHYLOGENETIC RELATIONSHIPS OF *CORNUS* L. SENSU LATO AND PUTATIVE RELATIVES INFERRED FROM *rbc*L SEQUENCE DATA[1]

*Qiu-Yun Xiang, Douglas E. Soltis, David R. Morgan, and Pamela S. Soltis*[2]

## ABSTRACT

A parsimony analysis of 46 *rbc*L sequences was performed to evaluate relationships among *Cornus* and putative relatives, as well as among subgroups within *Cornus*. Our results indicate that *Alangium*, nyssoids (*Nyssa*, *Davidia*, and *Camptotheca*), mastixioids (*Diplopanax* and *Mastixia*), *Curtisia*, and genera of Hydrangeaceae are the closest relatives of *Cornus*. These taxa, plus *Cornus*, constitute a "cornaceous clade," which differs from all previously proposed *Cornus* alliances. Within this cornaceous clade, four major lineages were identified; (i) *Cornus Alangium*, (ii) nyssoids–mastixioids, (iii) *Curtisia*, and (iv) hydrangeoids. The relationships among the four major lineages within the cornaceous clade remain unresolved. Sequence data from *rbc*L also reveal that *Corokia*, *Helwingia*, *Aucuba*, *Garrya*, and *Griselinia*, previously placed in Cornaceae by some authors, are only distantly related to *Cornus* and other members of the cornaceous clade. Four major lineages were identified within *Cornus* by *rbc*L sequence data, but relationships among these groups are incompletely resolved.

Relationships among members of the dogwood family (Cornaceae) have long been problematic due to the morphological diversity of the family. There is, for example, no consensus regarding the circumscription of the family; from 1 to 15 genera have been ascribed to Cornaceae by various authors. The troubled taxonomic history of Cornaceae is briefly reviewed below and summarized in Table 1.

Harms (1898) included 15 genera divided among seven subfamilies in his Cornaceae (Table 1), a treatment that largely followed Hooker (1867). Of these 15 genera, by far the largest and most widespread is *Cornus*, which comprises approximately 45–60 species. Many of the remaining 14 genera are small and/or localized in geographic distribution (Table 2). The considerable debate concerning the composition of Cornaceae is illustrated by the fact that 11 of the 15 genera included in Harms's (1898) Cornaceae have been treated as monotypic families by at least one author based on one or several distinctive morphological features (all original references cited in Takhtajan, 1987, except Chen, 1988): *Davidia* (Li, 1955), *Camptotheca* (Chen, 1988), *Mastixia* (Calestani, 1905), *Aucuba* (Agardh, 1858), *Curtisia* (Takhtajan, 1987), *Garrya* (Lindley, 1834), *Alangium* (de Candolle, 1828), *Melanophylla* (Takhtajan ex Airy Shaw, 1972), *Griselinia* (Takhtajan, 1987), *Helwingia* (Decaisne, 1836), and *Toricellia* (Hu, 1934).

For brevity, we will review only the treatments of Takhtajan (1980, 1987), Cronquist (1981, 1988), and Eyde (1988), because they illustrate well the magnitude of the differences among proposed taxonomic schemes regarding the treatment of Cornaceae and putative relatives. Takhtajan (1980) retained only *Cornus*, *Curtisia*, and *Mastixia* in Cornaceae, placing them in three separate subfamilies (Table 1). Many of the genera originally placed in Cornaceae by Harms (1898) were treated as distinct families and considered to be only distantly related to *Cornus* (e.g., *Corokia*, *Griselinia*, *Helwingia*, *Melanophylla*, *Kaliphora*, and *Toricellia*) by Takhtajan (1980) (Table 1). More re-

[1] We thank G. Plunkett and R. G. Olmstead for providing unpublished sequences; D. E. Boufford, E. Wood, I. Hay, S. Yankowski, P. Goldblatt, S. Brunsfeld, J. Wen, Y.-C. Tang, Z.-H. Ji, K.-Y. Pan, H.-N. Qin, E. K. Cameron, T. Edwards, E. G. H. Oliver, B. H. Macmillan, A. H. M. Jayasuriya, Arnold Arboretum, U. S. National Arboretum, Strybing Arboretum, Missouri Botanical Garden, and The Royal Botanical Gardens, Kew, England, for help in obtaining leaf material; and R. Olmstead and M. Chase for helpful comments regarding data analysis. This project was supported by NSF grant BSR 9007614, a WSU travel grant, and grants from Sigma Xi, the American Society of Plant Taxonomists, and the Northwest Scientific Association.

TABLE 1. Comparison of taxonomic treatments of *Cornus* and putative relatives. Genera are not listed under monotypic families and subfamilies. An asterisk (*) indicates a family or an order that contains several genera or families, but only the genus or family listed has been considered a *Cornus* relative by some taxonomists. Hutchinson (1967) and Takhtajan (1987) divided *Cornus* into six segregate genera; for simplicity, only *Cornus* is listed below in their treatments.

| Harms (1898) | Wangerin (1910) | Hutchinson (1967) | Takhtajan (1980) | Cronquist (1981) | Takhtajan (1987) | Eyde (1988) |
|---|---|---|---|---|---|---|
| Cornaceae | Garryaceae | Araliales | Saxifragales* | Cornales | Hydrangeales* | Cornaceae |
| Garryoideae | Nyssaceae | Cornaceae | Escalloniaceae* | Alangiaceae | Argophyllaceae* | Nyssoideae |
| Nyssoideae | *Nyssa* | *Aucuba* | *Corokia* | Nyssaceae | *Corokia* | *Nyssa* |
| *Nyssa* | *Camptotheca* | *Cornus* | | *Nyssa* | Griseliniaceae | *Camptotheca* |
| *Camptotheca* | *Davidia* | *Corokia* | Cornales | *Camptotheca* | Melanophyllaceae | *Davidia* |
| Davidioideae | Alangiaceae | *Curtisia* | Davidiaceae | *Davidia* | *Melanophylla* | Mastixioideae |
| Alangioideae | Cornaceae | *Griselinia* | Nyssaceae | Cornaceae | *Kaliphora* | Cornoideae |
| Mastixioideae | Mastixioideae | *Kaliphora* | *Nyssa* | *Aralidium* | | |
| Curtisioideae | Curtisioideae | *Melanophylla* | *Camptotheca* | *Aucuba* | Cornales | |
| Cornoideae | Cornoideae | *Toricellia* | Alangiaceae | *Cornus* | Davidiaceae | |
| *Aucuba* | *Aucuba* | Alangiaceae | Cornaceae | *Corokia* | Nyssaceae | |
| *Cornus* | *Cornus* | Garryaceae | Cornoideae | *Curtisia* | *Nyssa* | |
| *Corokia* | *Corokia* | Nyssaceae | Curtisioideae | *Griselinia* | *Camptotheca* | |
| *Griselinia* | *Griselinia* | *Nyssa* | Mastixioideae | *Helwingia* | Cornaceae | |
| *Helwingia* | *Helwingia* | *Camptotheca* | Aucubaceae | *Kaliphora* | Curtisiaceae | |
| *Kaliphora* | *Kaliphora* | *Davidia* | Garryaceae | *Mastixia* | Mastixiaceae | |
| *Melanophylla* | *Melanophylla* | Araliaceae* | Melanophyllaceae | *Melanophylla* | Aucubaceae | |
| *Toricellia* | *Toricellia* | *Helwingia* | *Melanophylla* | *Toricellia* | Garryaceae | |
| | | Caprifoliaceae | *Kaliphora*? | Garryaceae | Alangiaceae | |
| | | | Griseliniaceae | | Aralidiales | |
| | | | Toricelliaceae | | Toricelliales | |
| | | | Helwingiaceae | | Apiales* | |
| | | | | | Helwingiaceae | |

cently, Takhtajan (1987) removed *Curtisia* and *Mastixia* from Cornaceae and recognized them as monotypic families (Table 1). However, he still considered these two genera close allies of *Cornus* and members of his Cornales.

Cronquist (1981), in contrast, retained a broader view of Cornaceae than Takhtajan (Table 1). Cronquist (1981) closely followed the treatment of Wangerin (1910) (Table 1), but added *Aralidium* to Cornaceae. Cronquist (1988) later added the nyssoids (*Nyssa*, *Davidia*, and *Camptotheca*) to Cornaceae following Eyde (1988) and included all of Harms's (1898) genera except *Alangium* and *Garrya* in his Cornaceae. He argued against dividing Cornaceae into a number of small or monotypic families as done by Takhtajan.

Attempting to synthesize all available evidence, Eyde (1988) considered the Cornaceae to consist of *Cornus*, nyssoids, and mastixioids (modern *Mastixia* and its fossil allies) (Table 1). Eyde also proposed that mastixioids may be the closest relatives of *Cornus* based primarily on a single shared trait: a two-armed surface hair formed from a single cell. The delimitation of Cornaceae became even less clear with the recent addition of *Diplopanax* to Cornaceae (Eyde & Xiang, 1990). *Diplopanax*, which consists of a single species (*D. stachyanthus* Hand.-Mazz.) occurring rarely in southern China and northern Vietnam, was previously placed in Araliaceae (Handel-Mazzetti, 1933).

Not only do concepts of Cornaceae vary greatly, but there is considerable disagreement regarding the closest relatives of *Cornus*. Different lines of evidence have suggested a wide array of closest relatives for *Cornus* (Table 3). Evidence from embryology, for example, suggests that *Alangium* is the closest ally of *Cornus* (Chopra & Kaur, 1965), whereas chromosome numbers suggest that *Nyssa*, *Davidia*, *Mastixia*, and *Garrya* are also close relatives of *Cornus* (Goldblatt, 1978). Seed structure (germination valves) provides a still different picture, suggesting a close relationship among *Cornus*, *Mastixia*, *Diplopanax*, *Nyssa*, and *Davidia* (Eyde, 1963, 1988; Eyde & Xiang, 1990). Evidence from palynology, wood anatomy, serology, secondary chemistry, and fatty acid chemistry each suggests a different suite of close relatives for *Cornus* (Table 3; Bate-Smith et al., 1975; Breuer et al., 1987; Fairbrothers & Johnson, 1964; Ferguson, 1977; Ferguson & Hideux, 1980; Li & Chao, 1954).

The taxonomic complexity of Cornaceae is further compounded by the extreme polymorphism of *Cornus*. Wangerin (1910) classified the genus into seven subgenera (Table 4) using primarily the morphology of the inflorescence, bracts, and fruits.

TABLE 2. Geographic distribution and species composition of *Cornus* and putatively related genera.

| | |
|---|---|
| *Alangium* | ca. 20 spp., mostly in Asia, a few in Polynesia, New Guinea, subtropical Australia, tropical Africa, Madagascar, Comoro Islands. |
| *Aralidium* | 3 spp., Malaya. |
| *Aucuba* | 3–11 spp., eastern Himalayas to Japan. |
| *Camptotheca* | 1 sp., southwestern and south-central China. |
| *Cornus* | ca. 45 to 60 spp., mostly in eastern Asia and North America, a few in Europe, 1 in Central America, 2 in South America, and 1 in tropical Africa. |
| *Corokia* | 6 or 7 spp., South Pacific islands. |
| *Curtisia* | 2 sp., southern Africa. |
| *Davidia* | 1 sp., southwestern China and western Hupei of China. |
| *Diplopanax* | 1 sp., southern China and northern Vietnam. |
| *Garrya* | 14 spp., southwestern United States, Mexico, West Indies. |
| *Griselinia* | 6 spp., New Zealand, Chile, and Brazil. |
| *Helwingia* | 3 spp., Himalayas to Japan. |
| *Kaliphora* | 1 sp., Madagascar. |
| *Mastixia* | 13 spp., southeastern Asia and western Pacific. |
| *Melanophylla* | 9 spp., Madagascar. |
| *Nyssa* | 7 spp., eastern Asia, eastern North America, northern Mexico. |
| *Toricellia* | 2 or 3 spp., eastern Himalayas and southwestern China. |

Wangerin's view of *Cornus* has been largely followed by most modern investigators (Eyde, 1987; Ferguson, 1966; Xiang, 1987). In contrast, *Cornus* has been divided by some into as many as six genera (Table 5; Hutchinson, 1942, 1967; Pojarkova, 1950). The complex history of this problem and the nomenclatural changes involved have been reviewed by Eyde (1987) and Ferguson (1966).

Phylogenetic relationships among species groups within *Cornus* have also been debated. *Cornus* can be roughly divided into four groups: big-bracted dogwoods, dwarf dogwoods, cornelian cherries, and bractless dogwoods. Emphasizing the distribution of iridoids, Bate-Smith et al. (1975) proposed that the big-bracted dogwoods are the most primitive species of *Cornus* and the bractless dogwoods are the most advanced. This view is supported by evidence from wood anatomy (Adams, 1949; Li & Chao, 1954) and floral anatomy (Wilkinson, 1944). Dermen (1932) proposed that based on chromo-

TABLE 3. Close relatives of *Cornus* as suggested by eight different lines of morphological, anatomical, karyological, and chemical evidence.

| Characters | Suggested close relatives |
|---|---|
| Cytology | *Nyssa*, *Davidia*, *Mastixia*, and *Garrya* (Goldblatt, 1978) |
| Pollen morphology | *Curtisia*, *Mastixia*, *Nyssa*, *Davidia*, and *Camptotheca* (Eramyan, 1971; Ferguson, 1977; Ferguson & Hideux, 1980; Eyde, 1988; Reitsma, 1970) |
| Floral anatomy | *Nyssa*, *Davidia*, *Mastixia*, and *Toricellia* (Eyde, 1967, 1988) |
| Fruit morphology | *Mastixia*, *Diplopanax*, *Nyssa*, and *Davidia* (Eyde, 1963, 1988) |
| Embryology | *Alangium* (Chopra & Kaur, 1965) |
| Wood anatomy | *Corokia*, *Helwingia*, *Schefflera*, *Nyssa*, *Garrya*, *Mastixia*, *Viburnum*, and *Griselinia* (Li & Chao, 1954) |
| Secondary metabolic products | *Mastixia*, *Curtisia*, and *Davidia* (Bate-Smith et al., 1975) |
| Fatty acid chemistry | *Curtisia*, *Mastixia*, and *Corokia* (Breuer et al., 1987) |

some numbers and sizes, the cornelian cherry group is basal within *Cornus*. Eyde (1988), in contrast, proposed that the genus early diverged into two main lineages, a bracted (or red-fruited) line in which the inflorescence has basal bracts, and a bractless (or blue- or white-fruited) line in which the bracts are rudimentary or lacking. The bracted line includes the big-bracted dogwoods, dwarf dogwoods, and the cornelian cherries. Using morphological characters and evidence from fossils and embryology, Eyde proposed that the bractless dogwoods are ancestral and connect *Cornus* to the nyssoids. He classified *Cornus* into four informal subgroups without giving these groups taxonomic rank: bractless dogwoods, cornelian cherries, big-bracted dogwoods (including the Mexican disciflorous dogwoods), and dwarf dogwoods.

TABLE 4. Intrageneric treatment of *Cornus* proposed by Wangerin (1910): 50 species divided into seven subgenera. All species are woody and have bisexual flowers except those indicated.

| | |
|---|---|
| *Thelycrania* | bractless dogwoods, 36 spp. with spreading cymes. |
| *Afrocrania* | African cornelian cherry, 1 dioecious species, with four small herbaceous bracts subtending an umbel-like cyme. |
| *Macrocarpium* | cornelian cherries, 4 spp. with four herbaceous bracts subtending an umbel-like cyme. |
| *Arctocrania* | dwarf dogwoods, 2 herbaceous spp. with four petaloid bracts subtending a condensed cyme. |
| *Discocrania* | Mexican disciflorous dogwood, 2 spp. with four small, herbaceous, and early deciduous bracts subtending a capitate inflorescence. |
| *Benthamidia* | North American big-bracted dogwoods, 2 spp. with four large petaloid bracts subtending a capitate inflorescence. |
| *Benthamia* | Asian big-bracted dogwoods, 3 spp. with four large petaloid bracts subtending a capitate inflorescence which subsequently develops into a compound fruit. |

From the above review it is apparent that another experimental approach is needed to help unravel the systematic problems posed by Cornaceae. We therefore employed comparative sequencing of *rbc*L with the following objectives: (1) clarify relationships among *Cornus* and putatively related genera, and (2) elucidate evolutionary relationships among the major subgroups within *Cornus*. The advantages of *rbc*L sequencing for addressing phylogenetic questions at this level have been well reviewed (e.g., Clegg & Zurawski, 1992; Palmer et al., 1988).

## MATERIALS AND METHODS

Species included in this study represent the major subgroups of *Cornus* as well as taxa that previously have been considered closely allied with *Cornus* by at least some investigators (e.g., *Cornus alternifolia* L.f., *C. canadensis* L., *C. chinensis* Wangerin, *C. florida* L., *C. kousa* Hance, *C. mas* L., *C. obliqua* Raf., *C. oblonga* Wall., *C. officinalis* Siebold & Zucc., *C. walteri* Wangerin; *Alangium chinense* (Lour.) Harms, *Aucuba japonica* Thunb., *Camptotheca acuminata* Decne., *Corokia cotoneaster* Raoul, *Curtisia dentata* (Burm.f.) G.A.Sm., *Davidia involucrata* Baill., *Diplopanax stachyanthus* Hand.-Mazz., *Garrya elliptica* Douglas ex Lindl., *Griselinia lucida* J.G. Forst, *Helwingia japonica* (Thunb.) F. Dietr., *Mastixia caudatilimba* C.Y. Wu ex Soong, *Nyssa ogeche*

TABLE 5. Comparison of several taxonomic schemes proposed for *Cornus* sensu lato, depicting the magnitude of the discrepancies that exist.

| Strict view | | Broad view | |

Marsh; see Appendix of this issue). The sequence for *Cornus kousa* was provided by R. G. Olmstead (unpublished). These taxa represent the major cast of characters required for a molecular phylogenetic analysis of *Cornus* and putative relatives. It would have been desirable to include in this study several additional genera (*Kaliphora*, *Melanophylla*, *Toricellia*, and *Aralidium*) of which we could not obtain either living or recent herbarium collections due to their rarity and/or geographically restricted distributions (Table 2).

Total DNAs were isolated from leaf tissue following the method of Doyle & Doyle (1987) as modified by Soltis et al. (1991). Double-stranded *rbc*L was amplified using thermostable DNA polymerase provided by either Promega or Epicentre Technologies. Primers used for amplifications are synthetic oligonucleotides. The forward or 5′ primer (Z1) is composed of the first 30 bases of *rbc*L of *Zea mays* L. Two different reverse primers were used. The one used most often (3′*rbc*L) is that of Olmstead et al. (1992), which consists of 34 bp beginning 103 base pairs outside of the terminus of the gene in *Nicotiana*. For *Diplopanax* and *Mastixia*, however, this Z1-3′*rbc*L primer combination did not yield a product so we used an internal reverse primer, a 30-mer beginning at position 1351 of *rbc*L in *Z. mays*.

The double-stranded products subsequently were used as templates, and the forward and reverse primers used individually for single-stranded DNA amplifications. Single-stranded products were precipitated with 20% PEG/2.5M NaCl. DNA pellets were washed once each with 70% and 95% EtOH, dried, and redissolved in TE. DNA sequencing followed the dideoxy method using Sequenase 2.0 enzyme and the Sequenase 3.1 kit (U.S. Biochemical Corp.). Sequencing primers were derived from the *rbc*L sequence of *Z. mays* and kindly provided by G. Zurawski (DNAX Research Institute). Both the forward and reverse strands were sequenced for all taxa.

Twenty-one sequences were generated in this study for *Cornus* and putatively related genera. Twenty-five additional sequences from Saxifragales, Apiales, and Asteridae (Fig. 1, also see Appendix, this issue) were included in a phylogenetic analysis to determine possible alliances of *Cornus*. *Cercidiphyllum* and *Daphniphyllum* (representatives of Hamamelidae) and *Itea*, *Saxifraga*, and *Astilbe* (representatives of Rosidae) served as outgroups for this analysis because they are close to, yet basal to, the taxa included in this broad *rbc*L sequence analysis. The choice of taxa and outgroups for use in our analysis was based on the results of the large phylogenetic analysis of 499 *rbc*L sequences for seed plants (Chase et al., 1993).

For all taxa but *Diplopanax* and *Mastixia*, 1377 bp of *rbc*L sequence data were compared beginning at position 31 and ending at base pair 1407. Due to the amplification strategy required for *Diplopanax* and *Mastixia* (see above), we analyzed 1320 bp for these genera, from position 31 to 1350. All parsimony analyses were conducted with PAUP version 3.0s (Swofford, 1991) using MULPARS and TBR branch-swapping with characters specified as unordered and unweighted. To ensure that all "islands" of shortest trees were found (Maddison, 1991), 100 tree searches were performed each with a different order of taxa addition. A bootstrap analysis using 100 replicates was also conducted to obtain estimates of reliability for each monophyletic group.

## RESULTS

The phylogenetic analysis resulted in 690 most parsimonious trees that were 1,185 steps long, all in one island (Fig. 1). Two major groups can be identified in all of the most parsimonious trees. One

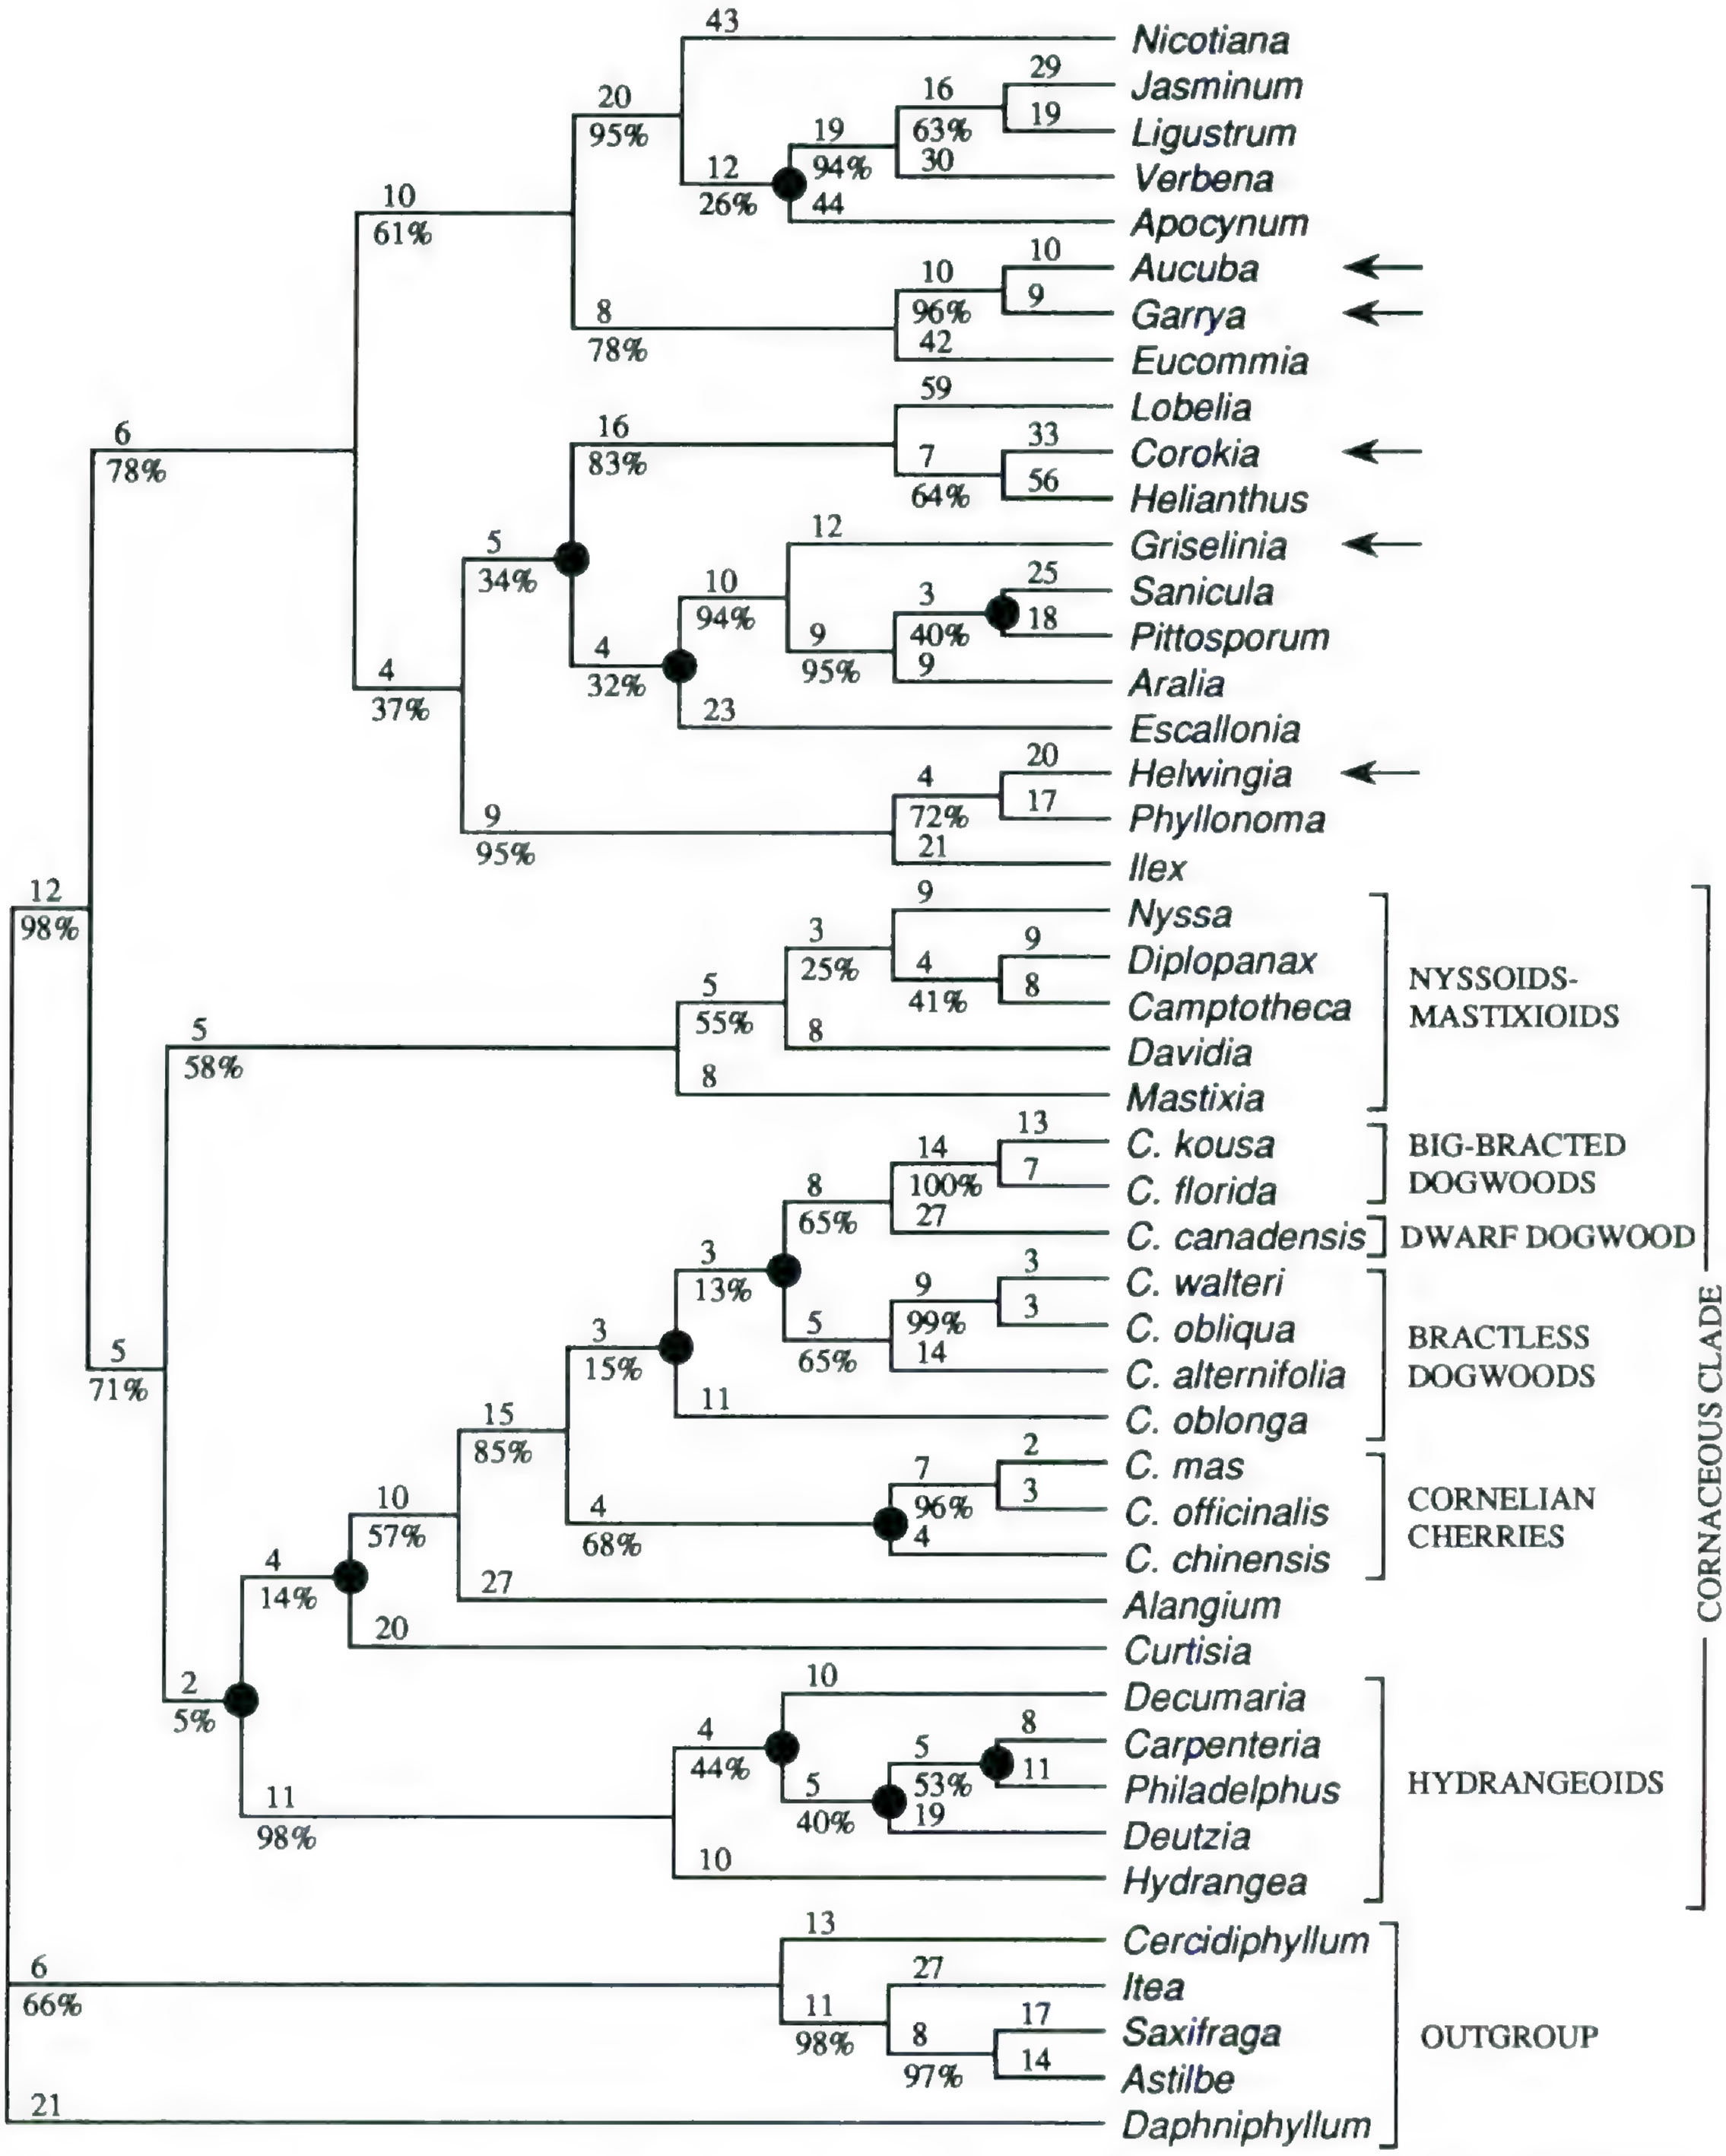

FIGURE 1. The majority-rule consensus tree including all compatible groupings constructed from 690 minimum length trees resulting from parsimony analysis of *rbc*L sequences of Cornaceae and additional taxa. This tree is one of the 690 shortest trees (length = 1,185 steps, consistency index = 0.470, retention index = 0.541). The tree is rooted using representatives from Hamamelidae (*Cercidiphyllum* and *Daphniphyllum*), and Rosidae (*Itea*, *Saxifraga*, and *Astilbe*). Numbers above lines indicate the number of nucleotide substitutions supporting each branch. Numbers below lines indicate the percentage of occurrence of each monophyletic group in the results of 100 bootstrap samples. Nodes that are not present in all 690 most parsimonious trees are indicated by black circles. Arrows indicate taxa outside the cornaceous clade that have been placed in Cornaceae by some investigators. Species of *Cornus* are abbreviated "*C.*"

of these groups comprises *Cornus*, *Alangium*, *Curtisia*, *Nyssa*, *Camptotheca*, *Davidia*, *Diplopanax*, *Mastixia*, and genera from Hydrangeaceae (*Decumaria*, *Carpenteria*, *Deutzia*, *Philadelphus*, and *Hydrangea*) (Fig. 1). This group, hereafter referred to as the "cornaceous clade," has a bootstrap value of 71% (Fig. 1). The analysis of Chase et al. (1993) similarly indicates a monophyletic group identical to the cornaceous clade. Four major lineages can be recognized within the cornaceous clade, although the bootstrap values for some are not high: (1) nyssoids (*Nyssa*, *Camptotheca*, *Davidia*)–mastixioids (*Diplopanax* and *Mastixia*) (58%), (2) *Cornus*–*Alangium* (57%), (3) *Curtisia*, and (4) hydrangeoids (*Decumaria*, *Carpenteria*, *Deutzia*, *Philadelphus*, and *Hydrangea*) (98%) (Fig. 1). The second major group contains all of the remaining taxa analyzed, including those that have been considered close relatives of *Cornus* (*Aucuba*, *Garrya*, *Helwingia*, *Griselinia*, and *Corokia*). These five taxa are not closely allied with the cornaceous clade (Fig. 1). *Griselinia* is the sister of a well-supported (bootstrap value of 95%) araliaceous group. *Corokia* is allied with Asteraceae. *Helwingia* has as its closest relative *Phyllonoma*, a genus usually placed in Escalloniaceae or treated as a distinct subfamily of Saxifragaceae sensu lato (discussed in greater detail by Morgan & Soltis, 1993). *Aucuba* and *Garrya* are close allies; both appear in a clade with *Eucommia* (Eucommiaceae: Hamamelidae). The phylogenetic positions of these five genera traditionally allied with Cornaceae are congruent with those derived from the broad analysis of Chase et al. (1993), and a detailed analysis of sequences from the Asteridae (Olmstead, unpublished).

The phylogenetic analysis of *rbc*L sequences reveals that *Cornus* is a well-supported monophyletic group (85%; Fig. 1). Four lineages can be recognized among the 10 species of *Cornus* sequenced, although these clades are not strongly supported in the bootstrap analysis: (1) big-bracted dogwoods–dwarf dogwoods (65%), (2) bractless dogwoods (65%), (3) cornelian cherries (68%), and (4) *C. oblonga*, a morphologically distinct bractless species (Fig. 1). Strongly supported lineages having bootstrap values of 96%–100% are further identified within three of these four lineages: the big-bracted dogwoods (*C. kousa* and *C. florida*), the opposite-leaved bractless species (*C. walteri* and *C. obliqua*), and two cornelian cherries (*C. mas* and *C. officinalis*) (Fig. 1). Sequence divergence among species of *Cornus* is very high. For example, *C. canadensis* differs from *C. kousa* by 54 base substitutions and *C. mas* differs from *C. canadensis* by 54 base substitutions (Fig. 1).

## Discussion

Numerous studies have demonstrated the great value of *rbc*L sequence data in reconstructing plant phylogenies (e.g., Doebley, 1990; Donoghue et al., 1992; Olmstead et al., 1992; Soltis et al., 1990; papers in this issue). The value of comparative *rbc*L sequencing for resolving phylogenetic questions in particularly troublesome groups is also illustrated by our analysis of Cornaceae. In this study, *rbc*L sequence data have (1) helped to identify an alliance composed of *Cornus* and related taxa (i.e., the cornaceous clade), (2) demonstrated that several genera traditionally allied with *Cornus* are only distantly related to this genus, and (3) suggested the presence of major lineages within the cornaceous clade and within *Cornus*.

### 1. The Cornaceous Clade

Our analysis reveals that *Cornus* is a well-supported lineage and suggests that nyssoids (*Nyssa*, *Davidia*, and *Camptotheca*), mastixioids (*Diplopanax* and *Mastixia*), *Alangium*, *Curtisia*, and hydrangeoids are the closest relatives of *Cornus* (Fig. 1). No suite of cornaceous relatives identical to those suggested by *rbc*L sequence data has been proposed previously, and only the proposals of Eyde (1988) and Takhtajan (1980, 1987) are somewhat close to the scheme suggested by our analysis of *rbc*L sequences.

*Alangium* has been widely recognized as a monotypic family (e.g., Cronquist, 1981, 1988; Hutchinson, 1967; Takhtajan, 1980, 1987; Wangerin, 1910). Our phylogenetic analysis of *rbc*L sequence data suggests that *Alangium* may be the sister group to *Cornus*. A close relationship between these two genera is also suggested by similarities in flowers, fruits, and embryology (Chopra & Kaur, 1965; Eyde, 1988), binucleate pollen (Brewbaker, 1967), and a base chromosome number of $x = 11$. In addition, one species of *Alangium* has the distinctive two-armed hairs (but with unequal arms) characteristic of *Cornus* (see Eyde, 1988). Eyde (1988) similarly concluded that *Alangium* was a close relative of *Cornus* using the above characters.

Nyssoids differ from *Cornus* primarily in having unisexual and polygamous flowers. However, nyssoids also share a number of important characters with *Cornus*: presence of iridoids (Bate-Smith et al., 1975), similar gynoecial vasculature (Eyde, 1967), germination valves on the fruit stone (Eyde,

1988), and H-shaped thinning of the pollen aperture (Eramyan, 1971; Ferguson, 1977; Ferguson & Hideux, 1980; Reitsma, 1970). Citing these features, Eyde (1988) proposed that nyssoids share a recent common ancestor with *Cornus*. Our sequence data, therefore, agree with these morphological, anatomical, and chemical similarities in suggesting that the nyssoids are closely related to *Cornus* (Fig. 1).

Relationships among nyssoids (*Nyssa*, *Davidia*, and *Camptotheca*) have long been controversial. The three genera of nyssoids are often placed in the family Nyssaceae (Cronquist, 1981; Hutchinson, 1967; Wangerin, 1910). Fruit and seed morphology, as well as evidence from wood anatomy and fatty acid chemistry (Breuer et al., 1987; Eyde, 1963, 1988; Hohn & Meinschein, 1976; Titman, 1949), suggests a close relationship among the nyssoids. However, *Davidia* has been recognized as a monotypic family by some authors (Takhtajan, 1980, 1987). Using wood anatomy, Titman (1949) proposed that *Davidia* is the most primitive nyssoid, with *Camptotheca* derived from *Nyssa*. This proposal was supported by evidence from fatty acids (Breuer et al., 1987; Hohn & Meinschein, 1976), and data from morphological, palynological, and fossil studies (Eyde, 1963, 1988). Chen (1988) argued, however, that *Camptotheca* was only distantly related to *Nyssa* based on his embryological studies of *Camptotheca*, *Nyssa*, and *Davidia* and proposed a new monotypic family, Camptothecaceae (Chen, 1988). Serological data (Fairbrothers, 1977; Fairbrothers & Johnson, 1964), on the other hand, support the separation of *Davidia* from *Nyssa* and *Camptotheca*. Our analysis of *rbc*L sequence data suggests instead that these three genera, together with *Mastixia* and *Diplopanax*, form a monophyletic group.

*Diplopanax* was placed previously in Araliaceae by Handel-Mazzetti (1933) based on the resemblance of its flowers, without observation of fruits, to those of the araliaceous genus *Dendropanax*. This family assignment was questioned by Hoo & Tseng (1978) and Tseng (1983). They found important similarities between the fruits of *Diplopanax* and *Mastixia* and suggested that *Diplopanax* is better placed in Cornaceae. Eyde & Xiang (1990) made a direct comparison of *Diplopanax* fruits with fossil fruits of mastixioids and restated that *Diplopanax* is closely allied with *Mastixia* because both share distinctive fruitstones, two-armed hairs that are one-celled on the leaf midveins, and hooked petals. These structural features place *Diplopanax* in the genus *Mastixicarpum*, part of a woody-fruited mastixioid complex that was thought to have gone extinct four million years ago. Although *Mastixicarpum* is the older name, nomenclatural rules require that the united group take the name of its modern component, *Diplopanax*.

Our *rbc*L sequence data place *Diplopanax* in the nyssoid group and support its removal from Araliaceae where it was initially placed (Handel-Mazzetti, 1933) and has since been classified (Hoo & Tseng, 1978; Hutchinson, 1967). Although *rbc*L sequence data indicate that *Diplopanax* is a close relative of *Mastixia*, whether *Diplopanax* is most closely related to *Mastixia* (as suggested by Eyde & Xiang, 1990) is still uncertain based on *rbc*L sequences. All of our analyses show *Diplopanax* to be closest to *Camptotheca*, but this relationship is not strongly supported by the bootstrap analysis (41%) (Fig. 1). *Diplopanax* and *Camptotheca* are similar in that both genera (as well as *Mastixia*) are diplostemonous. Further assessment of possible relationships between *Diplopanax* and the nyssoid genera are not presently possible because of the lack of embryological, chemical, and anatomical evidence for *Diplopanax*, a result of the geographic isolation and rarity of the genus.

*Mastixia* has been assigned to a diverse array of families (e.g., Caprifoliaceae, Nyssaceae, Aquifoliaceae, Araliaceae, Icacinaceae, and Cornaceae; Matthew, 1976). Phylogenetic analysis of *rbc*L sequence data reveals that *Mastixia* is a member of the cornaceous clade. A number of lines of evidence (Table 3) suggest a close relationship between *Mastixia* and *Cornus*. However, based on *rbc*L sequences, *Mastixia* does not appear to be the sister of *Cornus* as suggested by Eyde (1988) but is more closely related to the nyssoids instead (Fig. 1). Thus, the two-armed surface hairs shared by *Mastixia*, *Diplopanax*, and *Cornus* (Eyde, 1988) may actually have evolved independently in each of these genera.

*Curtisia*, comprising two species endemic to South Africa, clearly is a member of the cornaceous clade in these analyses of *rbc*L sequences. Similar chemical patterns were observed in *Cornus* and *Curtisia* by Bate-Smith et al. (1975), adding further support for a close relationship between the two genera. *Curtisia* also has been linked with *Mastixia* based on chromosomal (Goldblatt, 1978) and palynological data (Ferguson, 1977; Ferguson & Hideux, 1980; Hideux & Ferguson, 1976). In contrast, Eyde (1988) did not consider *Curtisia* to be a close ally of *Cornus*, *Mastixia*, and nyssoids (his Cornaceae) because of its small pollen grains

and distinctive fruit-stone vascular bundles. *Curtisia* generally is placed in Cornaceae as a separate subfamily (Harms, 1898; Takhtajan, 1980; Thorne, 1983; Wangerin, 1910) or recognized as a monotypic family placed close to Cornaceae (Takhtajan, 1987; Thorne, 1992). Both of these views are concordant with *rbc*L sequence data.

The relationships of hydrangeoids have long been controversial (see review of this topic by Morgan & Soltis, 1993). Our analysis of *rbc*L sequences clearly supports their position as close relatives of *Cornus*, *Alangium*, *Curtisia*, nyssoids, and mastixioids, as suggested previously by Breuer et al. (1987), Takhtajan (1987), Philipson (1977), and Krach (1977) based on other lines of evidence. Hydrangeoids are similar to other members of the cornaceous clade in general flower structure: flowers 4–5-merous with an epigynous disk, calyx tube adnate to the ovary, petals free, ovary inferior (sometimes incompletely inferior as in *Hydrangea* or superior as in *Carpenteria*) with 2–5 locules, and ovules usually pendulous. In addition, both hydrangeoids and other members of the cornaceous clade produce iridoids. Several features, however, clearly separate the hydrangeoids from other members of the cornaceous clade. Hydrangeoids possess numerous ovules per locule, capsular fruits, and central bundles in the gynoecial vasculature. All other members of the cornaceous clade, in contrast, have a solitary ovule in each locule, typically bear drupes (*Camptotheca* has subsamaroid fruits), and lack central bundles in the gynoecial vasculature. Furthermore, hydrangeoids have unitegmic tenuinucellate ovules whereas nearly all the other members of the cornaceous clade (excluding *Curtisia* for which ovule type is unknown) have unitegmic crassinucellate ovules (Philipson, 1977). An exception is found in the bracted species of *Cornus*, which like the hydrangeoids have unitegmic tenuinucellate ovules (Erdelska, 1986; Eyde, 1988).

Although analysis of *rbc*L sequences has identified a well-supported cornaceous clade comprising four major lineages, relationships among these four major lineages are not resolved. To clarify more fully relationships within the cornaceous clade, sequences of more rapidly evolving nuclear or chloroplast genes will be required.

## 2. DISTANT RELATIVES OF CORNACEAE

Not only do *rbc*L sequence data indicate the presence of a cornaceous clade, these data also reveal that *Aucuba*, *Garrya*, *Corokia*, *Griselinia*, and *Helwingia*, all traditionally placed in Cornaceae, are not closely related to *Cornus* or to other members of the cornaceous clade (Fig. 1). Our findings are consistent with the broad phylogenetic analysis (Chase et al., 1993), which similarly indicates that these five genera are distantly related to the cornaceous clade. These genera have been placed in Cornaceae or Cornales by different taxonomists because of their tree or shrub form, vessel-segments usually with scalariform perforations, 3–5-merous and inconspicuous flowers, partially united sepals, separate petals, epigynous discs, inferior ovaries, solitary ovules per locule, and mostly drupaceous fruits. Each of these genera is discussed individually below.

*Aucuba* was placed in Cornaceae by Harms (1898), Wangerin (1910), and Cronquist (1981) and considered a close relative of Cornaceae by Takhtajan (1980, 1987). Our *rbc*L sequence analysis reveals, however, a distant relationship between *Aucuba* and the cornaceous clade. The distant relationship of *Aucuba* to the cornaceous clade is also supported by its distinctive wood structure and pollen morphology (Adams, 1949; Ferguson & Hideux, 1980). The closest relative of *Aucuba*, based on *rbc*L sequence data, is *Garrya*, a genus of 15 species in North America and the West Indies. *Garrya* has also been placed in Cornaceae (Harms, 1898) or recognized (as Garryaceae) as a close relative of Cornaceae (Cronquist, 1988; Hutchinson, 1967, 1969; Takhtajan, 1987; Thorne, 1983, 1992). The close affinity between *Aucuba* and *Garrya* suggested by sequence data is also supported by similarities in gynoecial vasculature (Eyde, 1964), phytochemistry (Bate-Smith et al., 1975), and fatty acids present in seed oils (Breuer et al., 1987).

*Corokia* is also far removed phylogenetically from *Cornus* in our analysis of *rbc*L sequences. Although *Corokia* traditionally has been placed in Cornaceae, more recently it has been considered closely related to *Argophyllum* (Escalloniaceae) based on pollen morphology and wood and floral anatomy (Eyde, 1988; Takhtajan, 1987). However, *rbc*L sequence data also reveal a distinct relationship between *Corokia* and *Escallonia*; an *rbc*L sequence is not available for *Argophyllum*.

Most treatments have placed *Griselinia* in Cornaceae (Cronquist, 1988; Harms, 1898; Hutchinson, 1967; Wangerin, 1910). It was, however, recognized as a monotypic family in Cornales by Takhtajan (1980), and later moved to his Hydrangeales (Takhtajan, 1987). Close affinities among *Griselinia*, *Aucuba*, and *Garrya* were proposed by Eyde (1964) based on gynoecial vascu-

lature. Phytochemical evidence also supports these relationships (Breuer et al., 1987). However, *rbc*L sequence data place *Griselinia* in a basal position in the araliaceous group, phylogenetically distant from *Aucuba* and *Garrya* (Fig. 1).

*Helwingia* was placed in Cornaceae by Harms (1898), Wangerin (1910) and Cronquist (1981). Our analysis of *rbc*L sequences reveals, however, that *Helwingia* is well outside the cornaceous clade. A distant relationship between *Helwingia* and *Cornus* is also supported by phytochemical data, as well as floral characters (Bate-Smith et al., 1975; Eyde, 1967), and both Adams (1949) and Eyde (1988) suggested that *Helwingia* be removed from Cornaceae. In our analyses, the genus is phylogenetically closest to *Phyllonoma*, a traditional member of Saxifragaceae sensu lato. *Phyllonoma* is similar to *Helwingia* in that both have flowers borne on the leaf blades. Although the two genera do share this rare characteristic, no previous authors have suggested a close relationship between *Helwingia* and *Phyllonoma* (see detailed discussion of this topic by Morgan & Soltis, 1993).

## 3. PHYLOGENETIC RELATIONSHIPS WITHIN *CORNUS*

The large amount of *rbc*L sequence divergence among species of *Cornus* is somewhat surprising given the conservative rate of evolution of *rbc*L. With this large amount of sequence divergence, our results demonstrate that *rbc*L sequence data can sometimes be used to study intrageneric relationships, as discussed below.

Varying schemes of intrageneric relationships have been proposed for *Cornus*, reflecting different hypotheses of morphological evolution and different emphases on available characters (Tables 4, 5). The major argument concerns the relative advancement within the genus of the bracted versus the bractless dogwoods. Our phylogenetic analysis of *rbc*L sequence data reveals four lineages: *C. oblonga*, big-bracted dogwoods—dwarf dogwoods, cornelian cherries, and bractless dogwoods. The latter three clades were also recognized in analyses of morphological characters (Eyde, 1988) and chloroplast DNA restriction site mutations (Brunsfeld et al., 1991; Xiang et al., 1991); insufficient material of *C. oblonga* was available for inclusion of this species in the cpDNA restriction site study. However, relationships among these four lineages are incompletely resolved by *rbc*L sequences (Fig. 1). The *rbc*L sequence analysis indicates that *C. oblonga*, a bractless species found in the eastern Himalayas and southwestern China, is a lineage distinct from cornelian cherries, the remaining bractless species, and the big-bracted dogwoods–dwarf dogwoods (Fig. 1). Several morphological, embryological, and anatomical features similarly suggest the distinctiveness of *C. oblonga* (Adams, 1949; Chopra & Kaur, 1965; Zhu, 1984). This species commonly has been viewed as the most primitive species of *Cornus*, and the hypothetical ancestral dogwoods were reconstructed based largely on its morphological characters (Eyde, 1988; Rickett 1950). Although *rbc*L sequence data do not suggest a basal position for *C. oblonga* in *Cornus*, sequence data do agree with other evidence in suggesting an isolated phylogenetic position of this species in the genus. However, the exact phylogenetic position of *C. oblonga* awaits the sequence analysis of more rapidly evolving chloroplast genes, such as ORFK.

In summary, our analysis of *rbc*L sequences has (1) identified a cornaceous clade that includes *Cornus*, *Alangium*, *Curtisia*, *Nyssa*, *Camptotheca*, *Davidia*, *Diplopanax*, *Mastixia*, and genera from Hydrangeaceae (*Decumaria*, *Carpenteria*, *Deutzia*, *Philadelphus*, and *Hydrangea*); (2) revealed that several genera previously placed in Cornaceae (e.g., *Aucuba*, *Garrya*, *Corokia*, *Griselinia*, and *Helwingia*) are only distantly related to *Cornus*; (3) identified four major lineages within the cornaceous clade and suggested four major lineages within *Cornus*. Other putative relatives of *Cornus*, such as *Toricellia*, *Aralidium*, *Melanophylla*, and *Kaliphora*, may ultimately be considered part of the cornaceous clade if material becomes available for analysis of *rbc*L.

# SYSTEMATICS OF THE ERICACEAE, EMPETRACEAE, EPACRIDACEAE AND RELATED TAXA BASED UPON *rbc*L SEQUENCE DATA[1]

*Kathleen A. Kron*[2,3] *and Mark W. Chase*[2,4]

ABSTRACT

The Ericaceae, Epacridaceae, and Empetraceae are usually recognized as closely related families of woody plants that share a preference for acidic soils, anthers that invert in development, and the presence of endosperm haustoria, among other characteristics. The Empetraceae are recognized as distinctive because of their often unisexual and wind-pollinated flowers. Epacridaceae are distinguished from Ericaceae by anthers that open by slits rather than pores and a primarily Australian distribution. Phylogenetic relationships of these related families are investigated using nucleotide sequences of the plastid gene *rbc*L. Parsimony analyses indicate a monophyletic, broadly defined Ericaceae that includes Empetraceae and Epacridaceae.

The Ericaceae are acid-loving woody plants found throughout the world but with major centers of diversity in the Himalayas, tropical Asia, montane South and Central America, and southern Africa. Traditionally, this family has been closely associated with two other woody plant families that also prefer acidic habitats: Epacridaceae (primarily Australian) and Empetraceae (amphitropical). These three families share morphological, developmental, ecological, and embryological features that have led almost all recent workers to consider them closely related (e.g., Ericales sensu Cronquist, 1981). These characteristics include the presence of endosperm haustoria at both the chalazal and micropylar ends of the embryo and anthers that invert in development (see Judd & Kron, 1993). The Empetraceae comprise three genera (*Ceratiola, Corema, Empetrum*) of predominantly anemophilous plants with reduced, often unisexual flowers. *Ceratiola* and *Corema* occur in the Northern Hemisphere primarily along both sides of the Atlantic, whereas *Empetrum* exhibits a bipolar distribution. The Epacridaceae are a much larger family almost entirely restricted to Australia, although some species occur in southern South America, New Caledonia, Indomalaysia, and New Zealand. Morphologically Epacridaceae show much variability, and there are no characters that consistently distinguish all members of this family from members of the Ericaceae (Judd & Kron, 1993; D. Morrison, pers. comm.). For example, the anthers of the Epacridaceae dehisce by slits rather than pores, the latter considered typical of the Ericaceae. However, several members of the Ericaceae have anthers that dehisce by slits or slitlike pores. Traditionally, the Epacridaceae have been considered the Australian correlates of the Ericaceae (Cronquist, 1981).

The Ericaceae (in the broad sense) are a large, extremely diverse, and essentially cosmopolitan family characterized by release of pollen in tetrads and/or sympetalous urceolate or campanulate corollas (Judd & Kron, 1993). Most members of the family are photosynthetic, but Cronquist (1981) segregated the Pyrolaceae and Monotropaceae out of the Ericaceae because of the following tendencies: reduction from shrubs to herbs, gradually increasing mycoparasitism, gradual loss of chlorophyll, and choripetaly.

This study is an investigation of phylogenetic relationships among the Ericaceae, Empetraceae, and Epacridaceae. The general position of the Er-

icales (Cronquist, 1981) within the flowering plants is addressed in Chase et al. (1993) and Olmstead et al. (1993). Because of the morphological diversity and the difficulty of determining homologous structures among members of the Ericaceae, Empetraceae, and Epacridaceae, a parsimony analysis of nucleotide sequences of *rbc*L (ribulose-1, 5-bisphosphate carboxylase oxygenase, large subunit) was performed. Although the problem of homoplasy is certainly not resolved with the use of sequence data in phylogenetic analysis (cf. Albert et al., 1993), the chance that patterns of homoplasy would have similar distributions in both morphological and *rbc*L sequence data is negligible.

## MATERIALS AND METHODS

The 17 genera (including *Pyrola*) chosen for study (Table 1) represent the range of morphological diversity of the Ericaceae for an initial approximation of the limits of the family. Many of these taxa were also included in a cladistic analysis of morphological characters (Judd & Kron, 1993). *Ceratiola* (Empetraceae) and five genera representing most of the major lineages of Epacridaceae (D. Morrison, pers. comm.) were included. *Cyrilla* (Cyrillaceae) and *Clethra* (Clethraceae) were also included because they are often considered closely related to the ericads (Cronquist, 1981). Whereas the focus of this study is the circumscription of the Ericaceae, representatives of several families within the subclass Dilleniidae (Cronquist, 1981) were included in a broad analysis (see Chase et al., 1993) to provide a context for previously hypothesized relationships with the ericalean taxa (e.g., Cronquist, 1981; Dahlgren, 1983; Hufford, 1992; Takhtajan, 1980; Thorne, 1983, 1992). These taxa have often been considered as either related

or ancestral to the Ericaceae. The sampling of "dilleniid" taxa is not complete. Thus assessment of relationships outside the Ericaceae s.l. is tentative (see the Appendix at the end of this issue for a list of vouchers).

Total DNA was extracted from fresh leaves via the modified CTAB procedure (Doyle & Doyle, 1987). The *rbc*L gene was amplified using engineered primers, cloned, and then sequenced using the standard dideoxy method (see Olmstead et al., 1993). Because of the size-conserved nature of *rbc*L, visual alignment of the sequences was easily performed. The sequences were analyzed with PAUP version 3.0s (Swofford, 1991) using heuristic search methods (see methods in Chase et al., 1993). This provided a clade as a starting point for the following analyses.

In the broad analysis, 41 of the "ericalean" and "dilleniid" taxa sampled appear in a single clade (length of this portion of the tree = 1,169 steps; see asterid III, figs. 13A, B in Chase et al., 1993) sister to the lineage that contains traditional "asterid" taxa (Cronquist, 1981). These 41 taxa (Fig. 1) were therefore used in subsequent "local" analyses. The sequences of these taxa were analyzed as a group, using PAUP 3.0s (Swofford, 1991). Eighteen of the 41 taxa (Table 1) in this clade functioned as outgroups (Maddison et al., 1984) for the Ericaceae s.l. Trees were arranged with the Primulales clade sister to the remaining taxa (Fig. 1). Two types of analyses were performed: (1) Ten replicates of random sequence addition were used to find the shortest tree (TBR, MULPARS, STEEPEST DESCENT, all characters and character states weighted equally). To select a tree to illustrate from among the numerous most parsimonious trees obtained, the weighting criterion of Albert et al. (1993) was applied. (2) A search (TBR, MULPARS) was made for trees up to and including five steps longer than the most parsimonious trees found in the first analysis. Consensus trees were constructed using the FILTER option at each step. In this analysis the following outlying taxa were removed to decrease the time involved in the search for longer trees: *Anagallis*, *Ardisia*, *Chrysophyllum*, *Clavija*, *Diapensia*, *Diospyros*, *Fouquieria*, *Impatiens*, *Polemonium*, *Styrax*, and *Symplocus*. This allowed us to assess the relative robustness of the clades within the Ericaceae obtained with maximum parsimony (cf. Bremer, 1988; Novacek, 1991). Thus, clades that collapse in trees one step longer (i.e., one step less parsimonious) are less robust than clades that remain intact in trees up to five steps longer than maximum parsimony. (This is the "decay index" of Mishler et al., 1991.) We realize that ten replicates may not reveal all islands of maximum parsimony (Maddison, 1991). However, in the decay analysis branch swapping was performed on all trees up to five steps less parsimonious, giving us greater confidence in the maximum parsimony of the initial analysis.

## Results

In the "local" analysis we performed on the 41 "ericalean" taxa, 85 trees of 1,166 steps were found with a retention index (R.I.) of 0.603. The application of the weighting criterion of Albert et al. (1993) to the 85 most parsimonious trees selected two of these trees as most parsimonious. These two trees differed only by the position of *Diospyros* (Ebenaceae). In one tree *Diospyros* is sister to the Primulales, in the second tree *Diospyros* is sister to the *Diapensia* (Diapensiaceae) *Polemonium* (Polemoniaceae) clade. Since these two trees are so similar only one is shown (Fig. 1). Decay analysis indicated that all relationships outside of the Ericaceae s.l. are weakly supported and decay at one step less parsimonious (Fig. 2).

The Ericaceae are monophyletic if Empetraceae, Epacridaceae, and Pyrolaceae are included. We will hereafter refer to this clade as Ericaceae s.l. The decay index for the branch leading to the Ericaceae s.l. indicates that the branch collapses in trees only two steps longer, indicating that there are few unique synapomorphies for the Ericaceae s.l. in the *rbc*L sequence data. This result agrees with the morphological study (Judd & Kron, 1993), where nearly all of the synapomorphies for the family show homoplasy within the family. Within the Ericaceae s.l. the currently recognized subfamilies (Stevens, 1971) Rhododendroideae and Vaccinioideae are paraphyletic. The Ericoideae are derived out of some of the "rhododendroid" taxa, and *Ceratiola* (Empetraceae) is nested within this clade. The Epacridaceae are monophyletic but are nested within the Ericaceae and are sister to some of the "vaccinioid" taxa. *Enkianthus* is the sister to the rest of the Ericaceae.

In the local analysis of the 41 "ericalean" + "dilleniid" taxa the Primulales (Cronquist, 1981) appear monophyletic with the *Clavija* (Theophrastaceae) sister to *Ardisia* (Myrsinaceae) and *Anagallis* (Primulaceae), and this clade is retained in trees one step longer (Fig. 2). The Ebenales (Table 1) are not monophyletic in this analysis. The probable paraphyletic nature of this order has already been noted by Dahlgren (1975) because of its embryological and chemical heterogeneity.

FIGURE 1. One of the 85 maximum parsimony trees (length = 1,166; C.I. (consistency index) = 0.520; R.I. (retention index) = 0.603) favored by the weighting criteria of Albert et al. (1993). Underlined taxa represent the Ericaceae s.l. This tree is arranged with the Primulales sister to all others in accord with the general results of Chase et al. (1993).

In all of the most parsimonious trees, members of the Ericaceae, Empetraceae, Epacridaceae, and Pyrolaceae form a clade. *Ceratiola* is nested within some members of subfamily Rhododendroideae (Stevens, 1971) of the Ericaceae.

## DISCUSSION

That Empetraceae may be derived from within the Ericaceae has been suggested by Moore et al. (1970) and Takhtajan (1969). Takhtajan (1969) postulated a close relationship of Empetraceae with Rhododendroideae. Harborne (1969) and Moore et al. (1970) showed that several members of the Ericaceae (e.g., *Rhododendron* and *Erica*), as well as *Ceratiola*, *Corema conradii* (Torrey) Torrey and *Empetrum* possess the rare yellow flavonol, gossypetin 3-galactoside. Thus, this chemical feature appears to unite these taxa. Rhododendroideae (Stevens, 1971) are paraphyletic, but the relationships among the members of this clade and those of the "ericoid" taxa (*Calluna* and *Erica*) are not resolved at maximum parsimony (Fig. 2). However, in at least some of the trees (Fig. 1) *Calluna* and

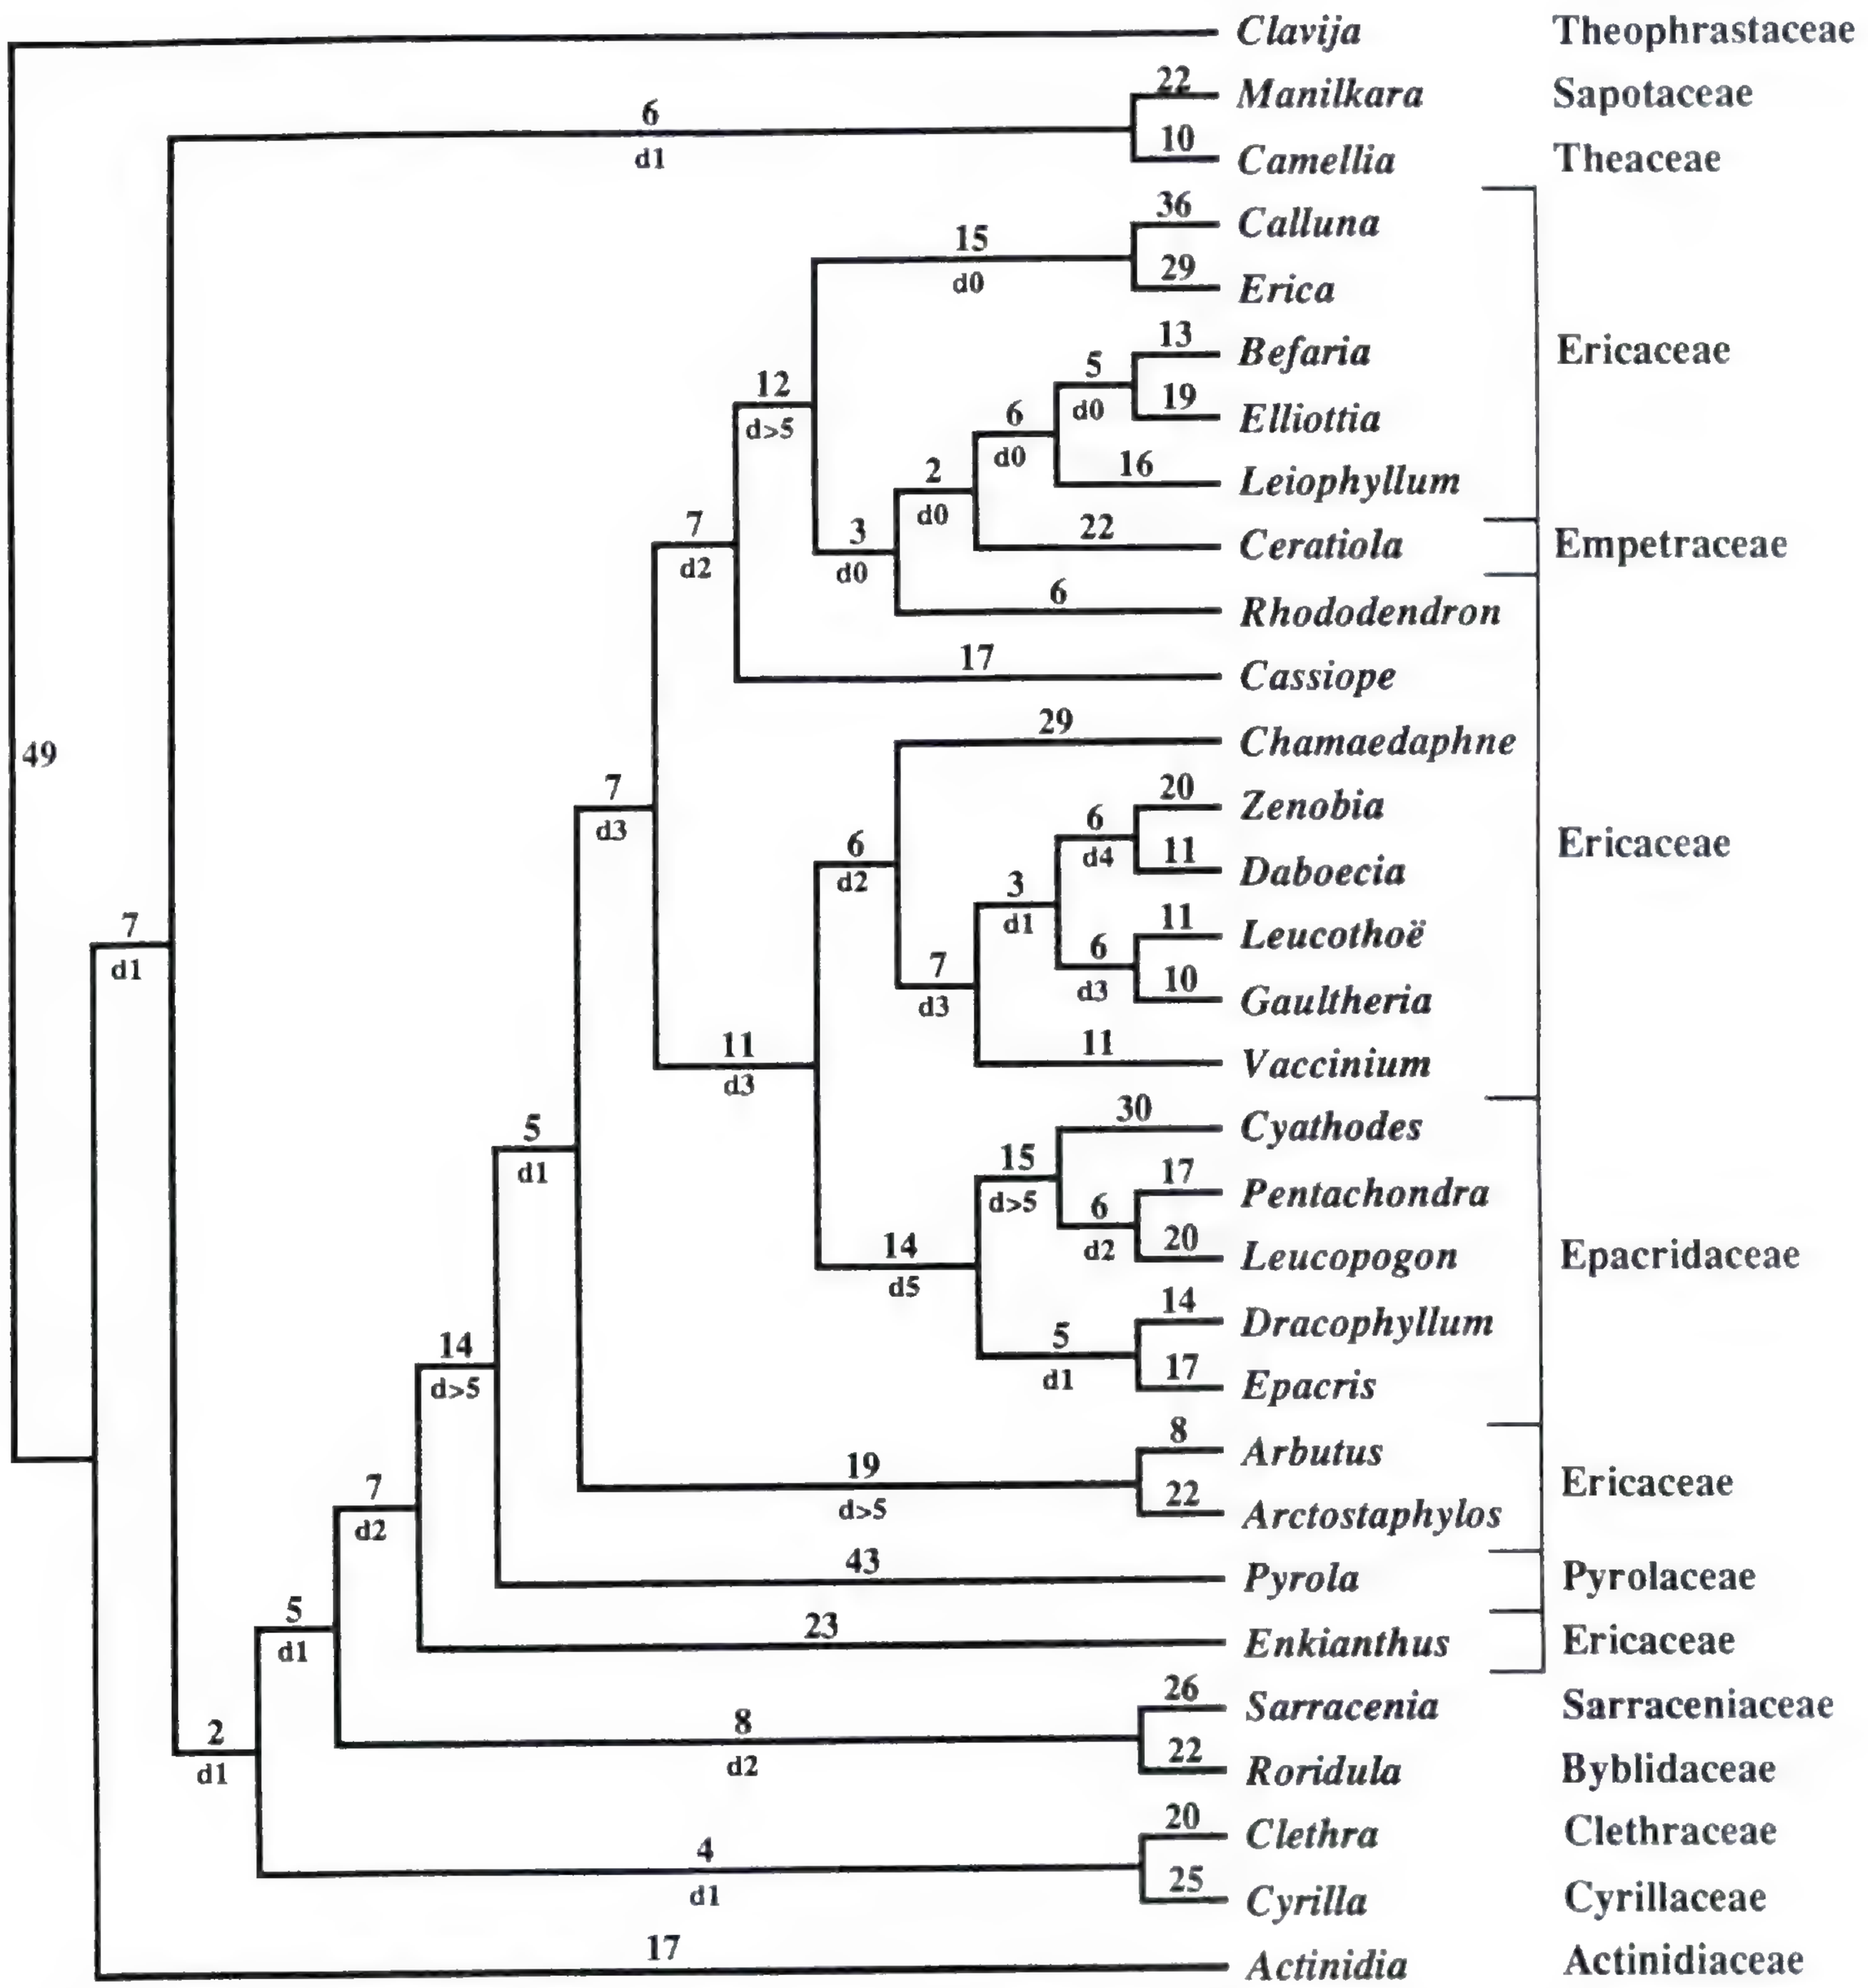

FIGURE 2. Decay of parsimony of the Ericaceae s.l. (Some outgroup taxa present in Fig. 1 were removed to reduce analysis complexity and time.) Numbers above branches are Fitch (unordered) lengths optimized with ACCTRAN of PAUP 3.0s. Numbers below branches are the decay indices or the number of steps less parsimonious at which the branch becomes a polytomy in the strict consensus tree of all trees at that length. A decay index of "d0" indicates that the branch is not present in the strict consensus tree of the 85 maximum parsimony trees; "d1" indicates that the branch is absent in the strict consensus tree of trees at maximum parsimony plus one step, etc.

*Erica* form a clade sister to the "rhododendroid" clade. This topology suggests that the "ericoid" type of leaf morphology found in *Calluna*, *Erica*, and *Cassiope* may be ancestral to the flat leaves of the "rhododendroid" taxa (Stevens, 1970). Within this clade there is also the change from gamopetalous corollas (*Cassiope*, *Calluna*, *Erica*, *Rhododendron*) to choripetalous corollas (*Ceratiola*, *Leiophyllum*, *Elliottia*, *Befaria*). This differs from the traditional view of choripetaly as the ancestral condition within the Ericaceae.

The "epacrids" are monophyletic in this analysis and are in the same clade as the "vaccinioid" taxa and *Chamaedaphne*. The "epacrid" clade is more robust (with a decay index of 5, Fig. 2) than the clade containing "vaccinioid" taxa (decay index of 3, Fig. 2). More sampling of taxa traditionally included in tribes Andromedeae and Vaccineae

(Vaccinioideae) is necessary before their relationships can be confidently evaluated.

*Arbutus* and *Arctostaphylos* (tribe Arbuteae, Vaccinioideae, Stevens, 1971) form a monophyletic group that branches before the clade leading to the bulk of the ericads. *Pyrola* is sister to the Arbuteae clade plus the above ericads. However, the relationships of *Pyrola* and Arbuteae (represented by *Arbutus* and *Arctostaphylos*) to the rest of the Ericaceae (except *Enkianthus*) are not robust in this analysis as the branch collapses in trees one step longer than maximum parsimony (Fig. 2). However, the branch leading to *Pyrola* plus the above noted ericads is well supported (decay index of >5 steps), indicating that *Pyrola* should not be recognized as a distinct family (see Judd & Kron, 1993, for supporting morphological evidence). Even though it appears that the achlorophyllous *Monotropa* lacks *rbc*L (repeated attempts to amplify the gene were not successful, see also Wolfe et al., 1992, for another achlorophyllous plant without a functional *rbc*L gene), this mycoparasitic taxon and its relatives should also be included (along with *Pyrola*, *Chimaphila*, etc.) in a broadly defined Ericaceae (Judd & Kron, 1993).

*Enkianthus* is sister to the rest of the Ericaceae (Fig. 1). This was also found in the shortest tree of Judd & Kron (1993) and A. Anderberg (pers. comm.), in studies based primarily on morphology. *Enkianthus* has been considered relatively isolated due to its combination of gamopetalous campanulate corolla, anthers opening by slits rather than pores, and pollen shed in monads rather than the tetrads characteristic of Ericaceae (Stevens, 1971). However, such a distinctive phylogenetic position has not been suggested previously. The position of *Enkianthus* as sister to the remaining Ericaceae suggests that the interpretation of a corolla with free petals as primitive (Abbott, 1936; Camp, 1941; Copeland, 1943; Stevens, 1971; Wood, 1961) within the family needs reevaluation. In fact, careful morphological studies (Copeland, 1943; Leins, 1964) show that at least in the case of members of *Rhododendron* subsect. *Ledum* (Kron & Judd, 1990), the corolla is actually slightly fused at the base early in development. The choripetalous condition may be derived within the Ericaceae in genera such as *Befaria* and *Leiophyllum*, in which the petals appear to be truly separate. However, since the sister clade to the Ericaceae s.l. may be choripetalous, it is possible that gamopetaly in *Enkianthus* is autapomorphic.

Whereas the general results obtained in this study (i.e., the inclusion of Empetraceae, Epacridaceae, and Pyrolaceae in a broadly defined Ericaceae) are supported by a cladistic analysis of morphological characters (Judd & Kron, 1993), the positions of *Cyrilla* and *Clethra* in the molecular analysis (Fig. 1) differ from those revealed in the morphological analysis. This is surprising because a close relationship of *Clethra* (Clethraceae) and *Cyrilla* (Cyrillaceae) to the Ericaceae appears to be well supported by morphology. These two genera have been included within the order Ericales by some (Cronquist, 1981; Dahlgren, 1983), although Thorne (1992) placed them in his Theales. In the morphological analysis of Judd & Kron (1993), *Actinidia* is sister to *Cyrilla* + *Clethra* + Ericaceae s.l. These taxa share the presence of an apical depression in the ovary and anthers that invert in development (modified in *Cyrilla*). In the molecular trees, the relative positions of *Actinidia*, *Cyrilla*, and *Clethra* may be resolved more fully upon inclusion of other representatives of the Cyrillaceae (*Cliftonia*, *Purdeaea*). Anderberg's (1992) cladistic study of the relationships of the Ericales to other "higher" dicots indicated Cyrillaceae and Clethraceae as branching before Roridulaceae, which is sister to Epacridaceae + Pyrolaceae + Ericaceae + Monotropaceae. These results also indicate a closer relationship of Cyrillaceae and Clethraceae to the Ericaceae s.l. than do the molecular data. However, neither the Anderberg (1992) nor the Judd & Kron (1993) studies included members of the Ebenales (sensu Cronquist, 1981) in their analyses.

## Summary

Sampling of taxa presents a major problem in molecular studies (Olmstead et al., 1993; Chase et al., 1993), and when taxa are sampled superficially spurious results are possible. We advocate and maintain a fair degree of suspicion concerning these results in two weakly supported portions of the topology and believe that increased sampling is likely to alter the estimates of relationships. One of these is the group identified as sister to Ericaceae s.l., in which significant divergence from other studies occurs (discussed above). The other area is within the Ericaceae (*Pyrola* and *Arbutus* + *Arctostaphylos*); we would expect weakly supported branches to be altered when a more even sampling is obtained. The strong internal support and congruence with results of other studies (Judd & Kron, 1993) for the positions of the segregate families (Empetraceae, Epacridaceae) make it unlikely that the general conclusions of this study will change as taxon sampling improves.

A monophyletic Ericaceae includes Empetra-

ceae, Epacridaceae, and Pyrolaceae (formally outlined in Judd & Kron, 1993). These conclusions are congruent with parsimony analysis of morphological data (Judd & Kron, 1993), which also indicates the inclusion of Monotropaceae in Ericaceae (cf. Anderberg, 1992). The agreement of these studies lends increased support to recognizing a more broadly defined Ericaceae.

## ABSTRACT

Nucleotide sequences of the chloroplast gene *rbc*L were analyzed to examine relationships among the large, distinctive family Asteraceae and eight putatively closely related families. Phylogenetic analysis of a total of 24 sequences of *rbc*L identified a lineage consisting of two families, the Goodeniaceae and Calyceraceae, as the sister group to the Asteraceae. In addition, a strongly supported major monophyletic clade consisting of Asteraceae, Goodeniaceae, Calyceraceae, *Corokia* (Cornaceae sensu Cronquist), Menyanthaceae, Lobeliaceae, and Campanulaceae was found. These results clearly distance from the Asteraceae certain groups previously considered closely related; moreover, the results support alternative hypotheses of affinity that were based upon floral and inflorescence morphology, biogeography, pollen morphology, chemistry, and pollen-presentation mechanisms.

The angiosperm family Asteraceae has long been recognized as one of the large, "natural" families with well-established limits defined by several specialized floral characteristics and distinctive secondary chemistry. Many recent studies have illuminated numerous phylogenetic controversies within the family (Bremer, 1987; Bremer et al., 1992; Jansen et al., 1990, 1991a, b; Jansen & Palmer, 1987a, b, 1988; Karis et al., 1992; Keeley & Jansen, 1991; Kim et al., 1992; Watson et al., 1991). However, relationships among the Asteraceae and other families have remained obscure, due to considerable parallel and convergent evolution of conventional characters used to infer affinities, lack of recent studies employing modern methods of phylogenetic analysis, and substantial confusion as to relationships among the various families within the subclass Asteridae itself (but see Olmstead et al., 1992).

At least 12 families have been proposed as closest relatives of the Asteraceae based on a variety of traditional taxonomic characters. Although Hutchinson (1969) noted the superficial similarity of the inflorescence of the Dipsacales (Caprifoliaceae, Valerianaceae, and Dipsacaceae) to that of the Asteraceae, he suggested convergence as the basis for this and identified the Campanulales (Campanulaceae and Lobeliaceae) as the closest relative. Aspects of the distinctive chemistry of the Asteraceae (e.g., alkaloids, polyacetylenes, terpenes, inulin for carbohydrate storage) have been noted in several members of the Campanulales (Campanulaceae, Lobeliaceae, Goodeniaceae, Stylidiaceae), while other chemical evidence has pointed to the Apiaceae and Araliaceae (Hegnauer, 1964, 1977). Cronquist (1955) advocated the Rubiales as closest relatives of the Asteraceae (grouped with the Gentianales in the system of Takhtajan, 1980), but also acknowledged strong similarities in floral and inflorescence morphology between the Asteraceae and the Calyceraceae (as did Takhtajan, 1980). An association with the Calyceraceae is also supported by biogeography and capitular structure (Turner, 1977) and pollen morphology (Skvarla et al., 1977). Others (reviewed in Skvarla et al., 1977) have noted a palynological resemblance of Valerianaceae, Goodeniaceae and Brunoniaceae to Asteraceae. In a morphological cladistic study of tribal relationships within the Asteraceae, stylar morphology, chemical characters, and pollen-presen-

[1] We thank D. Morgan and D. Soltis for providing an unpublished *rbc*L sequence of *Corokia*. We are grateful to M. Chase, D. Soltis, and T. Lammers for comments on the manuscript. tation mechanism were identified by Bremer (1987) as potential synapomorphies linking the Lobeliaceae and Asteraceae. Finally, strong similarities to the highly specialized secondary pollen-presentation mechanism of the Asteraceae have been documented in Goodeniaceae, Brunoniaceae, Campanulaceae, and Lobeliaceae (Leins & Erbar, 1990). As noted in many of the above attempts to resolve this controversy, most of the morphological or chemical characters that support a particular hypothesis of ancestry are often also found in several related groups, and some must certainly be the product of parallel evolution.

Several of the recent molecular advances in elucidating phylogenetic relationships within the family have employed restriction site analysis of chloroplast DNA. However, this approach is generally unsuitable at the interfamilial level because the homology of site changes becomes doubtful due to increased levels of both nucleotide sequence divergence (causing multiple "hits" within restriction sites) and length variation causing problems in alignment of sites (Downie & Palmer, 1992b; Palmer et al., 1988). At higher taxonomic levels, restriction site analysis of only the more conserved inverted repeat region of chloroplast DNA may be used to circumvent these problems (e.g., Downie & Palmer, 1992a), but fewer characters are generated than in whole genome surveys. DNA sequence analysis of the slowly evolving chloroplast gene *rbc*L and nuclear rRNA genes has proven highly effective in resolving higher-level relationships in plants (Chase et al., 1993; Hamby & Zimmer, 1992; Palmer et al., 1988; Ritland & Clegg, 1987; Zurawski & Clegg, 1987). In particular, recent studies by a number of researchers employing comparative sequencing of the chloroplast gene encoding the large subunit of the photosynthetic enzyme ribulose-1,5-bisphosphate carboxylase (*rbc*L) indicate an appropriate size and rate of evolution for providing a sufficient number of characters for phylogenetic studies at the familial and ordinal levels (Donoghue et al., 1992; Kim et al., 1992; Olmstead et al., 1992; Soltis et al., 1990). In this paper we analyze nucleotide sequences for *rbc*L from representatives of the Asteraceae and eight putatively related families to determine evolutionary relationships among the families and identify the sister group of the Asteraceae.

## Materials and Methods

New *rbc*L sequences were determined for six taxa in the Asteraceae and eight representatives of putatively closely related families in the subclass Asteridae. For these sequences, fresh leaf material obtained either from the field or seedlings was used to isolate DNA as purified chloroplast DNA by the sucrose gradient method (Palmer, 1986) or as total cellular DNA by a modified CTAB procedure (Doyle & Doyle, 1987) followed by CsCl gradient purification. The *rbc*L gene was isolated for cloning by one of two methods. (1) For most taxa, fragments containing the entire *rbc*L gene were gel-isolated from either Sac I or Sac I/BamHI digests and ligated into the plasmid vector Bluescript (Stratagene, Inc., LaJolla, California). Recombinant, *rbc*L-containing colonies were confirmed by Southern hybridization to cloned *rbc*L fragments from peas. The coding region was sequenced from a single-stranded template by the dideoxy chain termination method (Sanger et al., 1977) using a series of primers based on *rbc*L sequences from maize and spinach (obtained from G. Zurawski, DNAX). (2) Sequences from *Pentas* and *Boopis* were obtained following amplification and cloning of a double-stranded fragment using the polymerase chain reaction following the methods of Olmstead et al. (1992).

Preliminary analyses included 14 new sequences (see Table 1 and Appendix to this issue) and one previously published sequence from *Flaveria* in the Asteraceae (Hudson et al., 1990) and, to serve as outgroups, sequences from *Spinacia* in the Caryophyllidae (Zurawski et al., 1981) and *Nicotiana* in the Asteridae (Shinozaki et al., 1988). These analyses (Michaels & Palmer, 1990) on only a subset of the data reported here identified a closest sister group identical to the present expanded analysis. The results of concurrent studies of *rbc*L sequences in the Saxifragaceae (Soltis et al., 1990), Asteridae (Olmstead et al., 1992), and 499 angiosperms (see Chase et al., 1993) have motivated the inclusion of data from other outgroups and from taxa not previously suspected to be associated with the Asteraceae. Data for *Heuchera* (Soltis et al., 1990), *Magnolia* (Golenberg et al., 1990), *Villarsia*, *Menyanthes*, *Hedera*, and *Coriandrum* (Olmstead et al., 1992) were obtained from published reports, whereas an unpublished sequence for *Corokia* was made available by D. Morgan and D. Soltis.

Although the coding regions for these taxa ranged from 1428 to 1458 bp, only a 1428 bp region was analyzed because no major insertions or deletions were found in this region, allowing alignment by eye, and because homology of positions beyond 1428 is uncertain. Analyses over longer sequences did, however, produce virtually the same results.

TABLE 1. Species of Asteraceae, related families, and outgroups compared by *rbc*L sequence. * = New sequence obtained for this study.

Analyses were also conducted in which transitions and transversions were differentially weighted (1.0: 1.3, Albert et al., 1993). Since weighted analyses did not alter the tree topologies, only the results of the equally weighted analyses are reported here. PAUP, Phylogenetic Analysis Using Parsimony, Version 3.0r (Swofford, 1991), was used to conduct Fitch parsimony analyses (Fitch, 1971). The HEURISTIC search option with 10 random replicates (Maddison, 1991) was used for tree building and branch swapping under the MULPARS and TBR options. Strict consensus trees were computed. To assess robustness of clades identified in the analyses, the bootstrap method (based on 500 replicates; Felsenstein, 1985) was used. In addition, a "decay" analysis was conducted (cf. Bremer, 1988; Donoghue et al., 1992; Hillis & Dixon, 1989) in which strict consensus trees were generated from all trees five steps longer than the most parsimonious ones. The FILTER TREES option was then used to identify all trees at each shorter tree length. Support for each clade was assessed by determining when each clade was no longer resolved in consensus trees from progressively less parsimonious solutions.

## RESULTS

Of the 1,428 nucleotide positions compared among the 24 *rbc*L sequences in the analysis, 452 were variable. Exclusion of autapomorphies resulted in 278 potentially synapomorphous characters, 204 of which were at third-codon positions, 45 at first, and 29 at second. The third position characters are essential sources of phylogenetic information, as their elimination from the data set results in little resolution (data not shown). Initial analyses (results not shown) used four taxa [*Magnolia* (Magnoliidae), *Spinacia* (Caryophyllidae), *Heuchera* (Rosidae), and *Nicotiana* (Asteridae)] as designated outgroups. These analyses established *Nicotiana* as the sister group to an ingroup consisting of the taxa proposed as outliers to Asteraceae. In subsequent analyses, the more distant outgroups *Magnolia*, *Spinacia*, and *Heuchera* were deleted, and trees were arranged using *Nicotiana*

alone as the designated outgroup. The heuristic search found four equally parsimonious trees (results not shown) of 833 steps with consistency index (C.I.) of 0.48 (autapomorphies excluded) and a retention index (R.I.) of 0.502. The strict consensus of the four trees (Fig. 1) shows a large, nested monophyletic group consisting of the Asteraceae, Goodeniaceae, Calyceraceae, *Corokia* (Cornaceae sensu Cronquist, 1981), Menyanthaceae, Lobeliaceae, and Campanulaceae. The two polytomies exist in either a more basal portion of the tree or within the Asteraceae. Among the putative relatives of the Asteraceae examined here, *Pentas* (Rubiaceae) was placed as the most basal clade. As in our earliest analysis with only a subset of these data, the expanded analysis identifies a clade consisting of *Scaevola* (Goodeniaceae) and *Boopis* (Calyceraceae) in the most proximal position to the Asteraceae. This sister relationship is supported by eight shared nucleotide substitutions.

The robustness of the sister relationship of the Goodeniaceae–Calyceraceae clade to the Asteraceae is indicated by two subsequent analyses. First, the results from 500 bootstrap replications using the heuristic search option indicate that this relationship is one of the more robust areas of the tree topology, occurring in 84% of the trees (Fig. 2). Relationships are, with some exceptions, poorly resolved within the Asteraceae (also see Kim et al., 1992) and also outside the "Asterales" (Lobeliaceae–Campanulaceae through Asteraceae) clade. Within the "Asterales" are three other well-supported groups besides the Asteraceae–Goodeniaceae–Calyceraceae clade: (1) the Asteraceae emerge as monophyletic in 97% of the bootstrap trees, (2) Campanulaceae and Lobeliaceae occur together in all bootstrap replicates, (3) the Goodeniaceae and Calyceraceae clade is monophyletic 86% of the time. Finally, the "Asterales" group as a whole appears in 86% of the trees.

Second, the strength of the relationship of the Goodeniaceae–Calyceraceae clade to the Asteraceae is indicated in the decay analysis by the persistence of this group in less parsimonious solutions. The sister position of this clade is maintained in 127 trees up to two steps longer than the most parsimonious trees. The strict consensus tree at three additional steps places the Goodeniaceae–Calyceraceae clade within an unresolved polytomy together with various unresolved lineages of the Asteraceae, while the Asteraceae–Goodeniaceae–Calyceraceae group forms an unresolved polytomy with the rest of the "Asterales" (*Villarsia*, *Corokia*, *Menyanthes*, *Campanula–Lobelia*). When the 964 trees up to four steps longer are included, most of the resolution in the tree is lost, and all but the strongest clades (i.e., Goodeniaceae–Calyceraceae, Campanulaceae–Lobeliaceae, Valerianaceae–Dipsacaceae, and *Helianthus–Flaveria*) disintegrate.

## Discussion

The *rbc*L data clearly indicate a close relationship among the Asteraceae and other families traditionally placed in the Asterales and Campanulales. This conclusion is supported not only in the local analysis presented here, but also in much broader analyses of the Asteridae (Olmstead et al., 1992, 1993) and in an analysis of 499 *rbc*L sequences from seed plants (Chase et al., 1993). The placement of the Campanulaceae, Lobeliaceae, Goodeniaceae, Calyceraceae, and Asteraceae in a single monophyletic group is consistent with the system of relationships proposed by Takhtajan (1987) and Thorne (1992), in which these groups (together with families in the Stylidiales) form the superorder Asteranae. This grouping is also distinguished in the system of Wagenitz (1977) and the recent review by Lammers (1992), but not in the systems proposed by Dahlgren (1975) or Cronquist (1981). Dahlgren aligned the Goodeniaceae and the Calyceraceae far from the Asteraceae, placing them in the Gentiananae and Cornanae, respectively. The topology inferred from the *rbc*L data is most divergent from the Cronquist system. Although Cronquist placed the Goodeniaceae together with the Campanulaceae and other families to form Campanulales, the Calyceraceae were assigned to the Dipsacalean group, while the Asteraceae were placed nearest the Rubiaceae. The latter association is clearly not supported by the *rbc*L data; *Pentas* (Rubiaceae) was consistently placed in the most distant position of all the putatively allied families under consideration as sister groups in this analysis.

The sister-group relationship of the Goodeniaceae–Calyceraceae clade to the Asteraceae is supported by evidence from a number of studies. The pollen-presentation mechanisms of the Goodeniaceae, Calyceraceae, and Asteraceae are similar, and they also resemble the mechanisms of the Campanulaceae, Lobeliaceae, and Brunoniaceae (Erbar & Leins, 1989; Leins & Erbar, 1990; Lammers, 1992; Wagenitz, 1992). Details of floral development (Harris, 1991; Erbar & Leins, 1989) also unite both Goodeniaceae and Calyceraceae with the Asteraceae. However, the particular development pattern they share is also found in Brunoniaceae, Campanulaceae, Stylidiaceae, Menyan-

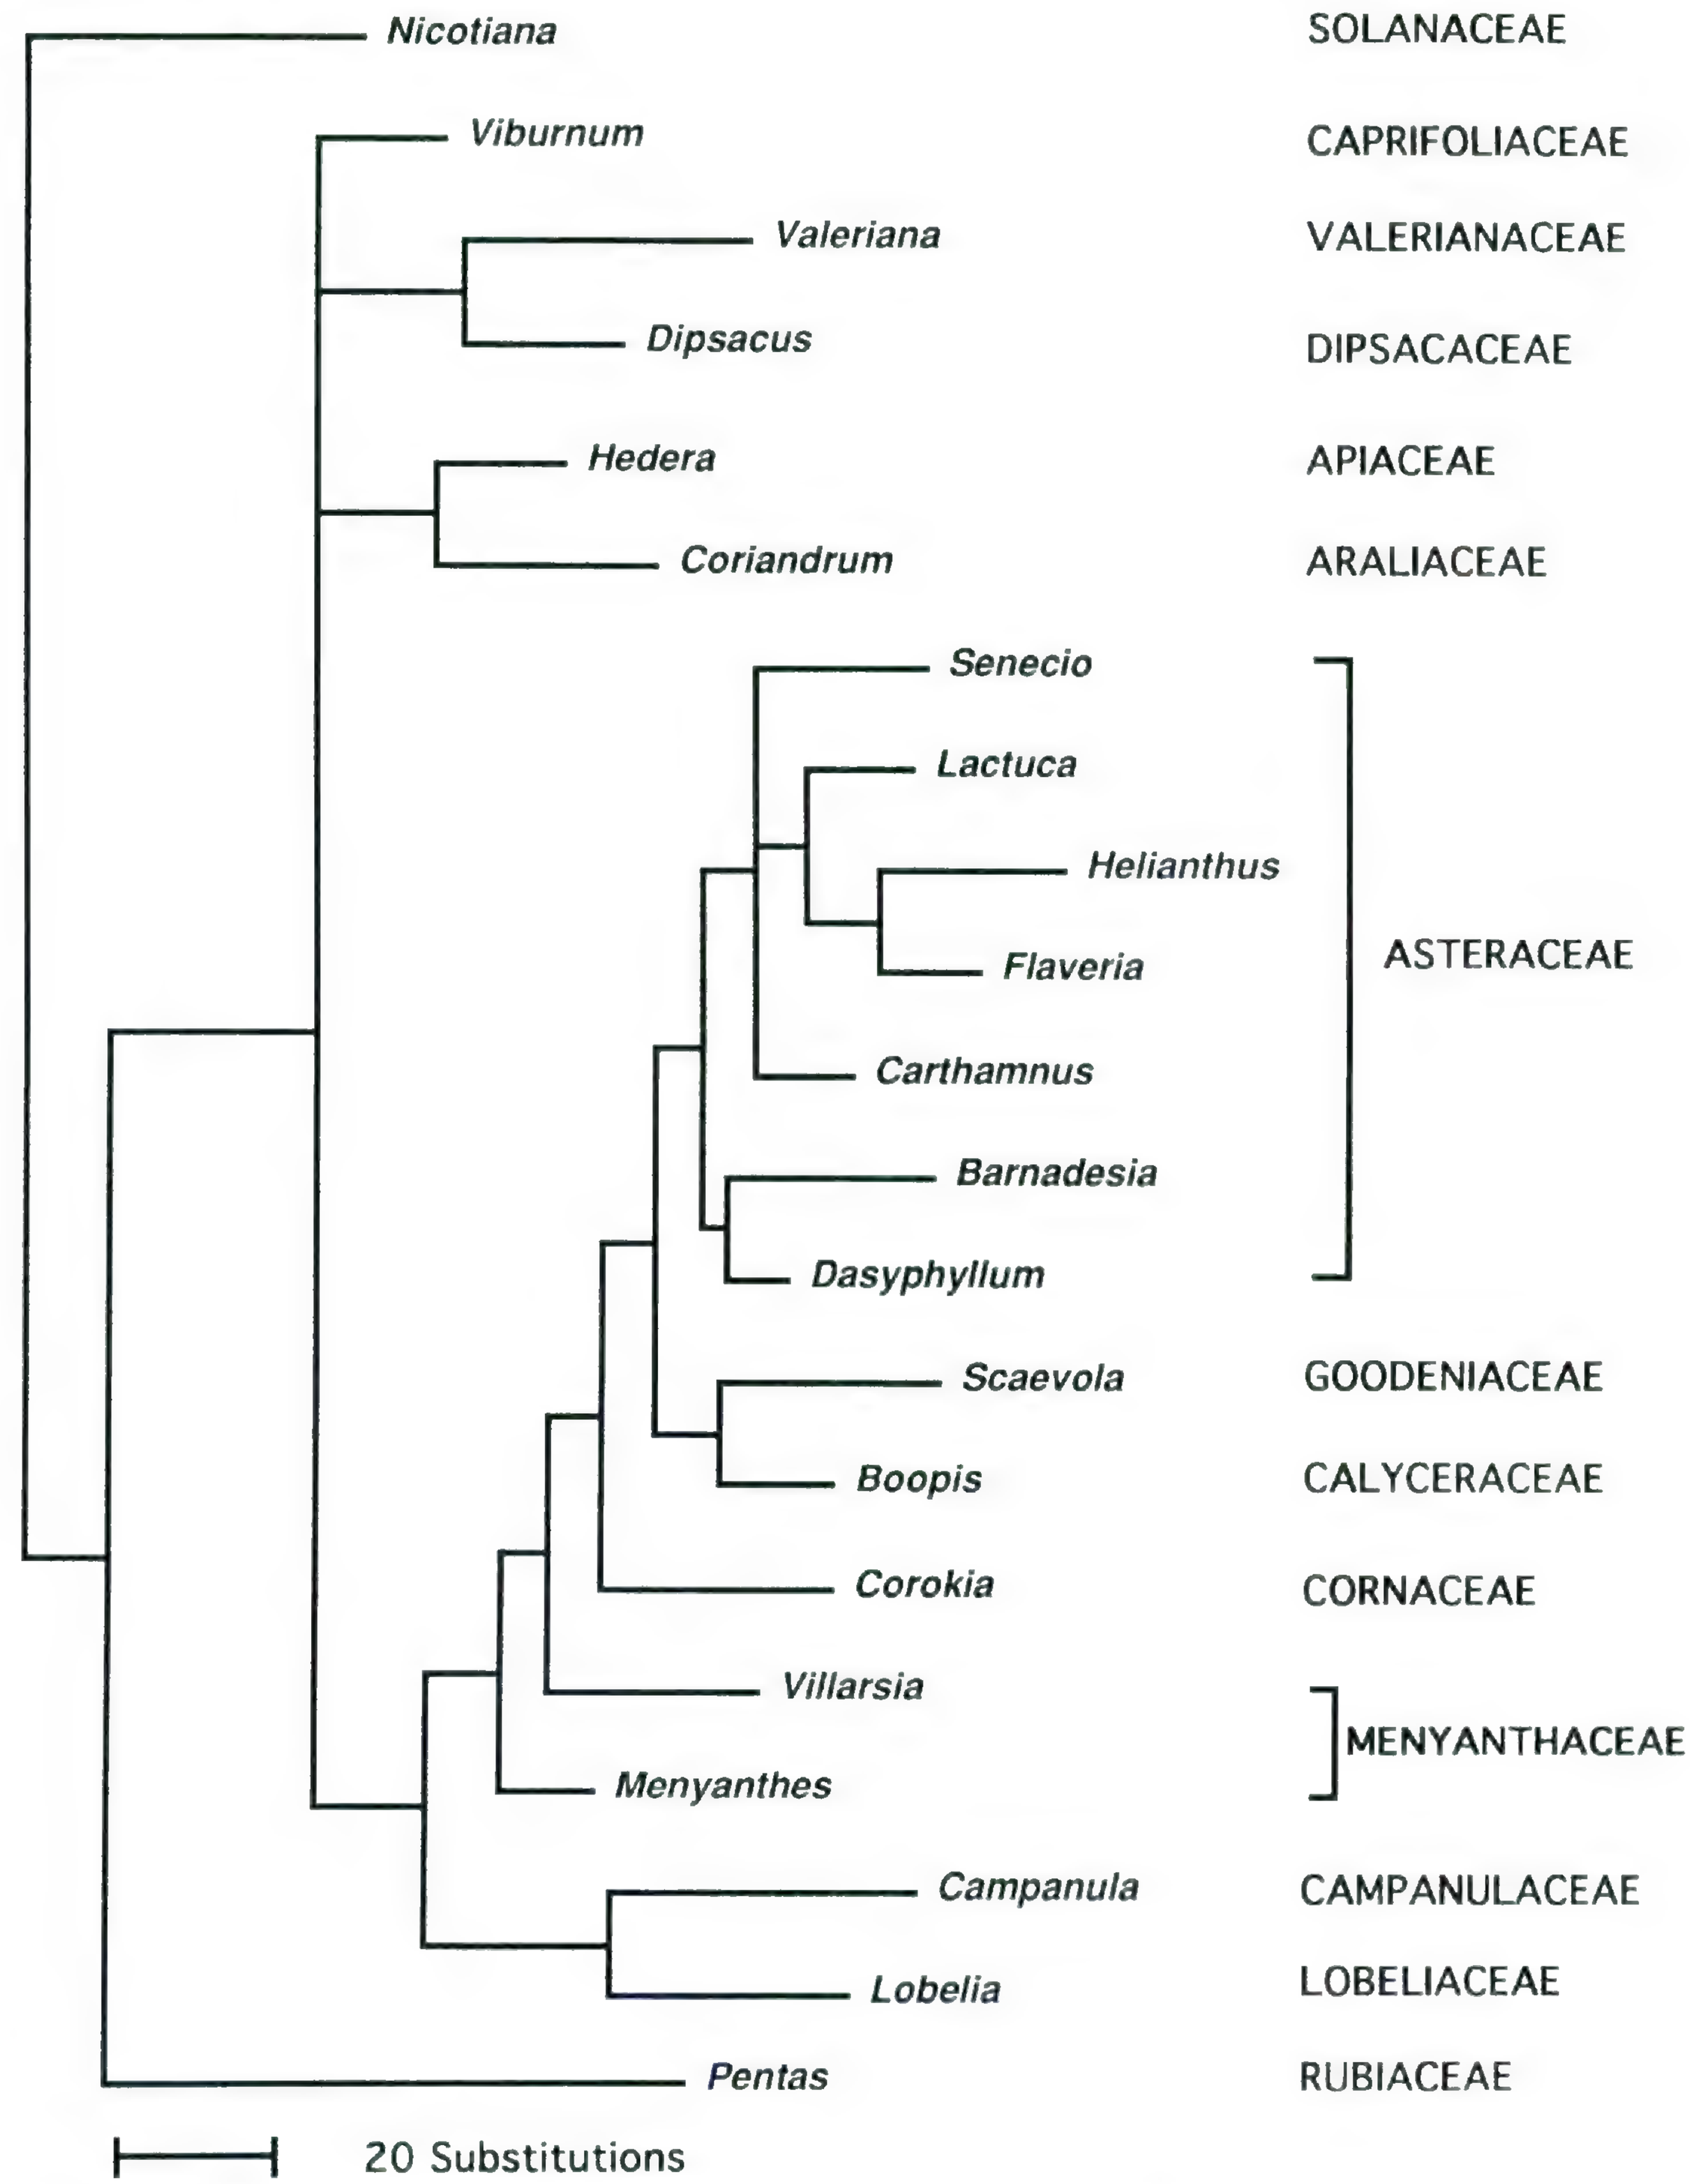

FIGURE 1. Strict consensus of four equally parsimonious trees (length = 833 steps, C.I. = 0.48, R.I. = 0.50) based upon *rbc*L sequences. Branch lengths are proportional to the number of nucleotide substitutions supporting a node or distinguishing a terminal lineage (note scale at bottom).

thaceae, Rubiaceae, and families of the Dipsacales (Erbar & Leins, 1989), and therefore this is probably a plesiomorphic character. Chemical characters such as carbohydrate storage as inulin (in Asteraceae, Calyceraceae, and Goodeniaceae, as well as Menyanthaceae, Campanulaceae, and Lobeliaceae; Pollard & Amuti, 1981) and phenolics (e.g., caffeic acid in Asteraceae, Calyceraceae, and

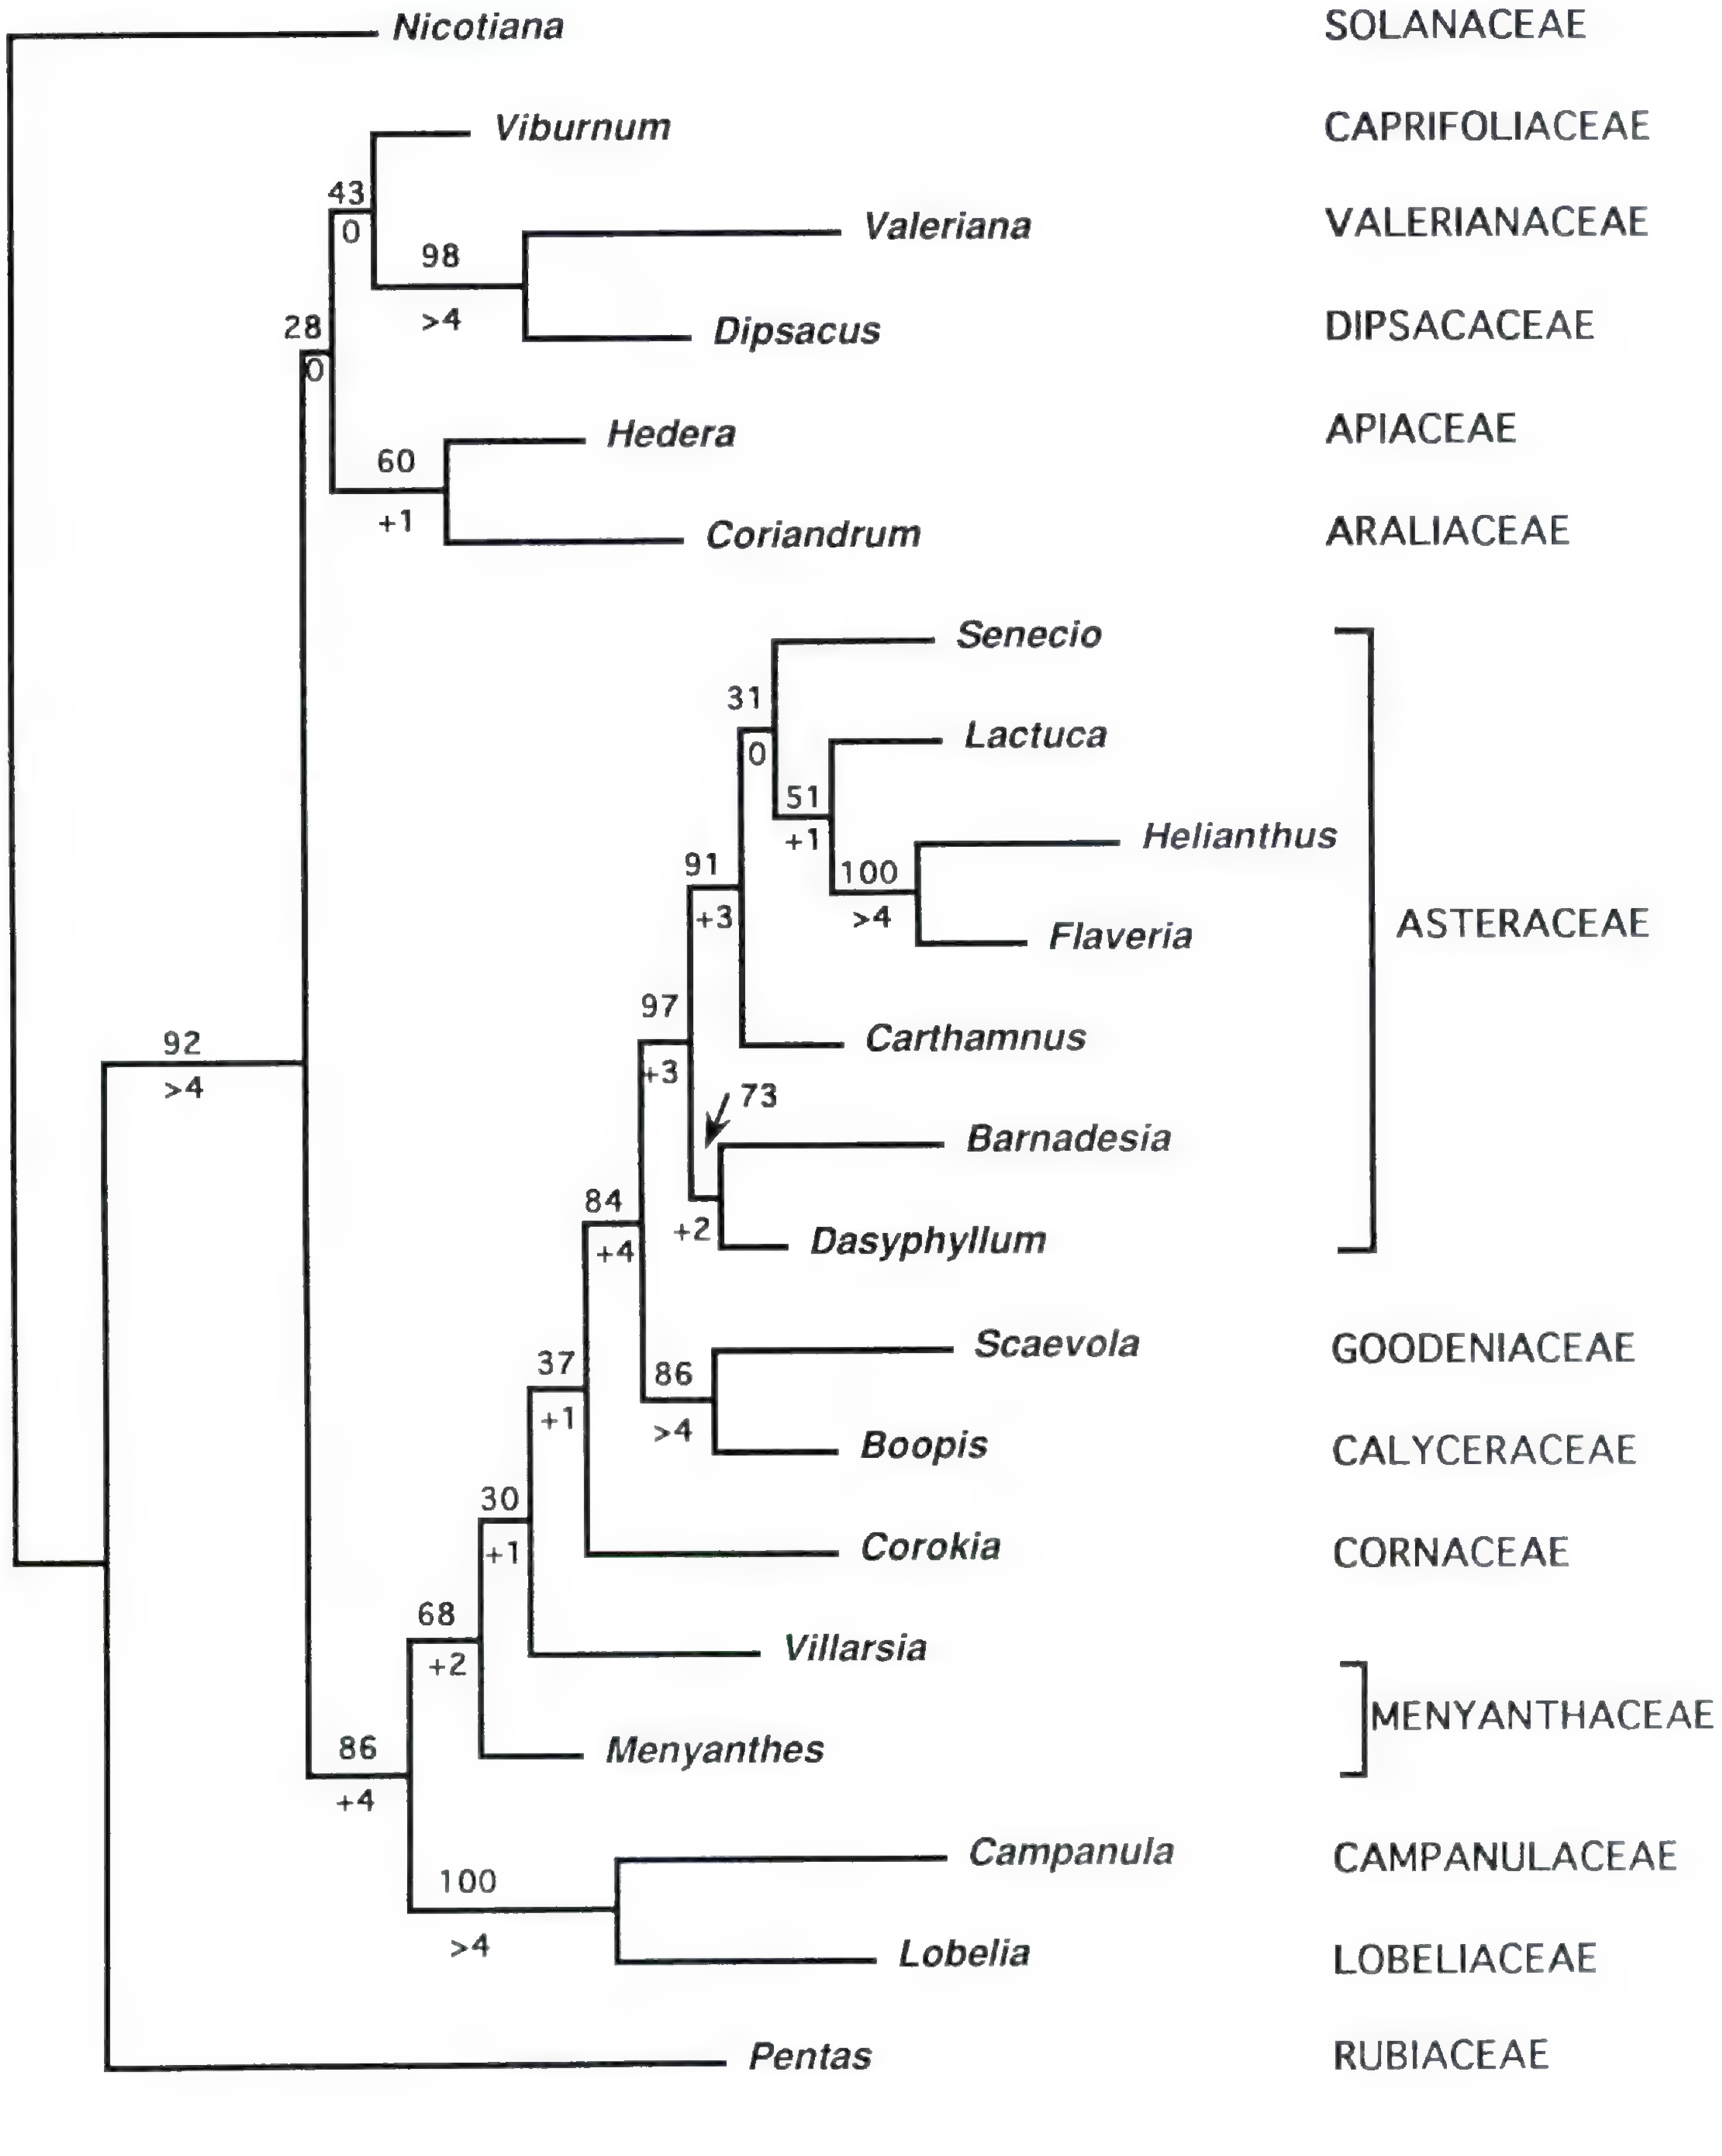

FIGURE 2. One of the four equally parsimonious trees based upon *rbc*L sequences with the results of the bootstrap and decay analyses. Branch lengths are proportional to the number of nucleotide substitutions supporting a node or distinguishing a terminal lineage (note scale at bottom). Bootstrap values from 500 replications are indicated above the branches. Numbers below indicate numbers of additional steps needed for a branch to collapse.

Goodeniaceae, as well as Menyanthaceae and Campanulaceae; Lammers, 1992) further support the position of the Goodeniaceae and Calyceraceae. Asteraceae, Goodeniaceae, and Calyceraceae also lack endosperm haustoria, have binucleate tapetal cells, and produce herbivore defenses through the mevalonate pathway, characters that are also shared with Menyanthaceae, but are absent from Campanulaceae and Lobeliaceae (Lammers, 1992).

Several other characters specifically support the sister placements of Goodeniaceae or Calyceraceae alone. Polyacetylenes, which are characteristically found in the Asteraceae, have also been reported from some Campanulaceae (Ferreira & Gottlieb, 1982), Lobeliaceae, and one Goodeniaceae (Lammers, 1992). Their distribution in Calyceraceae, Menyanthaceae, or other families that place near the Asteraceae in our analysis is unknown. The Calyceraceae were proposed as a sister group to the Asteraceae by Jeffrey (1977). Evidence in support of the placement of Calyceraceae seen in our *rbc*L analyses derives from chloroplast DNA restriction site data (Downie & Palmer, 1992a; unfortunately, due to their unusual genome organization, Goodeniaceae could not be included in this study) and floral development, as noted above, but also from pollen morphology, capitulum structure, and biogeography. Skvarla et al. (1977) concluded that the ultrastructure of Calyceraceae exine is nearly identical to that of the Asteraceae, while the Goodeniaceae are among five families listed with pollen similar enough to "suggest distinct linkages." As previously advocated by Turner (1977), the structurally homologous capitula and floral features, and congruent core distributions of the Asteraceae and Calyceraceae in South America are particularly compelling arguments supporting a shared phylogenetic history.

This analysis suggests a particularly strong sister-group relationship for the Goodeniaceae and Calyceraceae, occurring in 86% of the bootstrap trees. This clade also remained intact throughout the decay analysis, a level of association seen only in other groups that have traditionally been strongly linked (e.g., *Helianthus* and *Flaveria* in the Heliantheae; Campanulaceae and Lobeliaceae; Dipsacaceae and Valerianaceae). As noted above, the Goodeniaceae and Calyceraceae are united by several characters, including pollen-presentation mechanism, floral development, pollen embryology, and secondary chemistry (e.g., seco-iridoids; Lammers, 1992). The *rbc*L trees and above evidence supporting the placement of the Goodeniaceae (a small family of 325 species distributed primarily in Australia and Tasmania) and the South American Calyceraceae are consistent with Turner's (1977) proposal of a Gondwanaland origin for the Asteraceae. Indeed, all the closest groups from Menyanthaceae to Goodeniaceae are distributed primarily in the Southern Hemisphere.

The *rbc*L gene was recently sequenced from two families previously suggested to have affinities with the Asteraceae (Olmstead et al., 1992). Both the Apiaceae (*Hedera*) and Araliaceae (*Coriandrum*) have been proposed as close associates of the Asteraceae based upon shared phytochemistry (Hegnauer, 1964, 1977). However, Lammers (1992) has argued that the synthesis of sesquiterpene lactones in these groups is due to parallel evolution. Parsimony analyses of *rbc*L indicate that, although neither is closely related to the Asteraceae, these groups do belong in the Asteridae rather than in their more traditional position in the Rosidae (Olmstead et al., 1992, 1993; Chase et al., 1993).

Although neither Menyanthaceae nor Cornaceae have ever been allied with the Asteraceae based on traditional data, they were included in this study because other recent chloroplast DNA analyses suggested close relationships. Based on *rbc*L sequences, Olmstead et al. (1992) found an unexpected association of the Menyanthaceae with the families more typically suggested to have affinities with the Asteraceae. A survey of restriction sites in the chloroplast DNA inverted repeat (Downie & Palmer, 1992a) also places the Menyanthaceae along with the Calyceraceae and Asteraceae. The most parsimonious solutions from Olmstead et al. (1992, 1993), which are based on a much larger sampling of taxa within the Asteridae, are consistent with the results reported here. Although Menyanthaceae are nearer to the Asteraceae than either the Campanulaceae or Lobeliaceae in this study, Calyceraceae retain the sister position (Goodeniaceae were not included in the Asteridae analyses of either Olmstead et al., 1992, or Downie & Palmer, 1992a). Several features shared by Menyanthaceae, Calyceraceae, and Goodeniaceae (the production of seco-loganin, carbohydrate storage as inulin, presence of multinucleate tapetal cells, absence of endosperm haustoria, and chromosome numbers based upon $x = 8$ or 9; Lammers, 1992) are consistent with the placement of Menyanthaceae in these analyses.

In addition, the analyses of Morgan & Soltis (1993) and Chase et al. (1993) indicate an unsuspected affiliation of *Corokia* (Cornaceae sensu lato) with the asteralean clade. The association of *Corokia* with Asteraceae and its near relatives was

confirmed in our analyses, which are more likely to produce optimal solutions, while the computational difficulties of the much larger analyses (Chase et al., 1993; Morgan & Soltis, 1993) may have precluded discovery of shortest trees. This radical departure from previous placements of *Corokia* (in Escallonioideae, Saxifragaceae sensu lato, Engler, 1928; in Cornaceae, Eyde, 1966 and Cronquist, 1988; or in Araliaceae, Phillipson, 1967) is consistent with several other characters: (1) biogeography (*Corokia* is distributed primarily in New Zealand and Australia; Eyde, 1966), (2) some aspects of morphology (inferior ovary, locules 1–3 with a single, apical, unitegmic ovule, and multicellular, T-shaped trichomes, found elsewhere only in the Asteraceae and three other unrelated families; Eyde, 1966), and (3) chemistry (presence of iridoids in Escallonioideae; Dahlgren et al., 1981). See also Morgan & Soltis (1993) for further discussion of evidence linking genera of the Escallonioideae with Asteridae. These unanticipated associations not only illustrate the heuristic value of the broader analyses and the benefits of widespread data sharing, but also motivate the acquisition of additional data from other sources that may corroborate these new hypotheses of relationships. For example, studies of floral developmental patterns, pollen ultrastructure and development, and embryogeny in Menyanthaceae and *Corokia* would be a logical direction for future work.

Finally, although many families that have been previously considered as serious contenders for sister group to the Asteraceae have been investigated in this study, several others remain to be examined. In particular, Brunoniaceae and Stylidiaceae have been associated with Asteraceae and Campanulaceae in Takhtajan's (1987), Wagenitz's (1977), and Thorne's (1992) classifications. Both are distributed primarily in Australia and share the floral developmental features found in Asteraceae, Campanulaceae sensu lato, Goodeniaceae, and Calyceraceae (Erbar, 1991). Brunoniaceae also possess a similar pollen-presentation mechanism to those found in the first three of these families (Leins & Erbar, 1990). Any comprehensive attempt to further explore the origins of the Asteraceae should include several other, poorly understood small families that have also been associated with Campanulales (Pentaphragmataceae, Cyphiaceae, and Sphenocleaceae; Lammers, 1992). The addition of data from these groups is likely to provide new insights into the phylogeny of the Asteraceae and further resolve the current picture of relationships of this distinctive lineage.

# CHARACTER-STATE WEIGHTING FOR CLADISTIC ANALYSIS OF PROTEIN-CODING DNA SEQUENCES[1]

*Victor A. Albert,*[2,3] *Mark W. Chase,*[2,4] *and Brent D. Mishler*[5]

## ABSTRACT

Nucleotide data are a restricted character system complex enough to confound phylogenetic analyses yet simple enough to permit establishment of probability models for sequence change and corresponding character-state weighting schemes. We have previously developed a general method for weighting DNA data that is here elaborated for protein-coding sequences. Included in the present model are corrections for (i) multiple substitution events, (ii) transition/transversion bias, and (iii) differential proportions of changes occurring at first, second, and third codon positions. This model is shown to be generally consistent for all phylogenetically useful data. Greater understanding of the properties of equal versus differential character-state weighting comes from consideration of numbers of terminal taxa and lengths of tree segments. With insufficient sampling of taxa, differential weighting attempts to correct for undetected multiple substitution events. Both equal and differential weighting should give the same result if sufficient numbers of terminal taxa permit the detection of historically misleading character-state changes. Nevertheless, spurious attraction of tree segments remains a systematic problem that is not easily resolved either by equal weighting or by our differential weighting model, which acts globally rather than adjusting for different probabilities of character-state change among tree segments. Artifactual segment attraction is best understood in terms of asymmetries in $\lambda$ (which represents state changes per character during a particular segment interval). We relate the consistency index to numbers of terminal taxa and $\lambda$, illustrating its dependence upon numbers of potential tree segments. Prospects for phylogenetic reconstruction from protein-coding nucleotide data are discussed with reference to the robustness of equal weighting (given our own model) with adequate taxonomic sampling.

Information derived from nucleotide sequences is becoming increasingly popular for phylogenetic studies, partially because of technological advances (such as automatic temperature cyclers and thermostable polymerases) that permit rapid and extensive data gathering. The deceptively simple properties of DNA data and their promise of more reliable phylogenetic hypotheses have changed the research emphasis of many systematists. DNA variation can indeed provide valuable characters for phylogenetic reconstruction when treated with an appropriate understanding of its properties, but it is not a panacea for phylogenetics (contra Gould, 1985). Reflecting perhaps a lack of understanding of first principles, too many cladograms derived from both molecular and morphological data are appearing in the literature without justified character analysis or choice of optimality criterion. Although our current understanding of molecular biology may be superior to that of the ontogeny and heritability of most morphological characters, "simple" molecular phenomena such as multiple substitution at particular sites (e.g., Brown et al., 1982) and paralogy in multigene families (Fitch, 1970) can confound phylogenetic analysis.

The apparent simplicity of DNA data in comparison with other data forms can be misleading. The pattern of DNA variation *is* simpler compared to most morphological data in that there are four basic character states (the nucleotides A, C, G, and T) with no intrinsic ordering into a transformation series. However, evolutionary independence of nu-

cleotide positions (a requisite if they are to be used as characters in cladistic analysis) cannot be automatically assumed. Protein-coding sequences are organized into triplet nucleotide codons that may be positionally intra- and interdependent because of constraints imposed by the genetic code and the function of the encoded protein. Such constraints may produce unequal and correlated probabilities of substitution among nucleotide positions (see Fitch & Markowitz, 1970; Fitch, 1986). Positional homology of nucleotides may be relatively easy to determine, but hypotheses of *character-state* homologies can be confused by multiple, undetected substitutions, which are themselves drawn from the same four possible states. Despite these underlying complexities, it has been possible to derive simple probability models that mimic properties of sequence evolution (e.g., Albert & Mishler, 1992; Albert et al., 1992; DeBry & Slade, 1985; Felsenstein, 1981a, 1992; Hendy, 1989; Hendy & Penny, 1989; Lanyon, 1988; Templeton, 1983). Some of these models have, in turn, been applied to maximum-parsimony inference of cladistic relationships (e.g., Albert et al., 1992; Chase & Palmer, 1992; Donoghue et al., 1992; Gastony et al., 1992; Kadereit & Sytsma, 1992; Olmstead & Palmer, 1992; Spooner & Sytsma, 1992; Wendel & Albert, 1992).

Characters and character states for cladistic analysis of DNA sequences are derived from either indirect or direct sequence sampling. The most widely used indirect approach is mapping of restriction endonuclease cleavage sites. When a particular restriction site is found to be present in some terminal taxa and absent in others, an underlying sequence difference is implied de facto. Wagner parsimony (Farris, 1970; Kluge & Farris, 1969) places no restrictions on underlying patterns of nucleotide substitution. In contrast, the Dollo criterion (Farris, 1977; see also Farris, 1983: 24–26) will not recognize substitutions that could lead to parallel gain of a recognition sequence, although parallel losses are tolerated. In a previous paper, we developed a character-state weighting scheme that treats both forms of homoplasy relative to differential probabilities of gain versus loss estimated for individual restriction sites (Albert et al., 1992).

The reasoning developed by Albert et al. (1992) was extended to direct sequence sampling by Albert & Mishler (1992); a character-state weighting scheme was erected to recognize the asymmetrical probabilities of transversion versus transition substitutions within nucleotide characters. Here, the model of Albert & Mishler (1992) is modified to incorporate asymmetrical probabilities of substitution among codon positions in protein-coding sequences. The model rests on the simplifying assumption of equal probability of change among first, second, and third codon positions (respectively). The model also provides a correction for multiple substitutions at particular positions and accommodates wide ranges of branch lengths, transition/transversion ratios, and codon position biases. After explaining the assumptions underlying our approach, we provide a heuristic examination of its properties by comparing it with the commonly used, equal-weighting parsimony criterion of Fitch (1971, 1977: a nonadditive, multistate generalization of the Wagner criterion; Farris, 1970; Kluge & Farris, 1969; cf. Swofford & Olsen, 1990). We evaluate consistency criteria in terms of permissible branch-length asymmetries and discuss expectations based on the number of taxa analyzed; branch length is incorporated into the consistency index (Kluge & Farris, 1969) to explain its dependence upon taxon number. We conclude with prospects for phylogenetic analysis of protein-coding sequence data, including the recognition that equal weighting is a robust assumption given a relatively even sampling of the true tree.

## The Model

Our previous character-state weighting models for restriction site (Albert et al., 1992) and nucleotide sequence data (Albert & Mishler, 1992) were designed for utility of execution. We have opted for simplified representations of the major known biasing factors in molecular evolution to provide generalized, robust weighting schemes employable with large numbers of taxa. Within-character weighting is easily accomplished by representing transformational costs between states in matrix form (Fitch & Ye, 1991; Sankoff & Cedergren, 1983; Swofford & Olsen, 1990; Williams & Fitch, 1989, 1990). As of this writing, stepmatrix weighting is available in PAUP 3.0 (Swofford, 1991), MacClade 3.0 (Maddison & Maddison, 1993), and a program available from Walter M. Fitch (Williams & Fitch, 1990). Application of stepmatrices is computationally expensive relative to Fitch parsimony because it requires dynamic programming (Sankoff & Cedergren, 1983; Swofford & Olsen, 1990). With PAUP 3.0, a single stepmatrix may be assigned to an entire data set, or individual stepmatrices may represent each character separately. If one understood how each nucleotide position bears on protein function, one could possibly assign individual probability models and individual weight-

ing stepmatrices over an entire sequence. This is not currently practical because it would require comparison across many taxa that in turn would have to be associated with a robust phylogenetic hypothesis. Furthermore, as will be shown below, minor heterogeneities in transformational probabilities have negligible effects on parsimony reconstructions.

## BRANCH LENGTH AND THE UNITS OF CHARACTER-STATE CHANGE

Branch length, $\Lambda$, refers to the total number of changes expected along a tree segment connecting either two nodes or a node to a terminal. In some models, including ours (Albert & Mishler, 1992; Albert et al., 1992; DeBry & Slade 1985), $\lambda$ is the symbol used to express branch length in per-character terms, i.e., $\Lambda = \Sigma \lambda_i$ over $I$ characters (where $\Sigma i = I$). This usage should not be confused with $\lambda$ = rate of character-state change with respect to time (a usage employed, for example, by Hendy, 1989; Hendy & Penny, 1989; Nei, 1987). That rate was referred to as $S_r$ by Albert et al. (1992), i.e., the *effective* substitution rate for a character (a nucleotide string of any defined length); effective substitutions are those that have been fixed in a lineage. The expected number of changes per character during a segment, $\lambda$, is thus equal to the product of the rate of change, $S_r$, and the time through which the branch existed, $T$. The units of time cancel, yielding a parameter that is expressed in terms of state changes per character per segment. Therefore, different combinations of rates and times can yield the same $\lambda$ value.

Observed mean branch length over all characters and all segments ($\bar{\lambda}$) can be used to estimate $\lambda$ under the simplifying assumption that all segments are of equal length (see discussion below on effects of unequal segment lengths). Because the number of segments in an unrooted tree is $[2n - 3 - p]$, where $n$ = the number of taxa, and $p$ = the number of segments in excess of 3 per node (i.e., polytomies),

$$\bar{\lambda} = \Delta/([2n - 3 - p]I) \qquad (1)$$

where $\Delta$ is the number of character-state changes observed over an entire tree and $I$ is the number of characters represented. An average $\lambda$ may also be estimated for the $i$th character over all segments:

$$\bar{\lambda}_i = \Delta_i/[2n - 3 - p] \qquad (2)$$

Likewise, branch lengths may represent averages for a specific set, $A$, of all characters $I$:

$$\bar{\lambda}_{I_A} = \Delta_{I_A}/([2n - 3 - p]I_A) \qquad (3)$$

Expression (1) was the strategy used by Albert et al. (1992) and recommended by Albert & Mishler (1992) for estimating $\bar{\lambda}$ values from DNA sequence data optimized onto robust, a priori cladistic hypotheses based on other character systems (see below). For the present purpose, however, individual $\bar{\lambda}_{I_i}$ values for each codon position are required. The simplest way to produce such values is to partition $\bar{\lambda}$ estimates with three multipliers ($\alpha_1$, $\alpha_2$, $\alpha_3$) representing the fraction of substitutions per codon position observed on an a priori topology.

## PROBABILITIES OF CHARACTER-STATE TRANSFORMATIONS

The premise behind the nucleotide character-state weighting model described by Albert and Mishler (1992) is that the probability of observing a transition is different (greater, in most cases) from that of observing a transversion. This asymmetry can be estimated by phylogenetic comparisons of sequences; nucleotide state changes are optimized onto an a priori cladogram, which provides a "phylogenetic correction" for multiple substitutions (Albert and Mishler, 1992; Albert et al., 1992). The phylogenetic correction does not reflect *all* substitutions that have occurred, only those that are effectively fixed in lineages and are observable given the taxa sampled (as will be discussed in detail below, if too few taxa are sampled, many multiple substitutions will go undetected). The Kimura two-parameter model (K2P; Kimura, 1980), which was designed to take into account transition and transversion information in order to estimate net substitutions in pairwise comparisons, provides a similar, albeit slightly higher, estimation of substitutions than does the phylogenetic estimate mentioned above (Albert et al., 1992). The K2P model has been reoriented for estimating transformational probability on phylogenetic trees by Swofford & Olsen (1990; in terms of transition and transversion rates) and by J. Felsenstein (cited in Albert & Mishler, 1992). Felsenstein's formulations are more useful for the present purpose because there are only two parameters—$\lambda$ and transition/transversion ratio (R):

$$P_{xi}(T) = \tfrac{1}{4} + \tfrac{1}{4}\exp\left[-\lambda\frac{1}{(\tfrac{1}{2})(1 + R)}\right] - \tfrac{1}{2}\exp\left[-\lambda\frac{(\tfrac{1}{2}) + R}{(\tfrac{1}{2})(1 + R)}\right] \qquad (4)$$

where $xi$ indicates that the probability is for a particular *transition*, and

$$P_{xv}(T) = \tfrac{1}{4} - \tfrac{1}{4}\exp\left[-\lambda\frac{1}{(\tfrac{1}{2})(1 + R)}\right]; \quad (5)$$

where $xv$ indicates that the probability is for a particular *transversion*.

Determining differential transformational probabilities for each of the three codon positions requires partitioning $\bar{\lambda}$ with the $\alpha_1$, $\alpha_2$, and $\alpha_3$ multipliers. As a result, three separate calculations for both expressions (4) and (5) are required. The partitioned $\bar{\lambda}\alpha$ values used here assume equal probabilities of character-state change within all first, second, and third codon positions, respectively. These probabilities only consider change as a function of entire trees (through the use of $\bar{\lambda}$); no adjustment is made for individual segments. These assumptions, although defensible as a first approximation, are simplifications relative to the covarion and covariotide hypotheses (Fitch & Markowitz, 1970; Fitch, 1986; cf. Hendy & Penny, 1989; Fitch & Ye, 1991) and branch-length asymmetries that may be present on true trees.

## CHARACTER-STATE WEIGHTS

Transformational probabilities and their corresponding character-state weights share a simple mathematical relationship. In fact, the following historical discussion highlights a conceptual link between maximum parsimony and maximum likelihood approaches to phylogenetic inference. In his Bayesian approaches to cladistic analysis, Farris (1973, 1977, 1978, cf. 1983, 1986) examined the posterior probability of a phylogenetic hypothesis—$P(hypothesis|data)$—through its proportionality to the joint probability—$P(hypothesis, data)$—for a given data matrix. This follows from Bayes's (1763) theorem of conditional probability:

$$P(hypothesis|data) = [P(data|hypothesis)P(hypothesis)]/P(data) \quad (6)$$

From expression (6), the following simplification can be made:

$$P(hypothesis|data) = [P(hypothesis,data)]/P(data) \quad (7)$$

For a particular parsimony analysis, the prior probability of the data, $P(data)$, is constant and the prior probability of a particular maximum parsimony tree, $P(hypothesis)$, may be considered equal over all such trees. Farris's derivation of $P(hypothesis,data)$ was expressed as repeated products of state transformation probabilities and their assignments to tree segments over all characters. Thus, $-\ln[P(hypothesis,data)]$ took the form of summation of these statements; by the nature of logarithms, minimizing the latter expression (and so tree length) is equivalent to maximizing the former (i.e., finding the tree length of greatest probability). Log-transformed probability factors not solely dependent upon the data matrix were considered to represent weights for character-state changes. Summation of these weights over all characters and their segment assignments (i.e., to produce a weighted tree-length) was interpreted as identical to the weighted parsimony criterion of Kluge & Farris (1969). Thus, taking the natural logarithm of $P(hypothesis,data)$ permits calculation of both character-state weights and the minimum number of weighted steps required to produce the most probable (i.e., most parsimonious) tree.

A similar argument for logarithmic conversion of probabilities into weights comes from maximum likelihood inference (Felsenstein, 1981b; cf. critique by Farris, 1983). From Bayes's theorem (Bayes, 1763; expression 6), likelihood—$P(data|hypothesis)$—is also proportional to the joint probability $P(hypothesis,data)$, but through $P(hypothesis)$ rather than $P(data)$:

$$P(data|hypothesis) = [P(hypothesis,data)]/P(hypothesis) \quad (8)$$

Likelihood depends entirely upon the model constructed for $P(hypothesis)$, as evident from different interpretations of the relationship between likelihood and parsimony obtained under different models (Farris, 1973; Felsenstein, 1973; cf. Sober, 1988). Felsenstein's likelihood justification of parsimony (1981b; see also Sober, 1988) involved a simple probability model in which binary data were assumed to contribute the bulk of the likelihood via a single (versus homoplastic) reconstruction of character states. In finding the maximum of the likelihood (nested repeated products), it is customary to find the natural logarithm of the expression (to produce nested summations and simpler calculation of minima; cf. Swofford & Olsen, 1990). Under Felsenstein's assumption of low rates of change (see discussion below), the log-likelihood term for a change of character $i$ in segment $j$ is simply $\ln(\lambda_{ij})$, based on Felsenstein's notation (1981b, his equations 4 and 5). The logarithm of $\lambda_{ij}$ will be negative when $\lambda_{ij} < 1$ and becomes more so as branch length decreases. Felsenstein (1981b) interpreted $|-\ln(\lambda_{ij})|$ values to represent the weights for such changes. Large weights reflect small probabilities of character-state change and vice versa (precedents for this relationship exist,

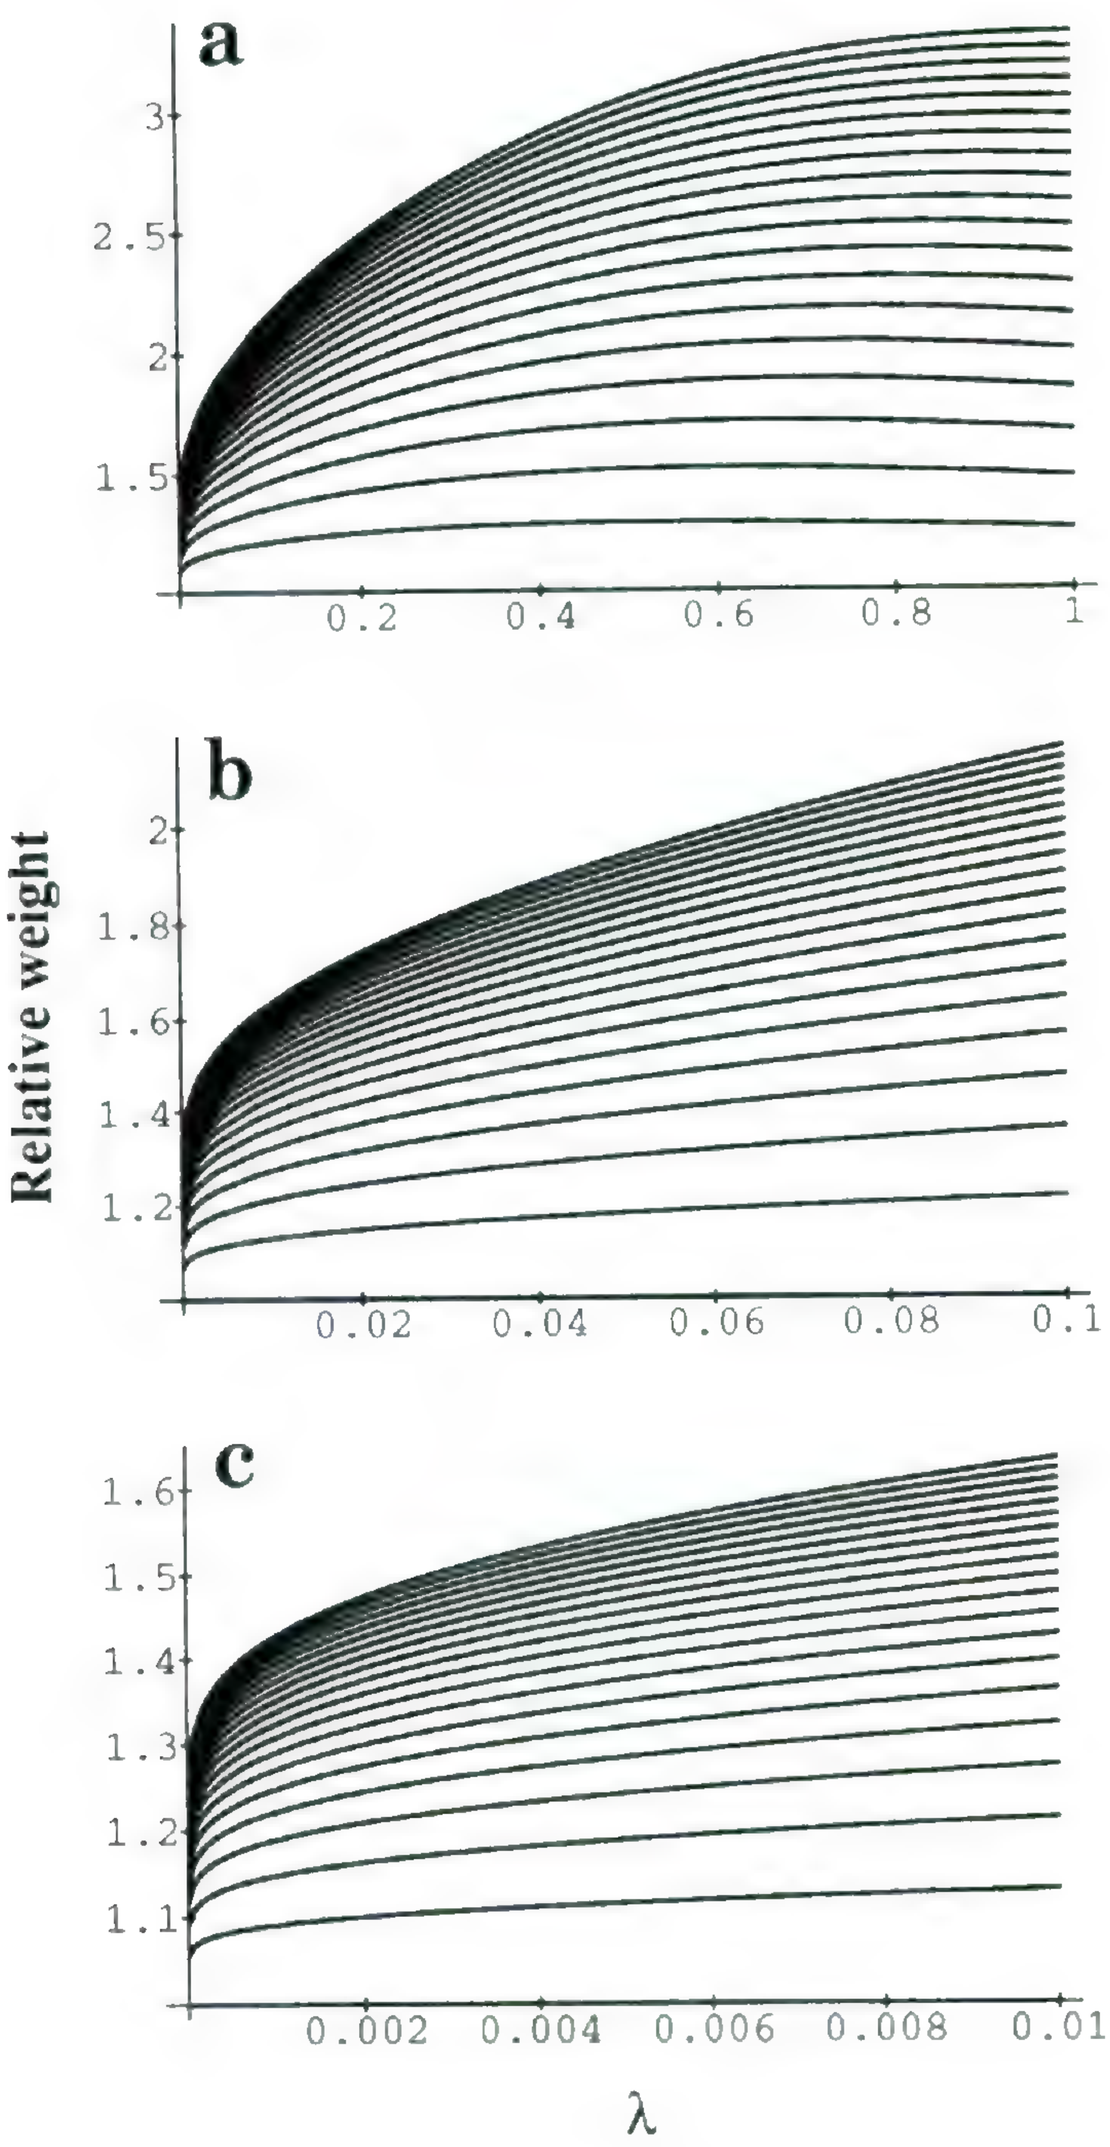

FIGURE 1. Relative weight of nucleotide character-state transformation (transversion weight divided by transition weight; Y axis) as a function of λ (X axis) and differential transition/transversion ratios (represented by the individual curves). λ values between 0 and 1.0 are represented in a; the smaller ranges from 0 to 0.1 and 0 to 0.01 are represented in b and c, respectively. Weights were determined from the ratio of the negative natural logarithms of probabilities obtained from expressions (5) and (4). Transition/transversion ratios evaluated (shown in increasing order along the X axis) were 0.5 (the ratio for randomness from a given starting nucleotide; thus, the result lies directly on the X axis, indicating equal weight) through 10.0 in increments of 0.5.

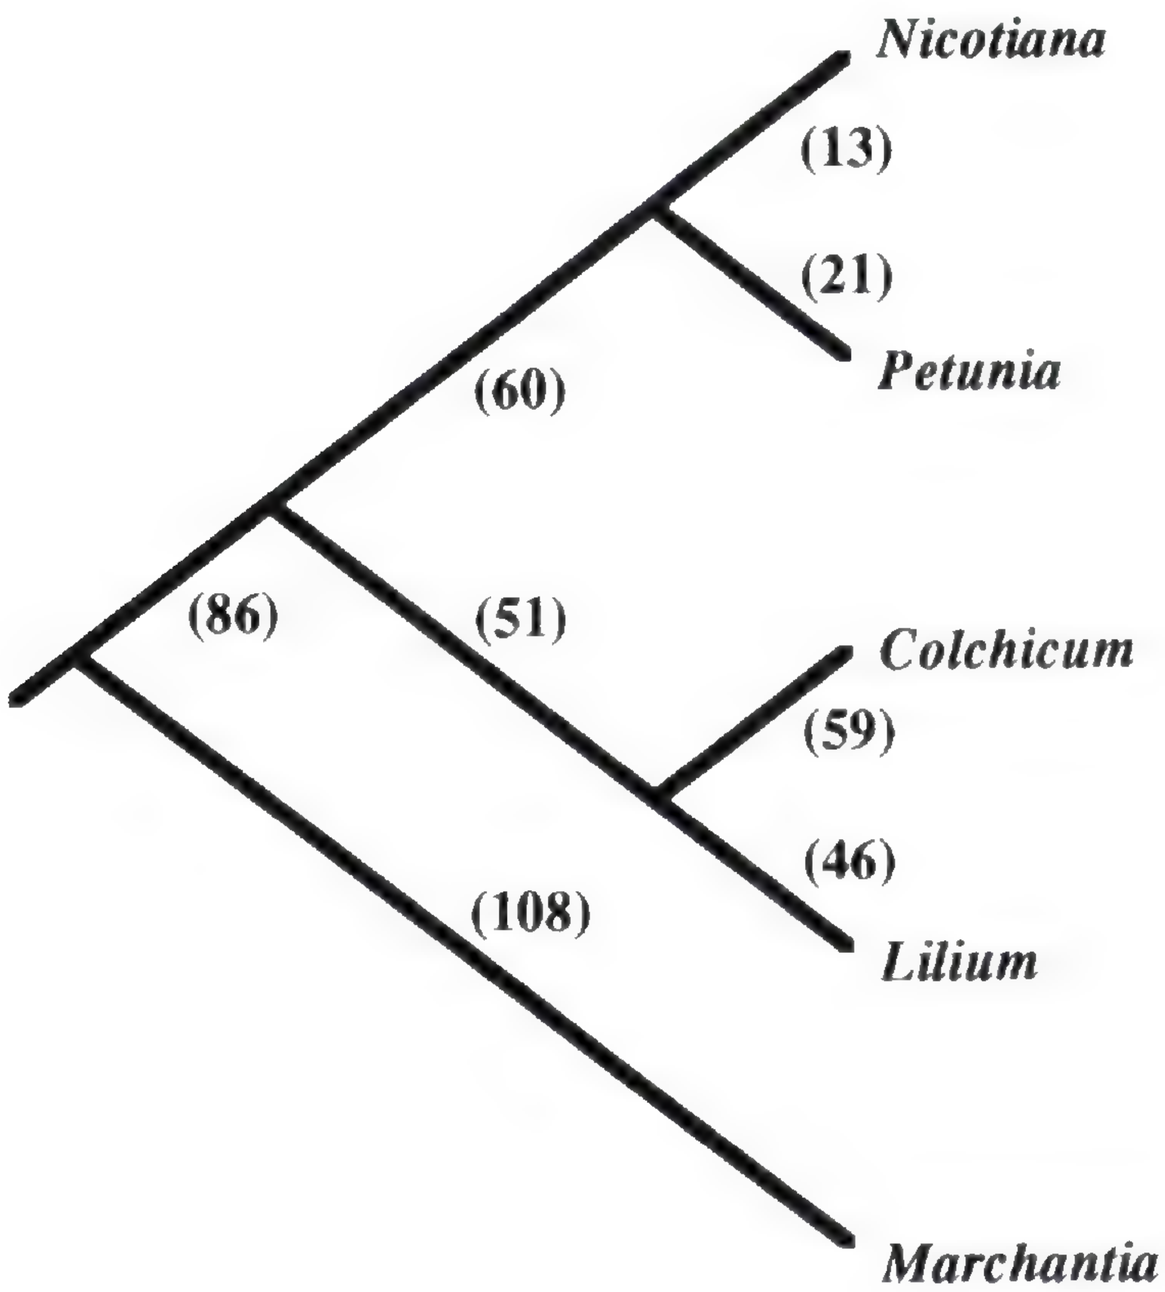
although suggested on other grounds or under different models; Farris, 1966, 1969, 1977, 1978; Kluge & Farris, 1969). Because likelihood inference chooses the topology that maximizes the likelihood, character-state changes with relatively large weights will be preferentially avoided (Felsenstein, 1981b). Maximizing the logarithm of the likelihood minimizes the sum of the weights of all character-state changes: hence the justification for weighted parsimony, which de facto minimizes the contribution of strongly weighted state transformations.

For the present model, character-state weights for a transversion over a transition are the ratios of the negative natural logarithms of expression (5) probabilities to those of expression (4). The behavior of these weights under a range of values for λ and R can be examined using two-dimensional plots (Albert & Mishler, 1992). In Figure 1, curves representing transition/transversion ratios (R) between 0.5 (parity) and 10 are shown as λ increases continuously from 0 to 1 (the ranges 0 → 0.01, 0 → 0.1, and 0 → 1 are shown separately). As would be expected, the weight approaches 1 as λ becomes smaller. The effect of increasing R is immediately apparent: as transitions become proportionally more frequent, a higher relative weight is assessed to a transversion. Another property of the weighting model is that the relative weight range for transversions over transitions is extremely shallow when λ is small (i.e., < 0.1). Albert et al. (1992) considered λ in some detail from a heuristic mathematical perspective and concluded that λ values ≤ ≈0.1 should be the limit for data that could be expected to reflect phylogenetic history (a λ of 0.1 is equivalent to 1 out of 10 characters changing per tree segment, on average). Under such conditions, $\bar{\lambda}\alpha$ partitions cannot yield substantially different codon position weights using any reasonable value of R (Fig. 1).

## INITIAL WEIGHTS FROM A PRIORI INFORMATION

Because the transversion/transition weight range is so small over all reasonable λ and R values, one could simply use weights (partitioned with appropriate $\bar{\lambda}\alpha$ values) that span this range (i.e., between 1 and ca. 2.2; Fig. 1b) in a series of analyses to search for robust topologies (see Albert et al., 1992). An alternative is to use a priori approximations of $\bar{\lambda}$, transition/transversion ratio, and proportions of substitutions among codon positions to provide initial weighting criteria for a single, optimal phylogenetic reconstruction. Such estimates of $\bar{\lambda}\alpha$ and R values are best derived by optimizing sequence data onto topologies accepted a priori based on robust cladistic analyses of other character systems; attempting to derive estimates solely from the data matrix at hand risks circular reasoning (see Albert & Mishler, 1992; Albert et al., 1992). If such estimates are to be useful, the a priori topology must be encompassing relative to the data to be analyzed, circumscribing variation within it



**total positions = 1398**
**total changes = 444**
**segments = 8**

**transitions = 267**
**transversions = 177**
**1st position changes = 75**
**2nd position changes = 32**
**3rd position changes = 337**

FIGURE 2. "Land plant" tree, modified from Albert et al. (1992). Accepted a priori based on robust cladistic analyses of morphological, anatomical, and biochemical information. Sequence data for *rbc*L (1,398 putatively homologous positions; corrected for 30-bp, 5′-primer nucleotides from the 1,428 positions used by Albert et al., 1992) were constrained to fit this rooted topology using ACCTRAN optimization (Swofford & Maddison, 1987). The numbers in parentheses at each of the 8 tree segments indicate the hypothesized numbers of character-state changes, totalling 444 for the entire tree. Thus, $\bar{\lambda}$ = 444/8/1,398 (= 0.0397). From inspection of the types of substitutions involved in these changes, R = 267/177 (= 1.5085), $\alpha_1$ = 75/444 (= 0.1689), $\alpha_2$ = 32/444 (= 0.0720), and $\alpha_3$ = 337/444 (= 0.7590). These values were used to estimate character-state weights for heuristic comparison with equal weights in parsimony analysis of nucleotide data (see Table 1).

using selected representatives and outgroups. To be trustworthy, the $\bar{\lambda}$ inferred should be less than ≈0.1, and R should be greater than 1 : 1.

The latter conditions return us to consideration of the number of tree segments. An a priori topology with few segments is expected to give conservative (i.e., relatively even) weight estimates. For example, with increasing phylogenetic depth (e.g., angiosperms analyzed together with *Marchantia* or also with *Chlamydomonas*; Albert et al., 1992), the excess of observable transitions (relative to transversions) becomes lower (probably due to multiple substitutions occurring at the same site despite the mutational bias favoring transitions; cf. Brown et al., 1982; Gojobori et al., 1982; Li et al., 1984), and first and second codon positions accrue larger proportions of total substitutions (many of which are probably amino acid replacement substitutions in contrast to third position "silent" substitutions; Albert et al., 1992; see also Brown et al., 1982).

Despite the restricted number of segments available for estimating effective substitutions and their asymmetries, the "land plant" tree of Albert et al. (1992; Fig. 2) is a robust, a priori topology. Albert et al. (1992) optimized *rbc*L sequence data onto this tree to derive values for use with their restriction-site weighting model. The plastid *rbc*L gene (which encodes the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase) has been sampled extensively for evidence of seed-plant relationships (see Chase et al., 1993, and other papers in this issue). Transformational probabilities and weights that may be relevant to such phylo-

TABLE 1. Character-state weights for *rbc*L sequences based on the "land plant" tree of Albert et al. (1992). State transformation probabilities, $P$, and corresponding character-state weights, $-\ln(P)$, for transition and transversion substitutions in each of the three codon positions, calculated using a priori values from Figure 2 and expressions (4) and (5). Initial weights for use with PAUP 3.0 stepmatrices could be the $-\ln(P)$ rounded to three significant digits and multiplied by $10^3$.

| Substitution type | Codon position | $P$ | $-\ln(P)$ |

genetic studies were calculated from expressions (4) and (5) using values obtained from the "land plant" tree (Fig. 2; Table 1). These weights may be designated in three stepmatrices, one assigned to each codon position in *rbc*L. The assumption block format for PAUP 3.0 (Swofford, 1991) is shown for first, second, and third positions, respectively:

```
usertype first = 4
        a       c       g       t
  [a]   —       6620    5520    6620
  [c]   6620    —       6620    5520
  [g]   5520    6620    —       6620
  [t]   6620    5520    6620    —
        ;
usertype second = 4
        a       c       g       t
  [a]   —       7470    6368    7470
  [c]   7470    —       7470    6368
  [g]   6368    7470    —       7470
  [t]   7470    6368    7470    —
        ;
usertype third = 4
        a       c       g       t
  [a]   —       5127    4039    5127
  [c]   5127    —       5127    4039
  [g]   4039    5127    —       5127
  [t]   5127    4039    5127    —
```

In such stepmatrices, the direction of transformation is indicated by [nucleotide] → nucleotide. Differential weighting may begin at the taxon-addition stage or may use starting trees found from prior, equally-weighted Fitch parsimony analyses (both following the recommendations made by Maddison (1991) for discovering all most-parsimonious trees). The latter strategy is significantly less time-consuming: the weights shown above are so close to a 1 : 1 : 1 : 1 assumption that Fitch topologies should include (or lie near) optimal weighted trees. Although this weighting scheme will select specific trees based upon the ad hoc assumptions of the model and the specific values given its parameters, it is useful in identifying neighborhoods of trees (defined by proximity in terms of branch rearrangements) that could provide better hypotheses of the true tree given the empirically observed character and character-state asymmetries. As such, character-state weights derived as above (i.e., Fig. 2; Table 1) should only be considered initial estimates to be supplemented by additional analyses using bracketing values, including equal weighting of character-state transformations (i.e., Fitch parsimony; cf. Albert et al., 1992).

## EXPECTATIONS OF PERFORMANCE: CONSISTENCY UNDER BRANCH-LENGTH ASYMMETRIES AND SENSITIVITY TO TAXON NUMBER

Felsenstein (1978) introduced considerations of statistical consistency for parsimony under the Camin-Sokal (Camin & Sokal, 1965) and Wagner (Farris, 1970; Kluge & Farris, 1969) optimality criteria. His model (a special case of the conditions established by Steel, 1989; Penny et al., 1991) included an unrooted tree of four taxa where two nonadjacent branches of equal length had accumulated much higher numbers of changes than the three others, which were themselves of equal length. A spurious reconstruction in which the taxa with the long branches were grouped because of shared homoplasies was shown to result from unequal rates of character-state change. This phenomenon is better recast in terms of λ because branch lengths (and hence the potential for spurious attraction) are a function of *both* rate and divergence time (Albert et al., 1992; Hendy & Penny, 1989).

Although we do not regard statistical consistency as necessary to justify the use of parsimony (see also Farris, 1983; Sober in Felsenstein & Sober, 1986; Sober, 1988), our previous λ-based heuristic examination of consistency for binary data shows that parsimony analyses *are* generally consistent (under the model specified by Felsenstein, 1978) for data that could be expected to show evidence of common ancestry (Albert et al., 1992). Hendy & Penny (1989) have suggested that breaking up long branches through the addition of appropriate

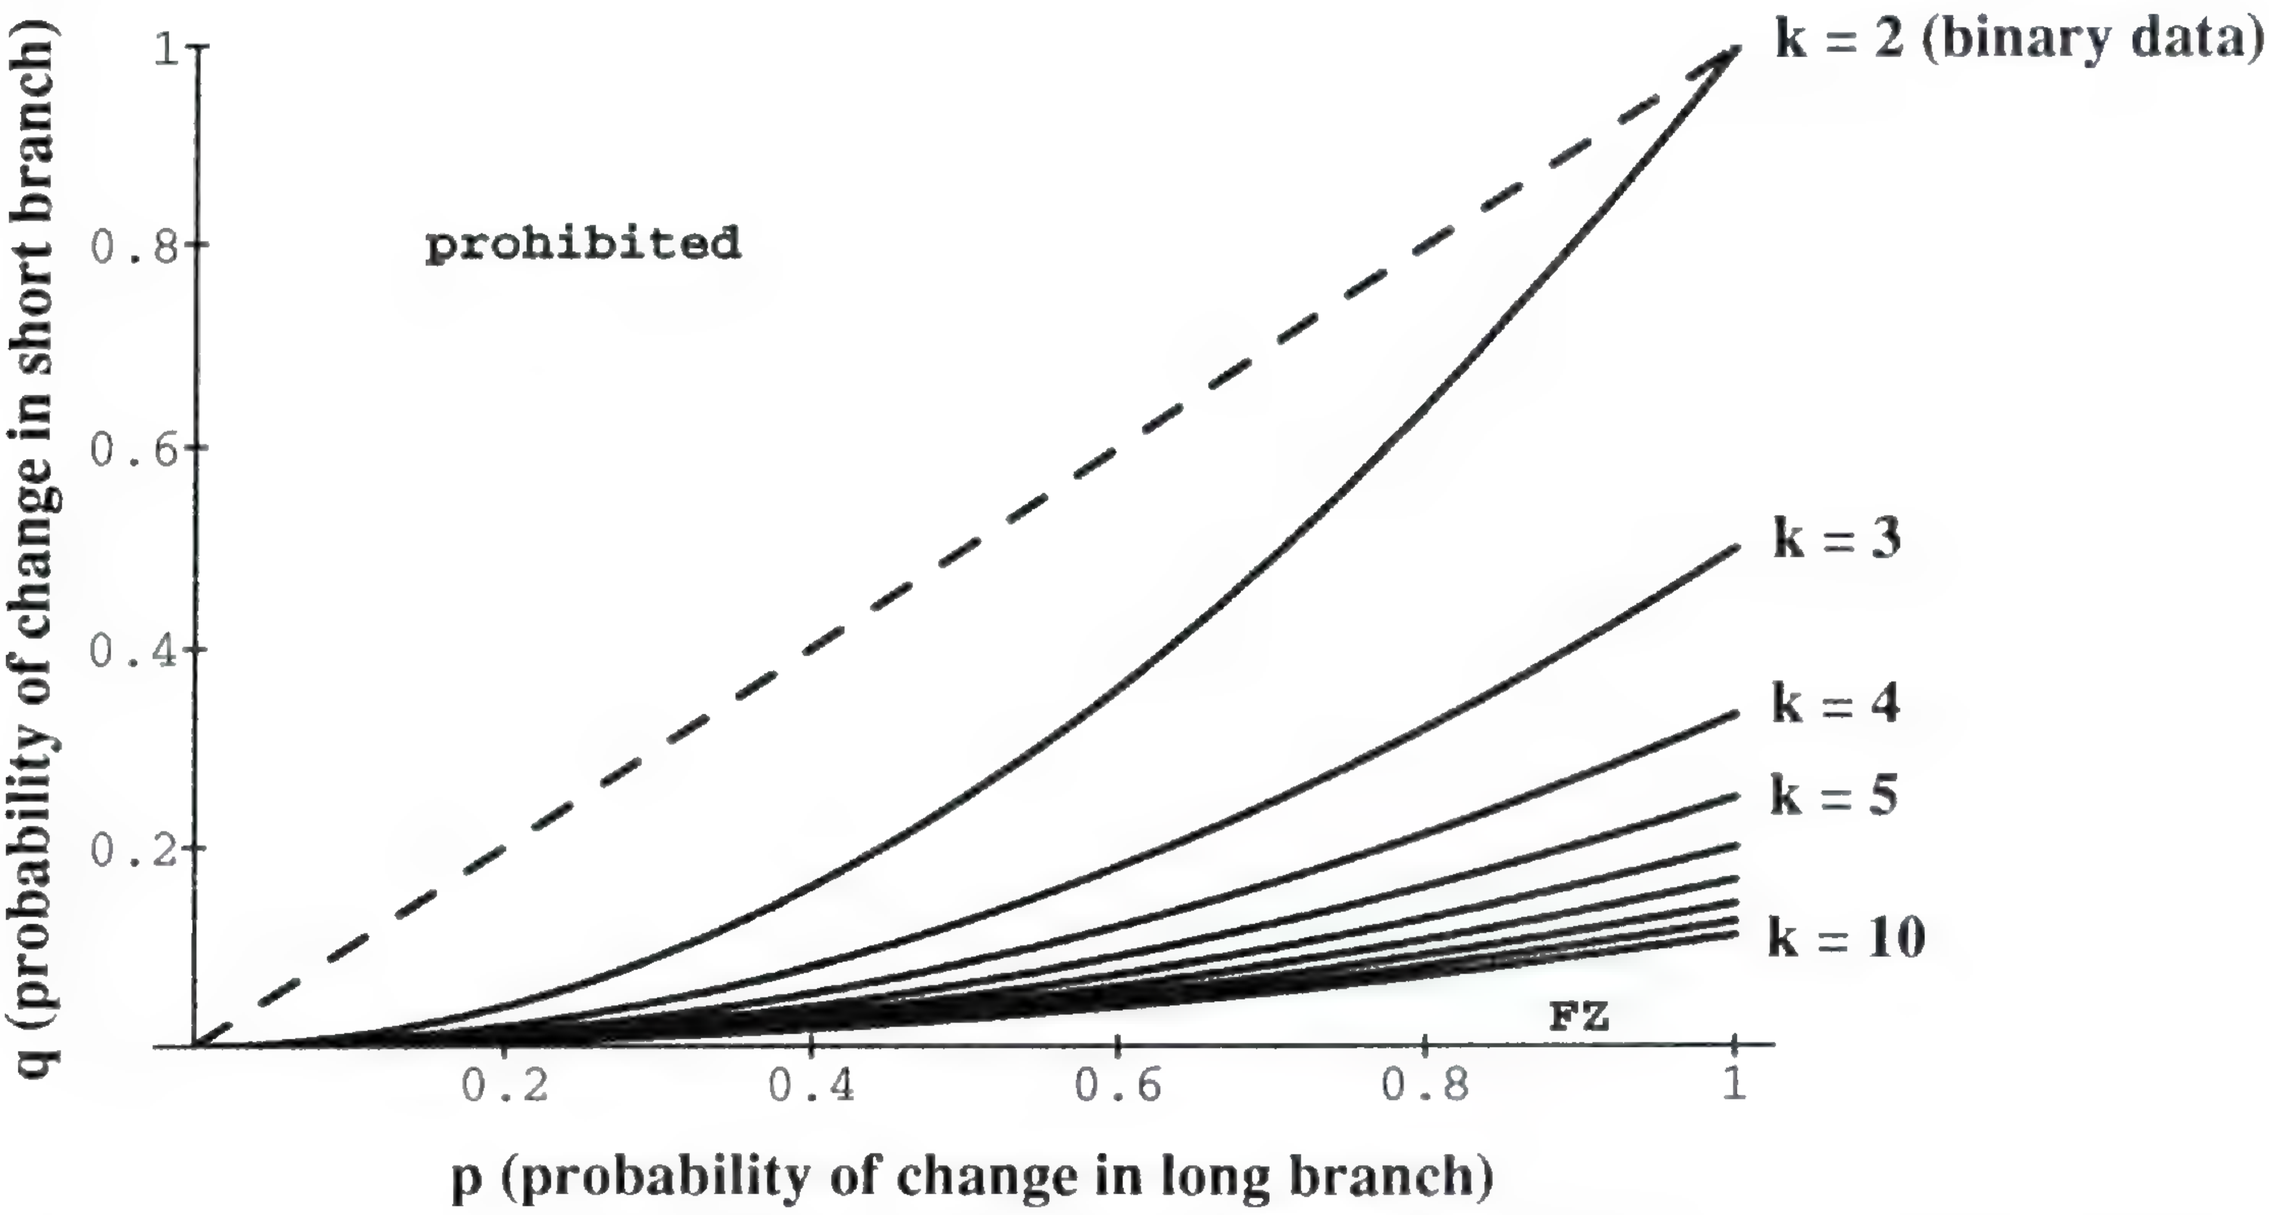

FIGURE 3. The relationship between Felsenstein's consistency model and the number of available character states. Given probabilities $p^2$ (for parallel changes on long, nonadjacent branches) and q (for a change in the same character on the short, connecting branch), the approximation $q > [1/(k - 1)]p^2$ must hold for parsimony to be consistent under Felsenstein's model. The X and Y axes represent p and q probabilities, respectively. By definition, $q > p$ (above the dashed line) is prohibited. Each curve appearing successively below the $q = p$ line represents $[1/(k - 1)]p^2$ for k = 2, 3, 4, 5, 6, 7, 8, 9, and 10. The first curve (for binary data) indicates a relatively large region of inconsistency (the area below; labeled FZ for Felsenstein zone). As the number of character states increases to 4 (as in nucleotide data; the third curve) and then 10 (the last curve), the region of inconsistency decreases dramatically. This behavior is attributable to the lower probability of a parallel change when more states are available. With binary data, q = 0.2 and p = 0.6 would be inconsistent, whereas this asymmetry would be acceptable with nucleotide sequence data.

taxa may permit parsimony to avoid systematic error (cf. Swofford & Olsen, 1990). Nevertheless, Steel (1989) and Penny et al. (1991) underscored that the range of cases where parsimony may be inconsistent increases as the number of taxa increases. Although this may be true, the practical consideration is not so much the absolute number of terminal taxa as an increase in those detracting from the evenness of sampling of the true tree (the shape of which is unknown). Perhaps with real data, the best strategy for limiting the occurrence of long, spuriously connected branches is always to examine many terminal taxa (within computational limits). Nevertheless, sampling considerations apply, such as the range and eccentricity of nucleotide variation being compared (V. A. Albert & K. Bremer, unpublished). Weighting is not expected to affect the frequency of spurious branch attraction greatly because false character-state identity, when it occurs, is an intrinsic and unquantifiable property of the data matrix. Nevertheless, there is heuristic value in comparing the consistency properties of the Fitch criterion with those of parsimony analysis using the present weighting scheme.

## FELSENSTEIN'S CONSISTENCY MODEL

If we imagine two equally long branches connected by a shorter branch to be the "true" topological relationship, avoidance of inconsistency using parsimony (after the model of Felsenstein, 1978) requires that the probability of parallel character-state changes in each of the long branches ($p^2$) be lower than the probability of a single change in the same character occurring in the connecting branch (q). This is expressed by the general approximation $q > [1/(k - 1)]p^2$, where k is the number of character states (J. Felsenstein, pers. comm.). Thus, for binary data, the simple inequality $q > p^2$ must hold (see Albert et al., 1992). For DNA data (k = 4), the approximation is $q > (\frac{1}{3})p^2$ (note that as k increases, $p^2$ becomes smaller; Fig. 3). Thus, $q - [(\frac{1}{3})p^2]$ must be positive for parsimony to be consistent under Felsenstein's model.

Relevant assumptions include (i) a large ($\rightarrow \infty$) random sampling of independent characters whose probabilities of character-state change are equal (see the pertinent objections of Farris, 1983) and (ii) the simplification that both long branches have equal probabilities of change. Assumptions (i) and (ii) are unrealistic in practice, because (i) actual data sets may consist of relatively few, nonrandomly selected characters that may show both interdependence and (ii) asymmetrical probabilities of change. Thus, Felsenstein's model can only approximate consistency behavior for real data.

If we assume a simple Poisson model of nucleotide substitution (as is appropriate for low probabilities of change; cf. Farris, 1973; Felsenstein, 1973; Goldman, 1990; Lanyon, 1988), the probability of a single character-state change in segment interval $T$, $P(T)$, may be estimated by $\lambda e^{-\lambda}$ (note, however, that for $\lambda \ll 1$, $\lambda e^{-\lambda} \approx \lambda$). This formulation ignores the possibility of multiple substitutions, which is an appropriate approximation because two or more changes are improbable at low $\lambda$. For the Fitch model, changes to any different nucleotide are equiprobable. Thus, substituting X for the short-branch $\lambda$ and Y for the long-branch $\lambda$ (as in Albert et al., 1992), the approximate consistency criterion becomes:

$$Xe^{-X} - (\tfrac{1}{3})Y^2e^{-2Y} > 0 \qquad (9)$$

An analysis of this approximation for all X, Y $\leq$ 0.1 demonstrates that a smaller region of inconsistency ("Felsenstein zone"; Fig. 4a) exists than that found for binary characters by Albert et al. (1992). This is explained by the smaller probability of parallel change when more character states are available (see Fig. 3).

The same scenario with four nucleotides can be extended to permit correction for the possibility of multiple substitutions. The expectation is that the Felsenstein zone would shrink because recognition of intermediate substitutions would limit hypotheses of parallel (homoplastic) character-state identities on long branches. Evaluation of this prediction can be accomplished by use of the Jukes-Cantor (J-C) random nucleotide substitution model (Jukes & Cantor, 1969). Using net probabilities of substitution (i.e., the probability of change to any of three potential derived states) during segment interval $T$, the approximate consistency criterion becomes:

$$(\tfrac{3}{4})[1 - e^{-(4/3)X}] - (\tfrac{1}{3})\left((\tfrac{3}{4})[1 - e^{-(4/3)Y}]\right)^2 > 0 \qquad (10)$$

Expression (10) further reduces the size of the Felsenstein zone beyond that observed for expression (9) or for the binary model of Albert et al. (1992; see Fig. 4b).

The K2P model that we use for the present weighting scheme (excluding $\bar{\lambda}\alpha$ partitions) also has an approximate consistency criterion (J. Felsenstein, pers. comm.):

$$[P_{xi}(T);\ X] + 2[P_{xv}(T);\ X] - [P_{xi}(T);\ Y]^2 + 2[P_{xv}(T);\ Y]^2 > 0 \qquad (11)$$

The probabilities indicated are from expressions (4) and (5), and the $1/(k - 1)$ correction for number of states is replaced by multipliers to indicate the two possible transversions from a particular starting nucleotide. Because parallelism on p branches could occur through either transitions or transversions, the consistency criterion must include both possibilities. The expectation is that the Felsenstein zone should be larger at high values of R because this bias would make parallel changes more frequent. When R is close to 1 (see expressions [4] and [5]), the K2P model yields a small realm of inconsistency (at R = 2 it is still smaller than for the J-C model; Fig. 4c). At higher but realistic values of R (e.g., 8) the Felsenstein zone is indeed larger, yet still small enough to permit a wide range of branch-length asymmetries (Fig. 4d).

The net result of this heuristic examination is that consistency itself is not a sufficient justification for favoring one weighting model (the present) over another (Fitch parsimony); the Felsenstein zone is insignificant in all of the scenarios studied. Aside from what this might imply about the necessity for considering consistency (i.e., that it may be irrelevant for justification of parsimony methods), it also suggests that some other factor(s) might have predictive value when comparing the expected performance of weighting models.

## NUMBERS OF TERMINAL TAXA

Breaking up long branches by the addition of more taxa to a data set may be impossible because appropriate taxa may not exist (Hendy & Penny, 1989). Nevertheless, we argue that increasing taxon number can decrease the likelihood of spurious branch attractions (despite the increased number of possibilities where inconsistency could occur; Steel, 1989; Penny et al., 1991) if $\lambda$ values remain relatively small throughout the data. Recall that the number of segments in an unrooted cladogram of $n$ taxa is $[2n - 3 - p]$. Assuming that the number of excess branches at nodes ($p$) remains fairly small for a data set (i.e., not approaching $n$), the number of available segments increases linearly with increasing $n$. Intuitively, one would expect

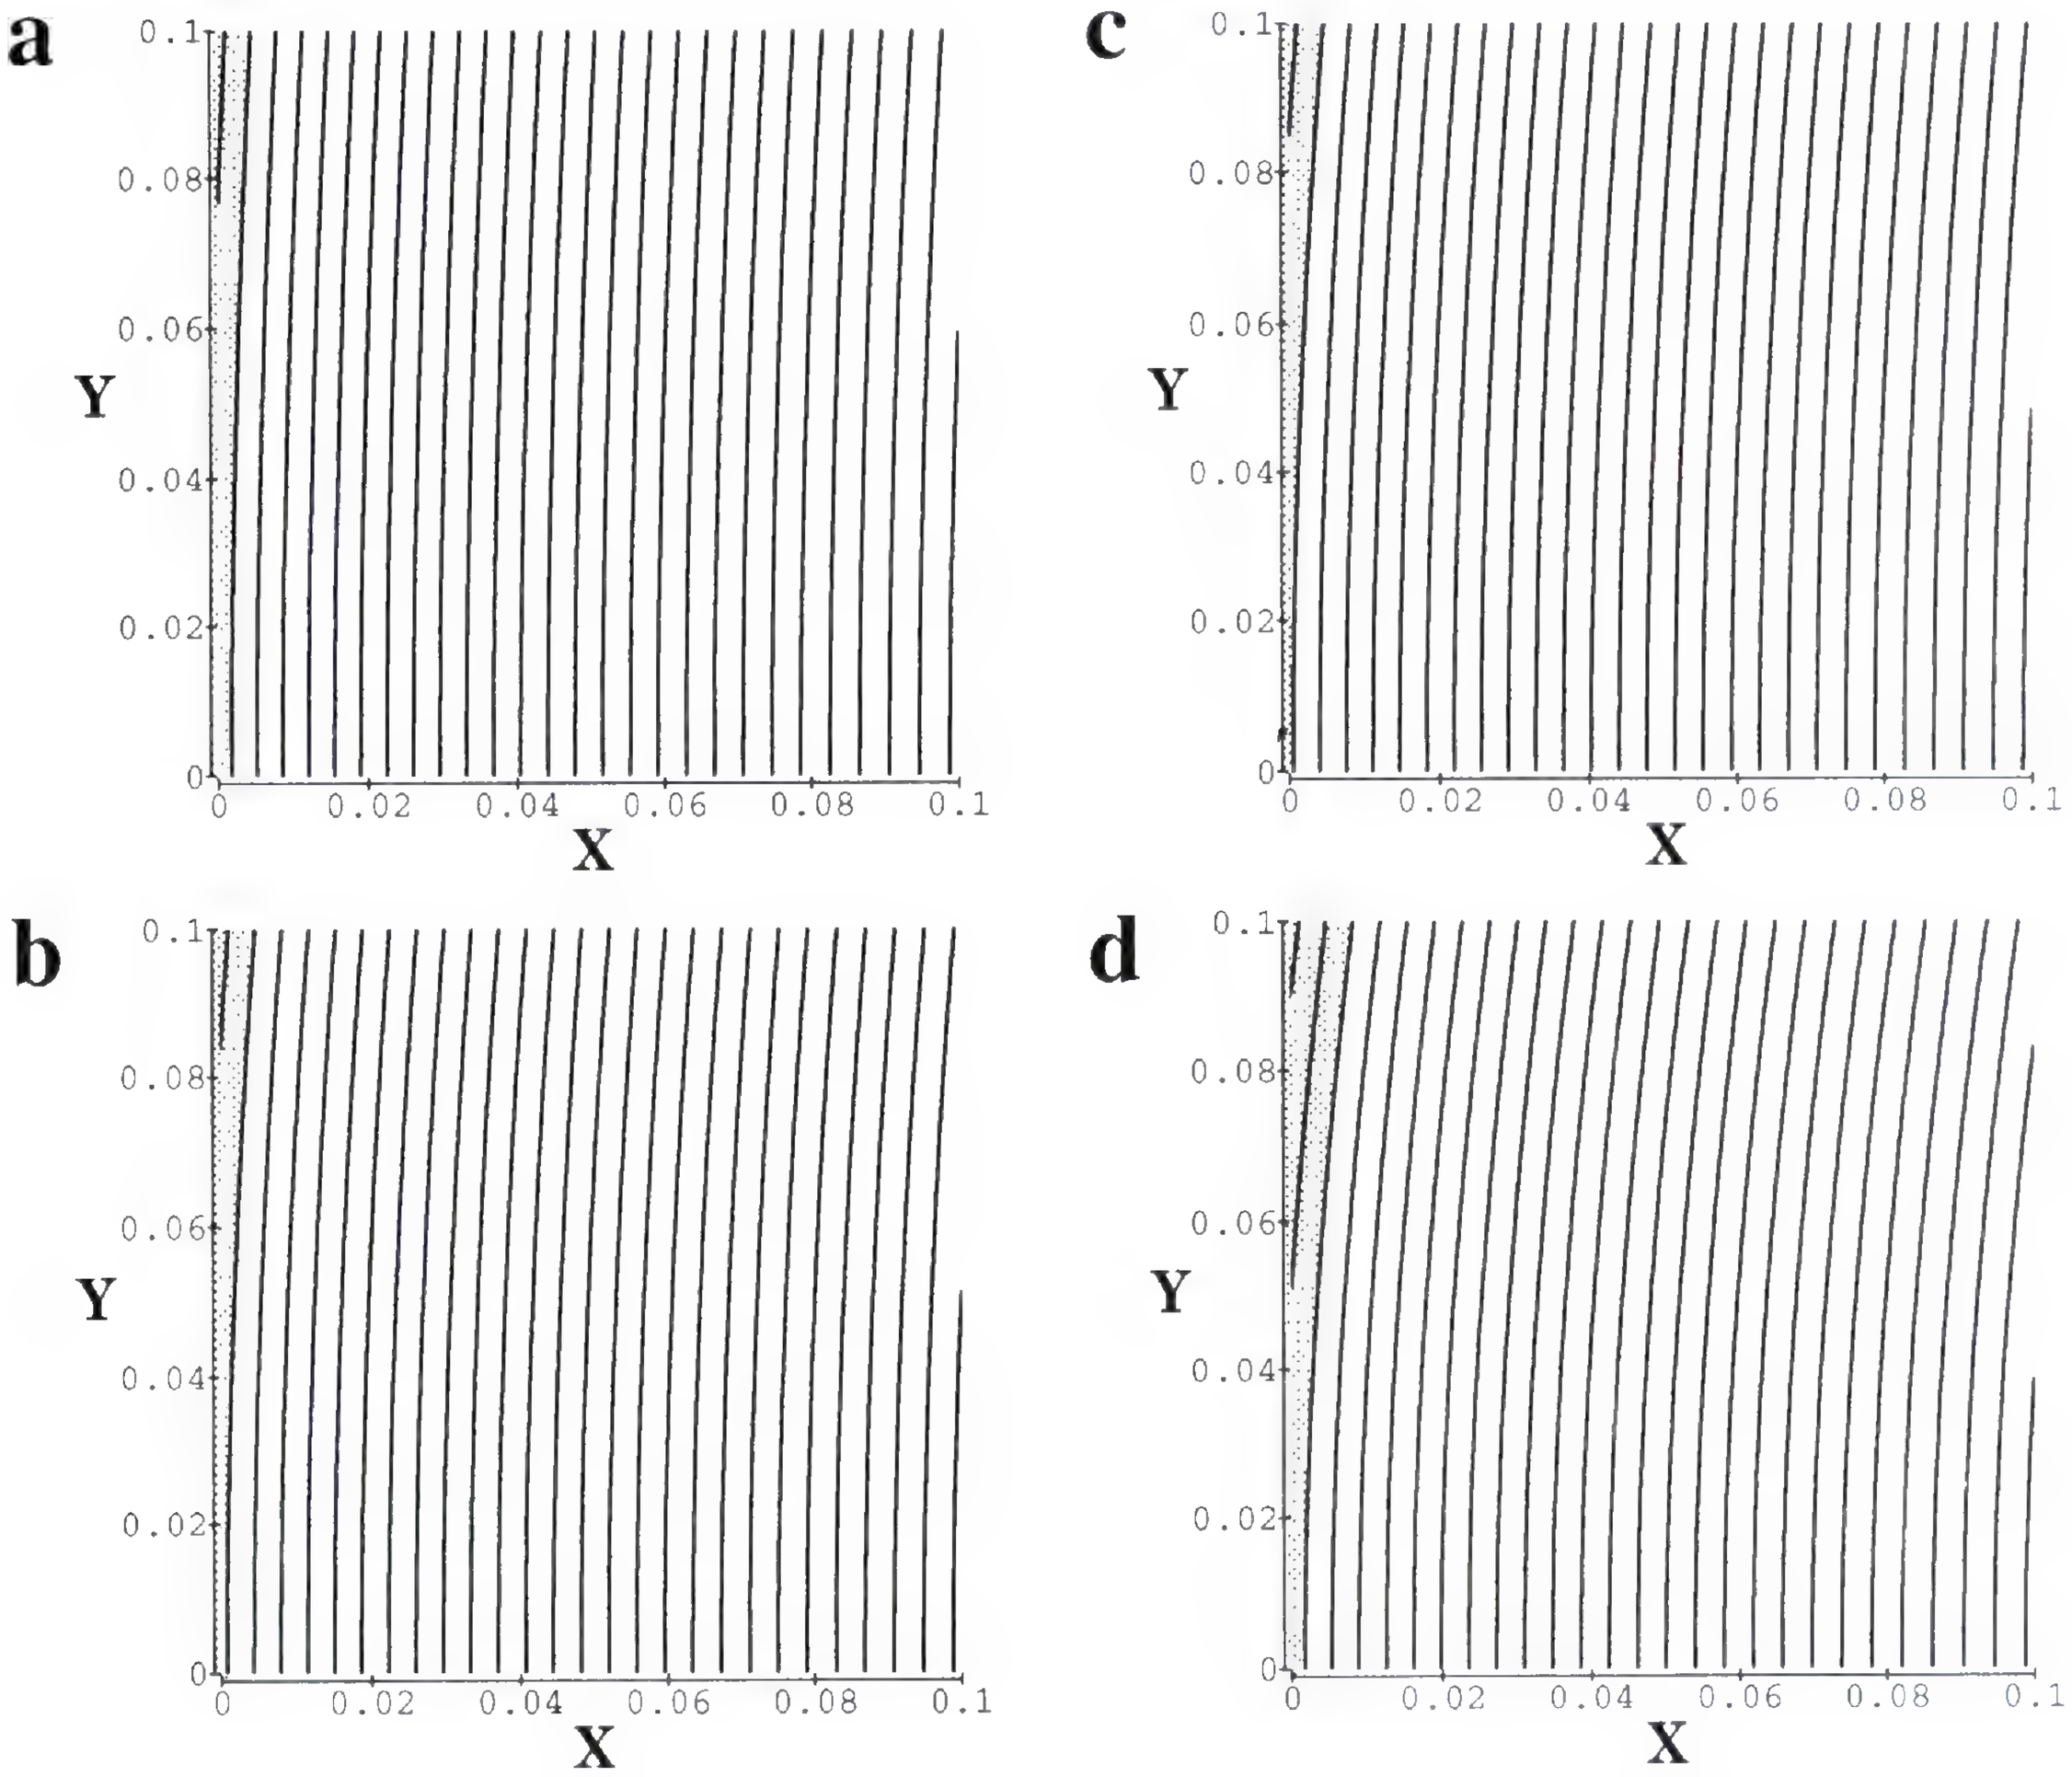

FIGURE 4. Contour plots representing expressions (9–11) for λ values of X and Y between 0 and 1.0, where X is λ for a short branch connecting two long branches with λ values of Y. The approximate region of inconsistency (where X, Y $\lesssim 0$) is shaded (note that the X and Y axes are reversed relative to Fig. 3). Separate plots are shown for the Fitch parsimony model (a), the Jukes-Cantor model (b), and the Kimura 2-parameter model (c: R = 2; d: R = 8). The realm of inconsistency is shown to be miniscule under all models.

Fitch parsimony to provide a more accurate phylogenetic reconstruction if more segments were available for it to discover otherwise hidden "intermediate" substitutions.

Saitou (1989) has formalized this expectation in his analysis of the underestimation of branch lengths by Fitch parsimony. In contrast to the single-state/branch assumption of the Fitch (1971) criterion, Saitou allowed for multiple substitutions (under the J-C model) to account for terminal states on simplified trees with no hierarchical structure (i.e., unresolved polytomies). He found that for all λ values between 0.01 and 1.0, the expected number of required nucleotide changes per branch per site over a tree of $n$ terminal taxa increases as $n$ increases. Saitou's (1989: 5) reasoning for this observation is much the same as for the intuitive example above: ". . . determination of the ancestral nucleotide X becomes more and more unambiguous as $[n]$ is increased, hence more parallel changes are detectable." Saitou also observed that underestimation of branch lengths (λ, under his model) remains small with a relative difference of 6.4% at all reasonable λ values (i.e., $\leq 0.1$; at $\lambda = 0.01$, the difference is only 0.7%). However, at $\lambda = 0.2$, the underestimation is by 12.2%, at $\lambda = 0.5$, 27.0%, and at $\lambda = 1$ (indicative of 1 expected change per character for every tree segment), Fitch parsimony not surprisingly "gives a gross underestimate [by 44.8%] of the branch lengths" (Saitou, 1989: 5). Thus, Saitou's observations independently support the range of λ values (i.e., $\leq$ 0.1) for which the Felsenstein zone was shown to be miniscule (Albert et al., 1992). Additionally, Saitou's calculations (1989, his table 5) suggest that appropriately small estimates of λ (i.e., 0.01

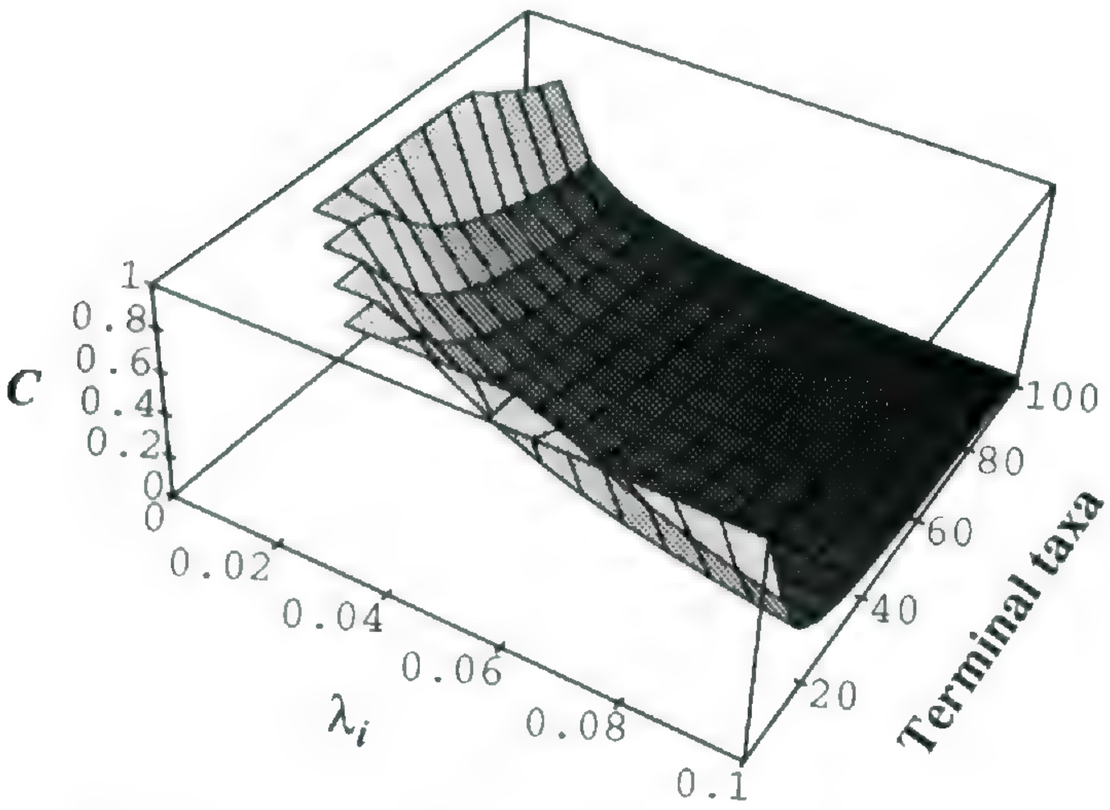

FIGURE 5. Three-dimensional representation of the relationship between the number of taxa, $n$ (X axis), segment length for a given character, $\lambda_i$ (Y axis), and the consistency index, $C$ (Z axis), for binary characters, from expression (14). The behavior of the function, under the simplifying assumption of $\lambda_i$ equality throughout a tree (i.e., $\bar{\lambda}_i$), clearly shows the decrease of $C$ as $\lambda_i$ values and the number of taxa get larger (ranging from 3 to 100). Underlying this behavior is the effect of segment number, here simplified to $[2n - 3]$ for unrooted trees; recall that the number of character-state changes in the $i$th character is, correspondingly, $\lambda_i[2n - 3]$. Only solutions less than or equal to the theoretical maximum of $C$ (1.0) are shown; impossible $n$ and $\lambda_i$ combinations were excluded from the surface.

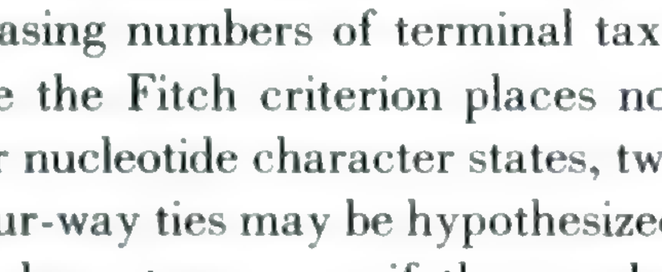
→ 0.1) should be stable under the Fitch criterion with increasing numbers of terminal taxa.

Because the Fitch criterion places no ordering on the four nucleotide character states, two-, three-, or even four-way ties may be hypothesized at nodes for some characters, even if the number of segments is large. The number of informative nucleotide positions usually differs when analyzing data with equal versus differential character-state weighting. For the Fitch criterion, only putative synapomorphies (e.g., 98 As and two Ts at a particular site in a 100-taxon comparison) can be used to justify most-parsimonious trees. Differential character-state weighting with stepmatrices imposes a partial transformation series among nucleotides. Because transitions and transversions are not given equal weight, state changes between nucleotides are differentially connected:



where $\theta$ indicates the unweighted path between any nucleotide pair, $\upsilon$, the weighted path for a transversion (shown as a bolder line to indicate its higher relative cost), and $\iota$, the weighted path for a transition. For example, a nucleotide position with 98 As, one T, and one C is considered informative for optimization under the present model. Consider a third case: 97 As, two Ts, and one C—the possible pathways between the various A and T states and the single C state are optimized along with all other available data, and the least costly transformations are hypothesized. Such hypotheses might include autapomorphy for C, synapomorphy for the Ts, an A → T → A → T transformation path with C autapomorphous, or even a path including all nucleotide variation, such as A → C → T → A → T. Because of the connectedness provided by weighted paths, what might be ambiguous states at nodes for the Fitch criterion should often be resolved by differential character-state weighting.

Despite (i) the greater proportion of available information used by our differential weighting method and (ii) the arguments given above concerning resolution of multiple substitutions with increased terminal taxa, a methodological caution is in order. Because of the limitations of current software (and available hardware), both the determination of maximum parsimony and the discovery of all most-parsimonious trees are difficult at best with large data sets (e.g., Chase et al., 1993). Therefore, our statements about taxonomic sampling should not be taken as "more is better" for empirical studies; rather, they are intended as logical arguments that may or may not be applicable to real-world scenarios.

## MEASURING CHARACTER-STATE CHANGE: THE CONSISTENCY INDEX IN TERMS OF λ AND NUMBERS OF TERMINAL TAXA

The ensemble consistency index, $C$ (Kluge & Farris, 1969; Farris, 1989a, b, 1991) is a useful measure of homoplasy with respect to a tree. Farris (1989b: 407) described the interpretation of $C$: "The consistency index assesses homoplasy as a fraction of the character change on a tree, and so the frequency with which states arise in parallel." Implicit in Farris's discussion of $C$ is dependence upon the number of terminal taxa in the analysis (as well as characters; Farris, 1989a, b, 1991). We will show that taxon dependence is in turn a function of the number of available tree segments and $\lambda_i$ values for each character. First define (in per-character terms, after Farris, 1989a) $c = m/s$, where $s$ is the number of observed state changes for a given character, and $m$ is the minimum amount of change a character may have on any tree.

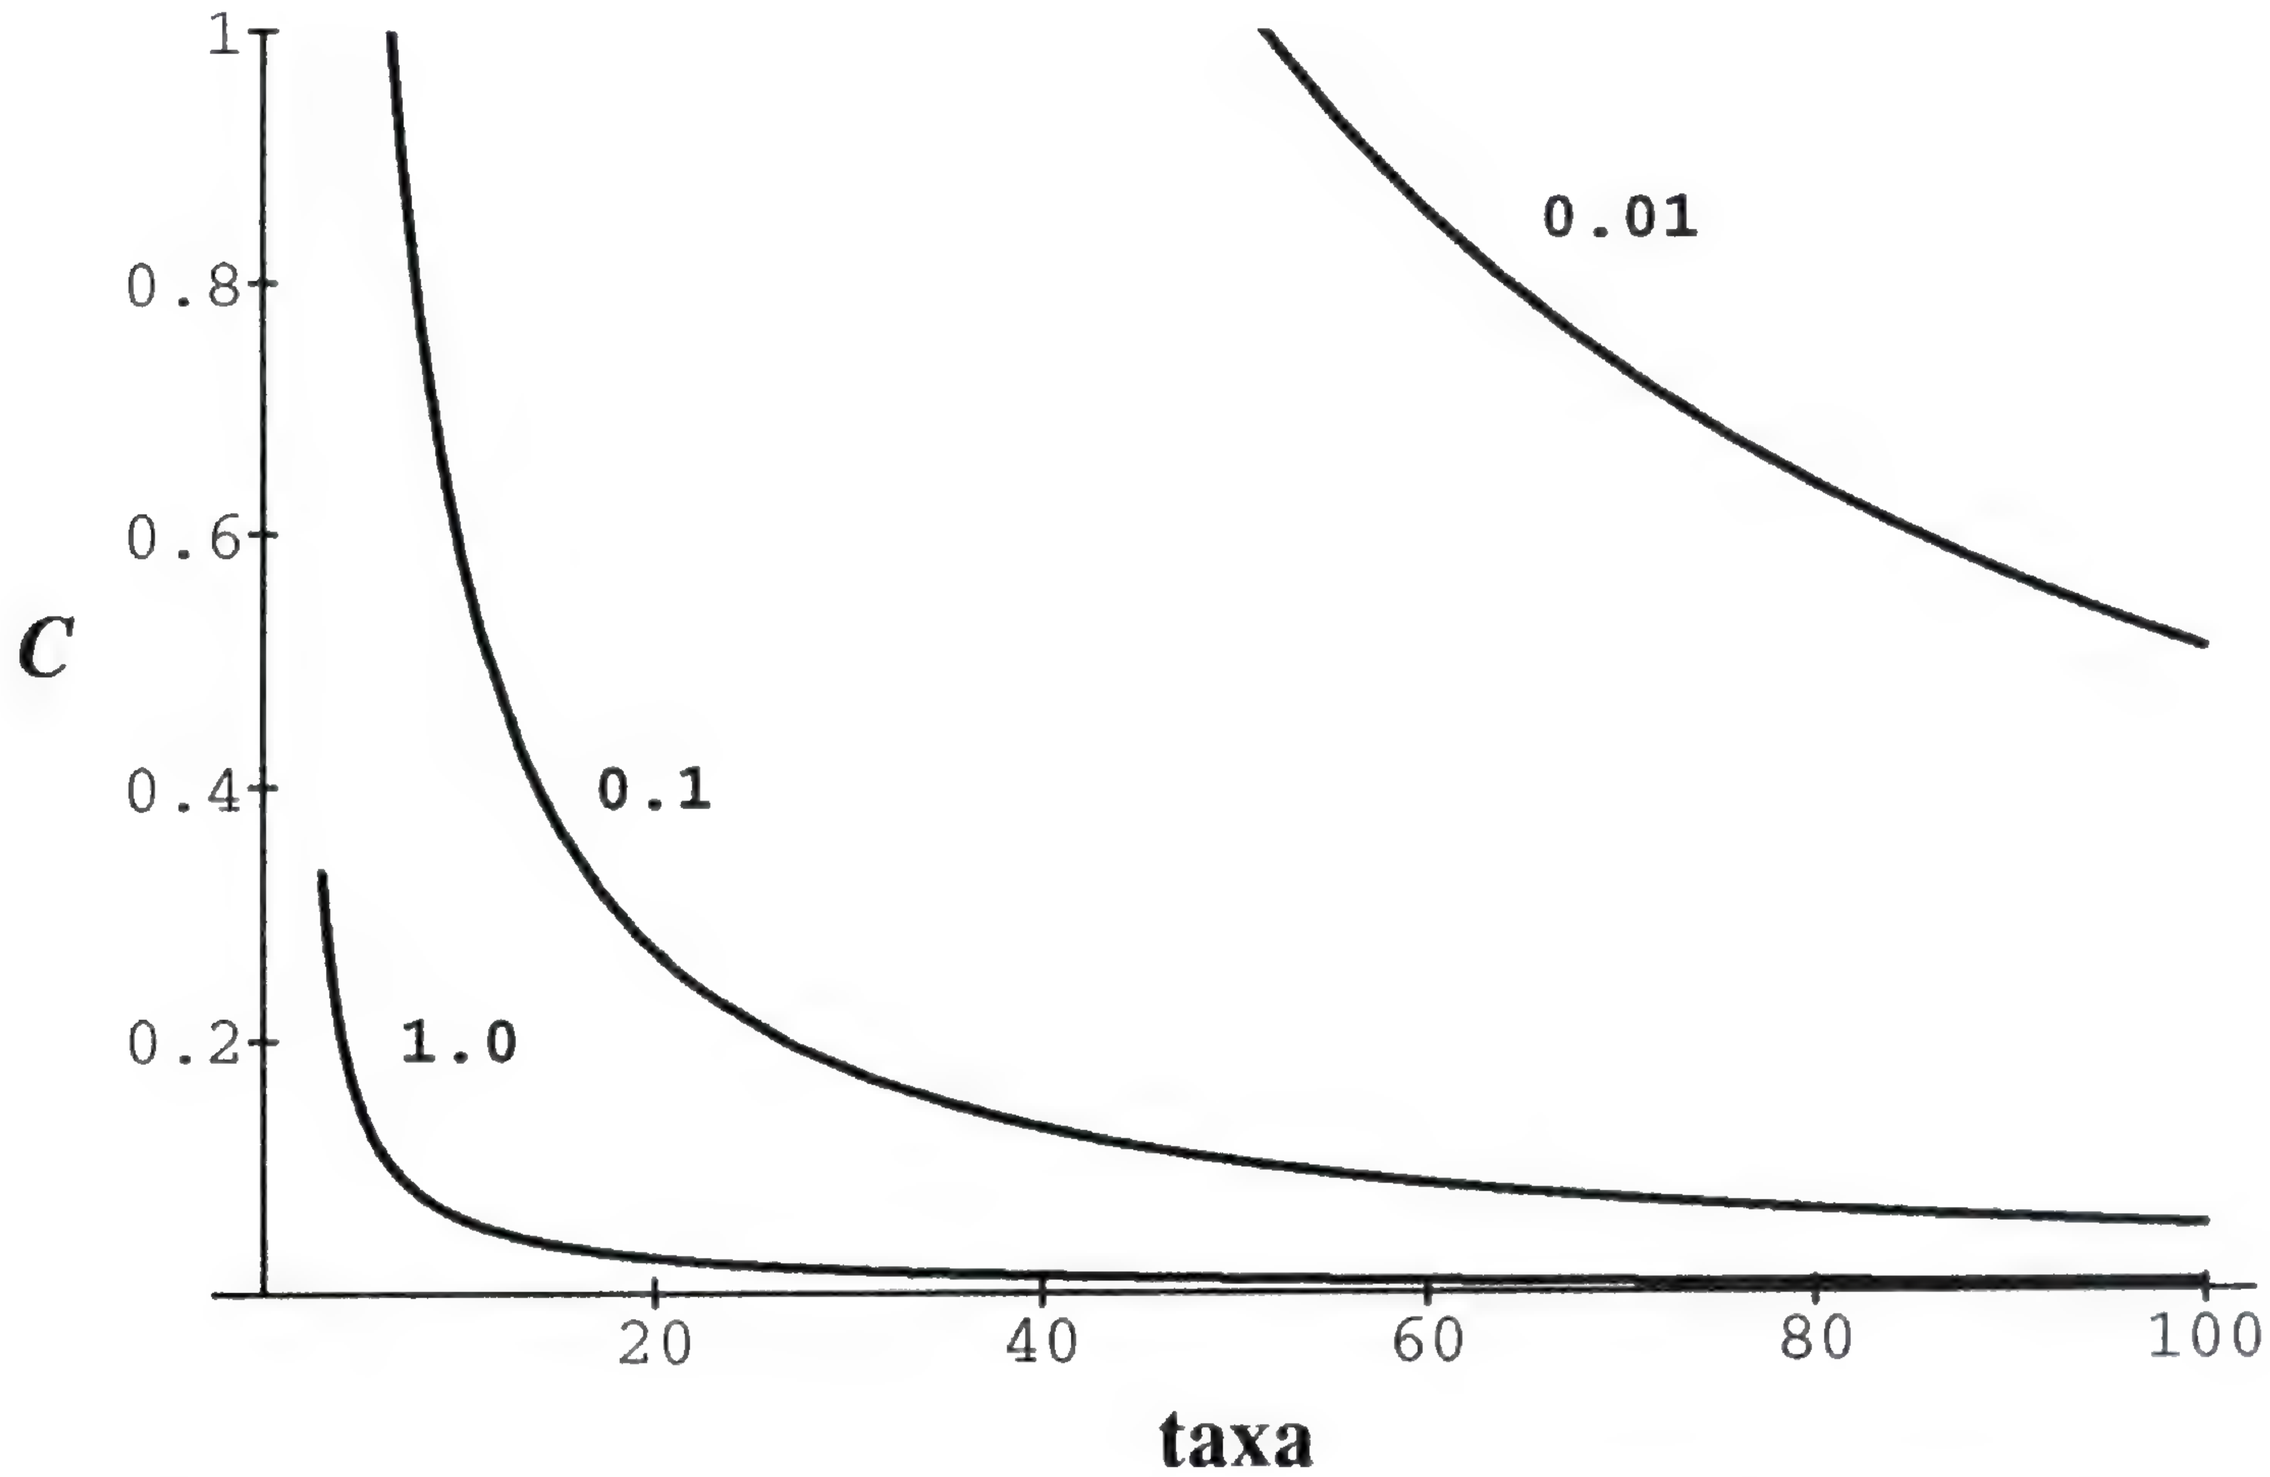


FIGURE 6. Behavior of the consistency index, $C$ (Y axis), under different assumptions of segment length for a given character, $\lambda_i$, and numbers of taxa (X axis), from expression (14). The three curves represent $\lambda_i = 0.01$, 0.1, and 1.0. Under this model for the consistency index, data with $\lambda_i = 1.0$ can never show the absence of homoplasy. This is to be expected because $\lambda_i = 1.0$ implies that $i$ changes state once per tree segment. The curve representing $\lambda_i = 0.1$ shows a behavior evocative of the results of Sanderson & Donoghue (1989), Goloboff (1991), and Klassen et al. (1991); $C$ decreases as the number of taxa (and so tree segments) increases. The $\lambda_i = 0.01$ curve displays a corresponding decrease, but $C = 1.0$ may be reached on trees with far greater numbers of taxa.

Rearranging expression (2) above to solve for $s$ (which is equivalent to $\Delta_i$),

$$s = (\bar{\lambda}_i)[2n - 3 - p] \tag{12}$$

$c$ for the $i$th character can be reformulated as:

$$c = \frac{m}{(\bar{\lambda}_i)[2n - 3 - p]} \tag{13}$$

Thus, ensemble consistency index may be expressed as:

$$C = M \Big/ \left[ \sum_{i=1} (\bar{\lambda}_i)[2n - 3 - p] \right];$$

$$\text{where } M \text{ is } \Sigma_m. \tag{14}$$

Consider the special two-state (binary) case where $m = 1$ and $M$ is equal to the number of variable characters in the data matrix (e.g., conversion of nucleotide data into purines/pyrimidines). Because adding terminal taxa (and so tree segments) increases the denominator in (13) for all possible $\bar{\lambda}_i$/tree-size combinations (i.e., those not violating the theoretical maximum of $c = 1.0$), both individual $c$ values and ensemble $C$ should decrease. A graphic representation of this relationship is shown by the three-dimensional surface in Figure 5; a two-dimensional plot (Fig. 6) highlights the behavior for specific $\bar{\lambda}_i$ values (compare the similar results obtained by Sanderson & Donoghue (1989, fig. 1a), Goloboff (1991, fig. 2a), and Klassen et al. (1991, fig. 3), which were calculated under other premises). Although this effect is seen here with the assumption that $\lambda_i$ values are equal throughout the tree (i.e., through use of $\bar{\lambda}_i$), the above formalization of the effect of increasing taxa and decreasing $C$ should hold for most empirical data (for reasonable $\lambda$s $\leq$ about 0.1, Albert et al., 1992; cf. Sanderson & Donoghue, 1989). Dependence effects based on the number of characters are not readily apparent, other than the implication that more characters means more independent and possibly $\lambda_i$-heterogeneous character-state distributions (among specific terminal taxa) to be considered during an evaluation of maximum parsimony.

## Prospectus

Our prediction of the performance of the character-state weighting model presented here relies on the relationship between numbers of terminal taxa (and so tree segments) and the ability to detect multiple substitutions; both are necessary to estimate λ values on phylogenetic trees. Because our weighting model is intended to provide a correction for multiple substitutions (differentially for each codon position), it should identify better-supported trees than Fitch parsimony for topologies that do not have sufficient numbers of segments for discernment of parallel, backward, and successive multiple-substitution events (cf. Saitou, 1989). The expectation is that analyses of data sets with large and sufficiently even samplings of terminal taxa will converge on the same most-parsimonious topologies (in whole or in part), using either equal or differential character-state weighting. This has been borne out in several studies (e.g., Albert & Chase, unpublished; Qiu et al., 1993). Perhaps indicating inadequate taxon sampling, the weighting method sometimes selects topologies that are slightly less parsimonious under equal weighting (e.g., Clark et al., 1993, in press).

Our conclusion, perhaps paradoxical from the title of this paper, is that our weighting model actually supports the use of the computationally simpler Fitch criterion for DNA sequence data, given adequate taxonomic sampling (see also Albert & Mishler, 1992; Donoghue et al., 1992). Albert et al. (1992) came to identical conclusions with regard to character-state weighting for restriction site data versus Wagner parsimony. Equal weighting of characters may be a strong assumption (see Swofford & Olsen, 1990), but the differential weighting schemes we have examined show that equal weighting is robust to large asymmetries in transformational probabilities among and within characters.

APPENDIX. Species analyzed in papers published in this issue of the *Annals of the Missouri Botanical Garden*. These are arranged alphabetically by families (dicots according to Cronquist; monocots according to Dahlgren); within families, they are arranged alphabetically by genus.

| Species | Family | Voucher/source | Sequence* | Literature citation† | Database accession‡ | Figure in Chase et al., 1993§ |
|---|---|---|---|---|---|---|
| *Acanthus montanus* T. Anderson | Acanthaceae | *Duke Univ. BG s.n.*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L12592 | 15A, B |
| *Aphelandra sinclairana* Nees | Acanthaceae | *Uppsala BG 0000-3212*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L01884 | 15A, B |
| *Barleria prionitis* L. | Acanthaceae | *Uppsala BG 1977-3036*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L01886 | 15A, B |
| *Hypoëstes forsskaolii* R. Br. | Acanthaceae | *Ensermu Kelbessa s.n.*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L12593 | 15A, B |
| *Justicia americana* (L.) Vahl | Acanthaceae | *Olmstead 90-011*, COLO | 27-745, 753-957, 965-1428 | Olmstead et al., 1993 | L14401 | 15A |
| *Justicia odora* (Forssk.) Lam. | Acanthaceae | *Hedrén et al. 746*, UPS | 29-1428 | Albert et al., 1992b (Hedrén) | L01930 | 15A, B |
| *Lepidogathis villosa* Hedrén | Acanthaceae | *Thulin et al. 7728*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L12594 | 15A, B |
| *Phaulopsis* sp. nov. | Acanthaceae | *Steiner & Manktelow 32*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | | 15A |
| *Ruellia graecizans* Backer | Acanthaceae | *Uppsala BG 1957-3039*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L12595 | 15A, B |
| *Ruttya fruticosa* Lindau | Acanthaceae | *Uppsala BG 1977-3070*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L02434 | 15A, B |
| *Thunbergia usambarica* Lindau | Acanthaceae | *Uppsala BG 1984-3474*, UPS | 29-1428 | Chase et al., 1993 (Hedrén) | L12596 | 15A, B |
| *Acer saccharum* L. | Aceraceae | *M. W. Chase 106*, NCU | 31-1428 | Albert et al., 1992b (Chase) | L01881 | 10A, B, 16 |
| *Actinidia chinensis* Planch. | Actinidiaceae | *Kron 2117*, NCU | 31-1428 | Albert et al., 1992b (Kron) | L01882 | 13A, B |
| *Adoxa moschatellina* L. | Adoxaceae | *Donoghue et al. 1*, WISC | 27-1428 | Donoghue et al., 1992 | L01884 | 14A, B |
| *Agave* sp. | Agavaceae | unknown | 32-1350 | Duvall et al, 1993 (Eguiarte) | | |
| *Beschornia* sp. | Agavaceae | unknown | 32-1350 | Duvall et al, 1993 (Eguiarte) | | |
| *Heperaloe* sp. | Agavaceae | unknown | 32-1350 | Duvall et al, 1993 (Eguiarte) | | |
| *Manfreda* sp. | Agavaceae | unknown | 32-1350 | Duvall et al, 1993 (Eguiarte) | | |
| *Yucca* sp. | Agavaceae | unknown | 32-1327 | Duvall et al, 1993 (Eguiarte) | | |
| *Trianthema portulacastrum* L. | Aizoaceae | *Rettig s.n.*, TAMU | 1-1428 | Rettig et al., 1992 | M62572 | 9A, B |
| *Akania bidwillii* (Hogg) Mabb. | Akaniaceae | *Fernando & Quinn 21606*, UNSW | 19-1428 | Gadek et al., 1992 | L12568 | 10B |
| *Alangium chinense* (Lour.) Harms | Alangiaceae | U.S. Natl. Arb. 49003 | 31-1407 | Xiang et al., 1993 | L11209 | 12A, B |
| *Alisma plantago-aquatica* L. | Alismataceae | *Les s.n.*, CONN | 29-1183 | Chase et al., 1993 (Les) | L08759 | 5A, B |
| *Sagittaria graminea* v. *chapmannii* J. G. Sm. | Alismataceae | *M. W. Chase 210*, NCU | 27-1208 | Chase et al., 1993 (Chase) | | 5A, B |
| *Sagittaria latifolia* Willd. | Alismataceae | *Les s.n.*, CONN | 29-1183 | Chase et al., 1993 (Les) | L08767 | 5A, B |
| *Alstroemeria* sp. | Alstroemeriaceae | *W. R. Anderson 13653*, NCU | 31-1428 | Chase et al., 1993 (Chase) | | 5A, B |
| *Amaranthus hypochondriacus* L. | Amaranthaceae | unknown | 1-1428 | Michalowski et al., 1990 | X51964 | 9A, B |
| *Clivia miniata* Regel | Amaryllidaceae | *Bradley 24976*, GMUF | 32-1351 | Duvall et al., 1993 (Duvall) | L05032 | 5A, B |
| *Amborella trichopoda* Baill. | Amborellaceae | *Thien 500*, NO | 29-1428 | Qiu et al., 1993 | L12628 | 4A, B |
| *Schinus* sp. | Anacardiaceae | *W. R. Anderson 13601*, MICH | 29-1428 | Chase et al., 1993 (Chase) | | 10A, B, 16 |
| *Annona muricata* L. | Annonaceae | *Qiu 90031*, NCU | 29-1428 | Qiu et al., 1993 | L12629 | 4A, B |
| *Asimina triloba* (L.) Dunal | Annonaceae | *Qiu 15*, NCU | 29-1428 | Qiu et al., 1993 | L12631 | 4A, B |
| *Cananga odorata* (Lam.) Hook. f. & Thomson | Annonaceae | *M. W. Chase 219*, NCU | 27-1351 | Qiu et al., 1993 | L12636 | 4B |
| *Chlorophytum comosum* Baker | Anthericaceae | *Bradley 7331*, GMUF | 32-1351 | Duvall et al., 1993 (Duvall) | L05031 | 5A, B |
| *Apium graveolens* L. | Apiaceae | *Plunkett 1334*, WS | 31-1407 | Albert et al., 1992b (Plunkett & Soltis) | L01885 | 14A, B |
| *Conium maculatum* L. | Apiaceae | *Plunkett 1266*, WS | 31-1407 | Chase et al., 1993 (Plunkett & Soltis) | L11167 | 14A |
| *Coriandrum sativum* L. | Apiaceae | none | 103-1428 | Olmstead et al., 1992 | L11676 | 14A, B |

APPENDIX. Continued.

| Species | Family | Voucher/source | Sequence* | Literature citation† | Database accession‡ | Figure in Chase et al., 1993§ |
|---|---|---|---|---|---|---|
| *Sanicula gregari* Bicknell | Apiaceae | *Ware 9898*, WILLI | 31-1407 | Chase et al., 1993 (Plunkett & Soltis) | L11170 | 14A, B |
| *Apocynum cannabinum* L. | Apocynaceae | none | 103-1428 | Olmstead et al., 1992 | L11678 | 15A, B |
| *Kopsia fruticosa* DC. | Apocynaceae | *B. Bremer 3033*, UPS | 128-1434 | Olmstead et al., 1993 | L14402 | |

* Amount of sequence used in 499-taxon analysis only (in some cases more incomplete sequences were used in 475-taxon analysis, Chase et al., 1993; note that some taxa were used only in studies other than Chase et al., 1993).

† Publication in which an *rbc*L sequence for this taxon was first cited. If this sequence was produced by someone other than one of the authors of the cited paper, then this person's name is listed in parentheses after the publication. In cases for which there are large numbers of authors, the specific author who produced the sequence is given in parentheses.

‡ Accession numbers prefixed by "D," "M," or "L" are GenBank; those with "X" are EMBL.

§ If no figure number is listed, then the taxon was included only in the cited publication (this issue) and not in Chase et al. (1993).

Abbreviations used: Arb., arboretum; BG, botanical garden; G, garden; Natl., national; RBG, Royal Botanic Gardens; Trop., tropical; U, university; USBG, United States Botanical Garden; herbarium acronyms are the standard ones.

## The Rupert Barneby Award

The New York Botanical Garden is pleased to announce that David Clarke, of the University of Illinois, Urbana, is the recipient of the 1992 Rupert Barneby Award. Mr. Clarke will use the award to complete a taxonomic treatment of *Acacia* series *Gummiferae* of the Caribbean, both as a part of his graduate thesis and as a contribution to the flora of the Greater Antilles.

The New York Botanical Garden also invites applications for the 1993 Rupert Barneby Award. The award of $1,000 is to assist researchers planning to come to the New York Botanical Garden to study the rich collection of Leguminosae. Anyone interested in applying for the award should submit their curriculum vitae and a letter describing the project for which the award is sought and how the collection at NYBG will benefit their research. Travel to NYBG should be planned between January 1, 1994, and January 31, 1995. The letter should be addressed to Dr. Enrique Forero, Director, Institute of Systematic Botany, The New York Botanical Garden, Bronx, NY 10458-5126 USA, and received no later than December 3, 1993. Announcement of the recipient will be made by December 17. Anyone interested in making a contribution to The Rupert Barneby Fund in Legume Systematics, which supports this award, may send their check, payable to The New York Botanical Garden, to Dr. Forero.

Volume 80, Number 3, pp. 523–786 of the Annals of the Missouri Botanical Garden
was published on August 13, 1993.

# Symposium Proceedings Published in Recent Issues of the *Annals of the Missouri Botanical Garden*

## Phylogeny of Asteridae

*Annals of the Missouri Botanical Garden* 79(2) (Spring 1992). The monophyly, sister group (or groups), and patterns of relationships of the Asteridae are discussed in the symposium "Phylogeny of Asteridae," organized by Larry Hufford of the University of Minnesota. The symposium was jointly sponsored by the American Society of Plant Taxonomists and the Botanical Society of America and was held at their annual meeting, 7 Aug. 1990, in Richmond, Virginia. 238 pages. $27.00, plus postage.

## The Lycopsida: A Symposium

*Annals of the Missouri Botanical Garden* 79(3) (Summer 1992). This symposium discusses the unique phylogenetic position and morphological distinctness of the Lycopsida; these are used as vehicles to study convergent structural evolution in vascular plants or limits on structural solutions to common problems such as light interception, propagule dispersal, and nutrient acquisition. The symposium was organized by William A. DiMichele and Judith E. Skog and was jointly sponsored by the Paleobotanical Society of America and the American Fern Society. The symposium was held on 8 Aug. 1989 as part of the American Institute of Biological Sciences meetings held in Toronto, Canada. 289 pages. $30.00, plus postage.

## Knowledge Brokering: The Mechanics of Synthesis

*Annals of the Missouri Botanical Garden* 80(2) (Spring 1993). This symposium, the 38th Annual Systematics Symposium of the Missouri Botanical Garden (held 4–5 Oct. 1991, in St. Louis, Missouri), discusses the value and future necessity of assimilating diverse biological information into new and broader syntheses, taking advantage of computer-based data-management systems. 41 pages (entire issue 230 pages). $35.00, plus postage.

# SYSTEMATICS OF *RUELLIA* (ACANTHACEAE) IN SOUTHERN SOUTH AMERICA[1]

*Cecilia Ezcurra*[2]

ABSTRACT

*Ruellia* comprises 23 species in southern South America, which display great diversification in flower and inflorescence morphology, presumably associated with a wide array of pollinators; this has resulted in the evolution of many different floral syndromes. It is suggested that this diversification could have evolved through heterochronic developmental changes associated with cleistogamy that produce morphological variation in flower form, selected by different types of pollinators. The generic limits of *Ruellia* are discussed in relation to this variation, and several generic names are considered synonyms, including *Penstemonacanthus*. Seven informal taxonomic groups of species are delimited: *Chiloblechum*, *Dipteracanthus*, *Ebracteolati*, *Hygrophiloidei*, *Physiruellia*, *Ruellia*, and *Salpingacanthus*. Within these, *Ruellia magniflora* is described as new, and more than 20 specific and subspecific names are treated as synonyms for the first time. *Ruellia lanceolata* is excluded from the genus and reduced to synonymy in *Justicia*. The species are described and illustrated, and keys to all the taxa are given.

*Ruellia*, one of the largest genera of the Acanthaceae, consists of approximately 250 species of perennial herbs, subshrubs, and shrubs, with a largely tropical and subtropical distribution. The New World is the most important center of diversity for this genus, especially with regard to inflorescence pattern and corolla morphology. This variation is probably correlated with selective pressures of a wide array of different types of pollinators, which have resulted in a great diversification of pollination syndromes.

Many of the North and Central American spe-

[1] I am grateful to the directors and curators of the herbaria mentioned for the loan of herbarium material and photographs or photocopies of types. Special thanks are given to Dick Brummit and Dieter Wasshausen for generous help during my stays at K and US, and to the many other people that collaborated with me during visits to herbaria. I very much appreciate the comments of Fernando Zuloaga and two anonymous reviewers on the manuscript. I also thank Vladimiro Dudas for the skillful line drawings, and all the friends and colleagues of Instituto Darwinion, San Isidro, and Laboratorio Ecotono, C.R.U.B., Bariloche, who provided helpful discussion or assistance in the preparation of this paper. I acknowledge Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) of Argentina for financial support, the Smithsonian Institution and Missouri Botanical Garden for short visit grants that allowed me to study Acanthaceae collections in North American herbaria, and the American Society of Plant Taxonomists for an award that financed my visits to herbaria of São Paulo and Rio de Janeiro, Brazil.

[2] Instituto de Botánica Darwinion, C. C. 22, San Isidro (1642), Buenos Aires, Argentina. Current address: Departamento de Botánica, Centro Regional Universitario Bariloche, Universidad Nacional del Comahue, C. C. 1336, Bariloche (8400), Río Negro, Argentina.

cies have been treated in local revisions, but the species in South America have only been included in a few regional floras and have never been the subjects of modern revisionary work. The number of species in the Americas is probably the largest in all continents, easily exceeding 100, and many of them have ornamental value because of their handsome, large, colorful flowers. The diversity in flower morphology has previously led to much confusion as to generic delimitation and sectional classification, but this variation also makes *Ruellia* an interesting model for the study of evolution of pollination syndromes.

The most recent overall taxonomic treatment of the genus, the subgeneric classification of Lindau (1895) in Engler & Prantl's *Die Natürlichen Pflanzenfamilien*, is currently inadequate when one takes into account the diversity encountered in the Neotropics. Nearly a century has elapsed since Lindau's works on the family (see Loesener (1924) for a complete list), and the many new specimens that have been collected in the New World since his death provide additional data on the morphology, variation, and distribution of the species.

This systematic treatment represents only a preliminary approach to the understanding of the neotropical taxa of this large and diverse genus. Although considerable study on a worldwide basis is needed to produce a more robust and permanent infrageneric classification of *Ruellia*, this revision, which covers southern South America and includes 23 species divided into seven groups on the basis of morphological affinity, is intended to encompass much of the diversity of the genus in the Neotropics. When extending the study to the rest of the Americas, corrections and additions may be necessary, but it is expected that this classification shall remain as a basic framework for future studies.

Most of the previous treatments, being of a regional character, have covered only a small portion of the ranges of the species. This has resulted in the proliferation of names associated with different regions, which in many cases are synonyms. This study therefore also aims to correctly delimit the species in the area and to clarify their nomenclature.

## Materials and Methods

This treatment covers Argentina, southern Brazil (states of Paraná, Santa Catarina, and Rio Grande do Sul), Paraguay, and Uruguay. Although this is a politically limited area, it is representative of all the neotropical floristic regions found in southern South America and includes nearly the entire basins of the rivers Paraná, Uruguay, and De la Plata, along with their tributaries. This implies that it is a geographically more or less isolated region, physically separated by watersheds from other basins in South America.

Although the present study is based mainly on herbarium material, live populations of most of the species were studied during collecting trips to northern Argentina in 1984 (with M. Ponce and A. Brown), 1985 (with R. Kiesling et al.), and 1986 and 1989 (with F. Zuloaga et al.). More than 1,000 specimens from the following herbaria were studied: AA, BA, BAB, BM, CTES, G, GH, HAS, HBR, ICN, K, LIL, LP, MBM, MO, MVFA, NY, P, PACA, PKDC, R, RB, SI, SP, SPF, US. Type specimens or photographs of types from other herbaria (e.g., BR, GOET, GZU, LE, M, W, S) were requested, or studied at US where some were on loan. In several cases, only a selection of specimens representative of the distribution and diversity of the species are cited, because the collections studied are too numerous.

The nomenclature of phytogeographical regions follows Cabrera in Cabrera & Willink (1980). Cabrera's floristic approach to phytogeographical classification has been preferred to a more physiognomic treatment such as Hueck's (1978), because the floristic composition is believed to be more related to the evolutionary history of the vegetation in an area.

Regarding hybridization, the most important character used in this work to recognize naturally occurring hybrids is morphological intermediacy between two known species, either in plants in the field or in herbarium specimens. Additionally, the sympatric occurrence of the presumed parental species in the same area as the putative hybrid was taken into account. In some cases decreased pollen viability has also been accepted as a criterion of hybridization by studying pollen stainability with anilin blue in lactophenol.

One of the major problems encountered during this work has been that the majority of names of taxa of Acanthaceae from southern South America were proposed by Nees (1847a, b), who did not formally designate nomenclatural types for them. In the case of species, he referred to the specimen or list of specimens he had studied and considered representative. Here no lectotypes have been designated from the syntypes when more than one specimen was cited, because in most species I have not had direct access to the whole set of syntypes,

as this material is generally found in several different European herbaria.

In the cases of species where Nees proposed several infraspecific taxa, he designated them with Greek letters. As he generally considered only one infraspecific rank, these should be regarded as varieties, following Article 35.3 of the *International Code of Botanical Nomenclature* (Greuter et al., 1988). In some descriptions he named and described an *alpha* variety and cited material for it, in which case no material is cited for the name of the species. In these situations the holotype (or syntypes) of the name of the species is here assumed to be that specimen (or specimens) cited under the infraspecific taxon designated with the Greek *alpha*. This assumption is based on the fact that in most cases of species with several infraspecific epithets, Nees only named and described alternative varieties *beta*, *gamma*, *delta*, *epsilon*, etc., and when listing the material of the species, he referred to the *alpha* variety as that described under the specific epithet, in the general description (e.g., *Arrhostoxylon affine* Nees, 1847a: 59).

In a few cases he did not refer to an *alpha* variety (e.g., *Dipteracathus macranthus* Nees, 1847a: 37) when citing material, but just listed in the first place the specimens he regarded as representative of the species, and secondly those representative of varieties *beta* or *gamma*, etc. In those cases it is clear that the holotype of the species is the specimen cited in relation to the description of the species, and the material listed for infraspecific taxa *beta*, *gamma*, *delta*, *epsilon*, etc. is excluded.

## Taxonomic History and Generic Delimitation

The complex taxonomic history of *Ruellia* has been discussed in detail by Long (1964, 1973). The following is only a summary of the prevailing ideas on the delimitation of *Ruellia* through time.

*Ruellia* was established by Linnaeus (1737), who included eight species in his *Species Plantarum* (1753), of which *Ruellia tuberosa*, a tropical American perennial herb with blue flowers, was chosen as lectotype (Britton & Brown, 1913: 241). Nees (1847a), who treated the Acanthaceae of South America for Martius's *Flora Brasiliensis* and the family on a worldwide basis for the *Prodromus* of De Candolle (Nees, 1847b), placed the species described by Linnaeus in various genera. He even described more new genera to accommodate the numerous different but morphologically related variations he encountered in the tropics, especially in the New World. Oersted (1854), who worked on the Acanthaceae of Central America, also treated the species in several separate genera.

Bentham (1876) established the now mostly accepted circumscription of the genus by "sinking" 18 genera, most of them described by Nees, into *Ruellia*. Lindau (1895) followed Bentham, including in *Ruellia* more than 100 species classified in 9 sections. This wide concept has been accepted by most modern authors.

The New World species have generally been treated in the broad generic sense, especially in North and Central America (e.g., Daniel, 1990; Durkee, 1978, 1986; Gibson, 1974; Leonard, 1936; Long, 1970; Tharp & Barkley, 1949; Turner, 1991; Wasshausen, 1966). In South America most authors have also followed Bentham and Lindau treating *Ruellia* in its wider sense (e.g., Chodat & Hassler, 1903; Dawson, 1979; Ezcurra, 1989; Ezcurra & Wasshausen, 1992; Leonard, 1951–1958; Lillo, 1937; Lindau, 1894; Rambo, 1964; Wasshausen & Smith, 1969). But perhaps because of the bewildering diversity that can be found in the tropics of South America, especially with respect to flower and inflorescence morphology, some authors have gone back to Nees' ideas in this area (Bremekamp, 1938, 1969; Bremekamp & Nannega Bremekamp, 1948; Rizzini, 1949). The result has been that some species names in *Ruellia* have recently been treated once again in combination with names of genera previously considered synonyms, such as *Arrhostoxylum* Nees (Bremekamp, 1969) and *Stephanophysum* Pohl (Bremekamp, 1938, 1969; Barker, 1986), or with new names, such as *Ulleria* Bremek. (Bremekamp, 1969).

This problem has led to the series of biosystematic works of Long (e.g., 1966, 1973, 1975, 1976a, b) that, through field studies, crossing experiments, and chromatographic comparisons of corolla pigments, have aimed to establish the relative taxonomic position of several species within *Ruellia* sens. lat., and at the same time provide an insight to the most natural circumscription of the genus. These works, together with the cytogenetic studies on the family performed by Grant (1955), Daniel et al. (1984, 1990), and Piovano & Bernardello (1991), generally support the idea that *Ruellia* consists of a large and morphologically diversified group of more or less phylogenetically related species, with one constant chromosome number, in which natural hybridization is frequent between closely related species.

In this treatment *Ruellia* is treated "sensu lato," being characterized by the generally large and showy, subactinomorphic flowers, the four, fre-

quently didynamous stamens, the oblong, symmetrical, basally rounded anthers, the spherical, porous, coarse-reticulate pollen, and the (2–)4–numerous-seeded capsules, with the placentas remaining attached to the walls at maturity (separating in a few species).

### Intrageneric Relationships

The most recent comprehensive treatment of *Ruellia*, Lindau's (1895) synopsis, separated the genus into nine sections, of which only five were considered by Lindau as "typical." Of these five, three of them included the majority of the species known at that time: *Euruellia* (which included species classified by Nees (1847b) as *Cryphiacanthus* Nees and *Ruellia* L. pro parte), *Dipteracanthus* (which included *Ophtalmacanthus* Nees, and *Dipteracanthus* Nees groups *Hygrophiloidei*, *Calycosi*, and *Genuini*), and *Physiruellia* (which included *Aphragmia* Nees pro parte, *Arrhostoxylon* Nees, *Dipteracanthus* Nees pro parte, *Siphonacanthus* Nees, *Stemonacanthus* Nees, and *Stephanophysum* Pohl). Most of the others were monotypic sections, created mostly to accommodate species of uncertain position. The characters he used in the delimitation of groups were capsule morphology and corolla shape. In this synopsis Lindau noted that both the delimitation of the species and the separation of the genus into sections were difficult in *Ruellia* because of the extraordinary richness he encountered in form, and that his classificatory scheme was provisional.

Recently, Ramamoorthy (1991, 1992) described two new sections from Mexico, *Chiropterophila* and *Urceolata*, mostly characterized by flower morphology; capsule structure was not taken into account.

In this treatment, the species are classified into groups without formal taxonomic recognition, principally on the basis of capsule structure correlated with inflorescence morphology. Corolla shape appears to have frequently been subject to rapid diversification through disruptive selection by different pollinators. This appears to have produced many parallel events in the evolution of the genus, i.e., homoplasies, and therefore this character is treated as secondary in group delimitation.

Although this classification is also provisional because it takes into account only a fraction of the species of the genus (probably less than 15%), this fraction is quite representative of the diversity of *Ruellia* encountered in the New World, as seen in the neotropical collections studied. But some important groups of species, such as those considered by some authors (e.g., Long, 1976b) as *Aphragmia* Nees (= *Dipteracanthus* group *Aphragmia* Nees, 1847a; *Dipteracanthus* group *Paniculati* Nees 1847b; *Ruellia* sect. *Physiruellia* group *Glandulosae* Lindau, 1895), are not represented in the area studied, and therefore have not been included. Thus the formal taxonomic position and rank of the groups will have to be worked out once all the species are taken into account on a worldwide basis.

### Morphology

*Habit.* Most of the species are perennial herbs or subshrubs, more rarely shrubs or small trees, the majority erect, sprawling, decumbent or prostrate, except a few semiscandent or rosettiform species. All have a basal rhizome with more or less thick, fibrous roots, and sometimes adventitious roots are also produced in decumbent branches where the nodes touch the ground. The young stems are frequently quadrangular, in some species more markedly so, in others subterete, and in some of group *Physiruellia* the regions over the nodes are swollen and geniculate. The swollen region fractures easily and may be important in the vegetative propagation of the plants by stem division.

*Leaves.* Leaves are opposite and generally petiolate, and only a few species (of group *Ruellia*) present leaves in rosettes. The blades are simple, with the margin entire, crenulate or crenate, more rarely dentate. The surfaces are pubescent or glabrate. The leaves sometimes intergrade into bracts toward the stem apices. Venation is pinnate, but, in the upper leaves transformed into bracts in some species of group *Chiloblechum*, the inferior secondary veins arise near or at the base of the blade, producing a subpalmate appearance.

*Indument and surface.* The trichomes in *Ruellia*, like in most Acanthaceae (Ahmad, 1978; Karlström, 1978), are of two types: glandular, with a sessile or stalked multicellular head, and eglandular, simple and uniseriate (Fig. 1A). Different types of pubescences can occur together in different proportions. In some species multicellular, sessile, disk-shaped or "patelliform" (Daniel, 1990) glands appear like small punctations on the surface of leaves, bracts, and calyx lobes (Fig. 1B). These glands are frequent in tropical and subtropical species of different taxonomic groups from open areas, such as *Ruellia bulbifera*, *R. coerulea*, *R. erythropus*, or *R. multifolia*, and could act as extrafloral nectaries secreting substances to attract ants.

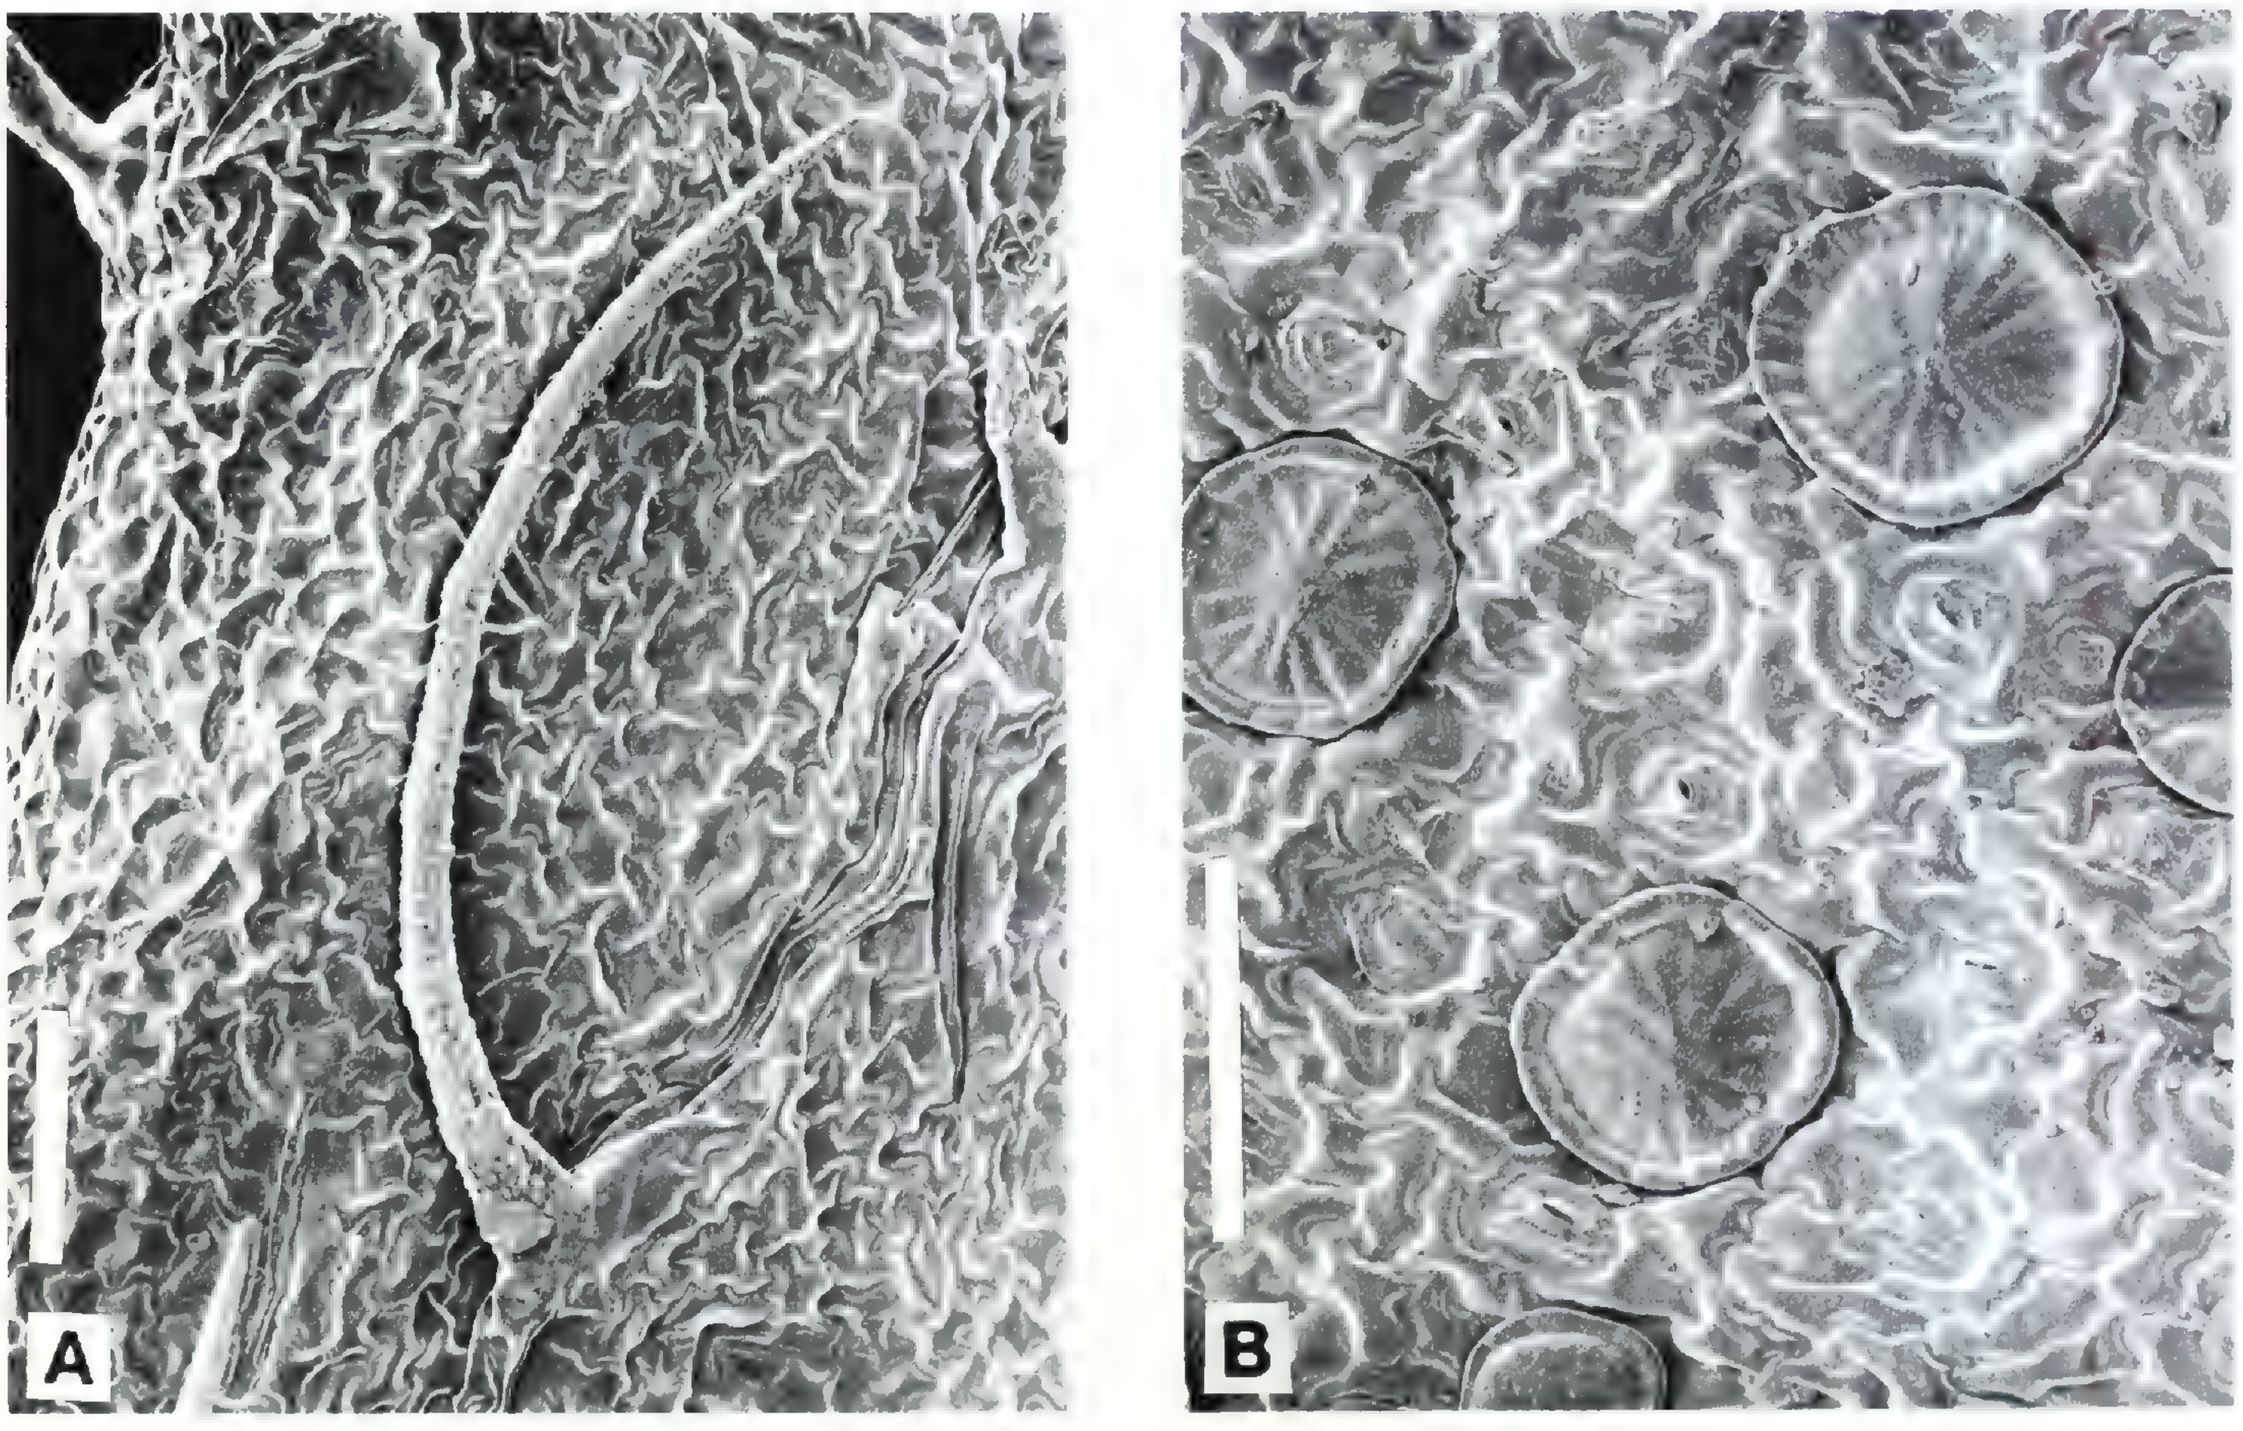

FIGURE 1. Indument of *Ruellia*. —A. Simple, uniseriate hair. —B. Sessile, patelliform glands. (SEM photographs from bract surface of *R. erythropus*, *Pensiero 1580*. Scale bar = 100 μm.)

Cystoliths are small mineral (calcium carbonate) concretions in the interior of epidermal cells and are present in most genera of Acanthaceae. In *Ruellia*, on the surfaces of vegetative organs, in dry material, the cystoliths appear as small, linear, more or less prominent structures, sometimes resembling appressed, strigose pubescence. In live material they are much less readily apparent.

*Inflorescence.* The basic inflorescence pattern in *Ruellia* consists of simple or compound dichasia that appear as lateral elements of the indeterminate axes (Sell, 1969a). Within this basic scheme, several variations that generally characterize different groups of related species can be found.

In groups *Physiruellia* and *Ruellia* the dichasia are often compound and pedunculate, forming multiflowered axillary cymes (Fig. 2A, B). These are sometimes condensed into terminal thyrses, especially in the latter group, producing an upper floral region differentiated from the purely vegetative basal region by modification of the terminal leaves into small bracts (Fig. 2B). In group *Hygrophiloidei* the dichasia are generally reduced to a more or less pedunculate solitary flower with two bracteoles, in the axils of the terminal leaves. In many of these cases the inflorescences are anisophyllous, i.e., only one cyme appears in each node, alternating sides (Fig. 2A).

In group *Dipteracanthus*, the dichasia are always simple and sessile, generally reduced to axillary, solitary sessile flowers with two bracteoles, these always subtended by the upper leaves (Fig. 2C). In groups *Salpingacanthus* and *Ebracteolati* the flowers also appear sessile and solitary in the axils of the upper leaves, but the reduction is even greater as the bracteoles are extremely reduced or absent (Fig. 2D). In group *Chiloblechum* the sessile flowers without bracteoles are grouped into a four-sided spike, the upper leaves generally being somewhat modified into sessile bracts (Fig. 2E). In this work, the correlation between inflorescence and capsule structure is used to define groups.

*Calyx.* In *Ruellia* the calyx is always five-parted, but in group *Salpingacanthus* and in some species of group *Chiloblechum* (e.g., *Ruellia erythropus*) the two lateral lobes are fused to the inferior ones, and thus a more or less three-lobed structure is formed.

*Corolla.* The corolla consists of a narrow basal tube, a more or less cylindrical, infundibuliform or campanulate throat, with the limb parted into two

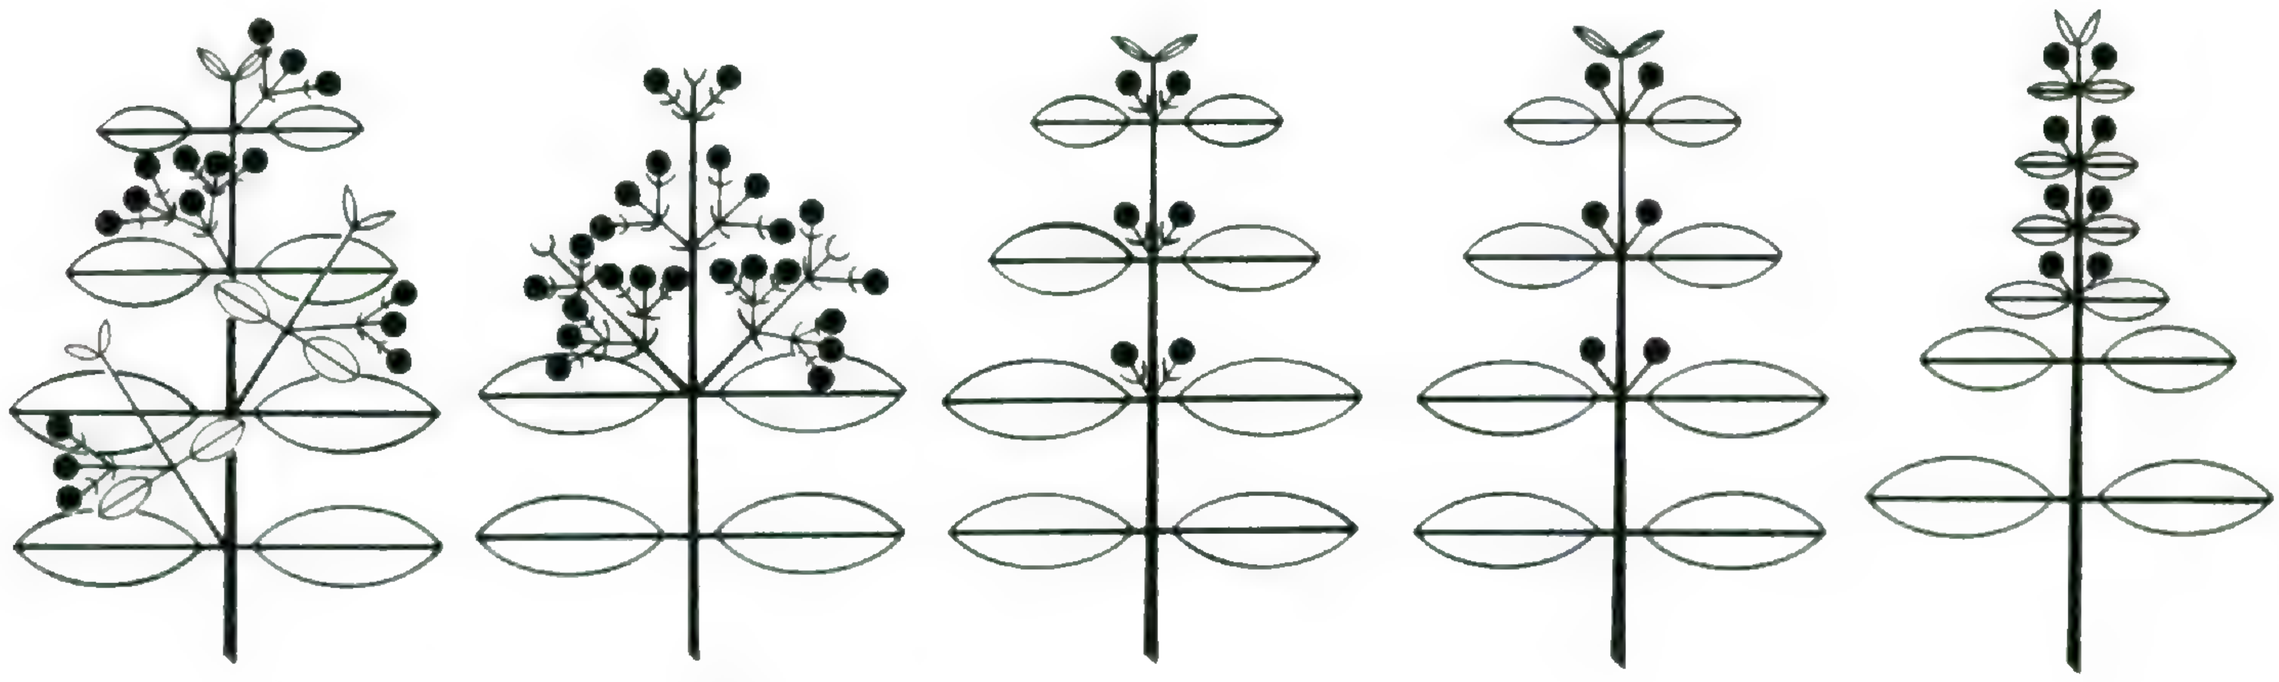

FIGURE 2. Inflorescence types in *Ruellia*.—A. *R. angustiflora* (group *Physiruellia*).—B. *R. ciliatiflora* (group *Ruellia*).—C. *R. multifolia* (group *Ruellia*).—D. *R. geminiflora* (group *Ebracteolati*).—E. *R. erythropus* (group *Chiloblechum*). (Schematic, from herbarium material.)

posterior and three anterior lobes more or less similar in size and shape, thus rendering it subactinomorphic in a basically zygomorphic family. This basic structure is widely modified in different species. The color also varies from blue, mauve, pink, red, and yellowish, to white. The lower part of the throat and/or the base of the anterior lobes is often marked with colored streaks or veins that probably function as nectar guides. Corolla morphology seems very plastic in *Ruellia* and has probably been subject to diversification due to the action of different pollination agents, even within groups of otherwise closely related species. The different sets of morphological characteristics of the flowers are here described in relation to presumed pollinating agents, as pollination syndromes.

Although there is no strict correlation between the different morphological types of corolla and the different groups, some types are present more often in some groups than others. The following classification is somewhat similar to that proposed by Barker (1986) for flower morphology of Australian Acanthaceae in general.

*Red tube flowers* (presumably pollinated by hummingbirds: ornithophilous) (Fig. 3A, B). The corollas are frequently horizontal or pendulous and red, the basal tube and the throat form a more or less narrow tube, sometimes anteriorly inflated, and the lobes are generally small and erect or semierect. This morphological type generally appears associated with multiflowered axillary cymes as inflorescences, with the peduncles and pedicels frequently weak. It is frequent in group *Physiruellia* (e.g., *Ruellia angustiflora*, *R. elegans*).

*Mauve or blue infundibuliform flowers* (presumably pollinated by large bees: melitophilous) (Fig. 3C–F). The basal tube is short, the corollas are blue or mauve and functionally zygomorphic, i.e., generally angled and tilted, with marked palate rib markings in the lower part of the throat, and with the lower lobes with nectar guides in the base. This type is common in groups *Ruellia*, *Dipteracanthus*, and *Ebracteolati* (e.g., *Ruellia ciliatiflora*, *R. brevicaulis*, *R. geminiflora*).

*White trumpet flowers* (presumably pollinated by

Blue hypocrateriform psychophilous flowers. (Photocopied from herbarium material: A, *R. brevifolia*; B, *R. angustiflora*; C, *R. ciliatiflora*; D, *R. bulbifera*; E, *R. geminiflora*; F, *R. brevicaulis*; G, *R. multifolia*; H, *R. macrosolen*; I, *R. erythropus*; J, *R. hypericoides*.)

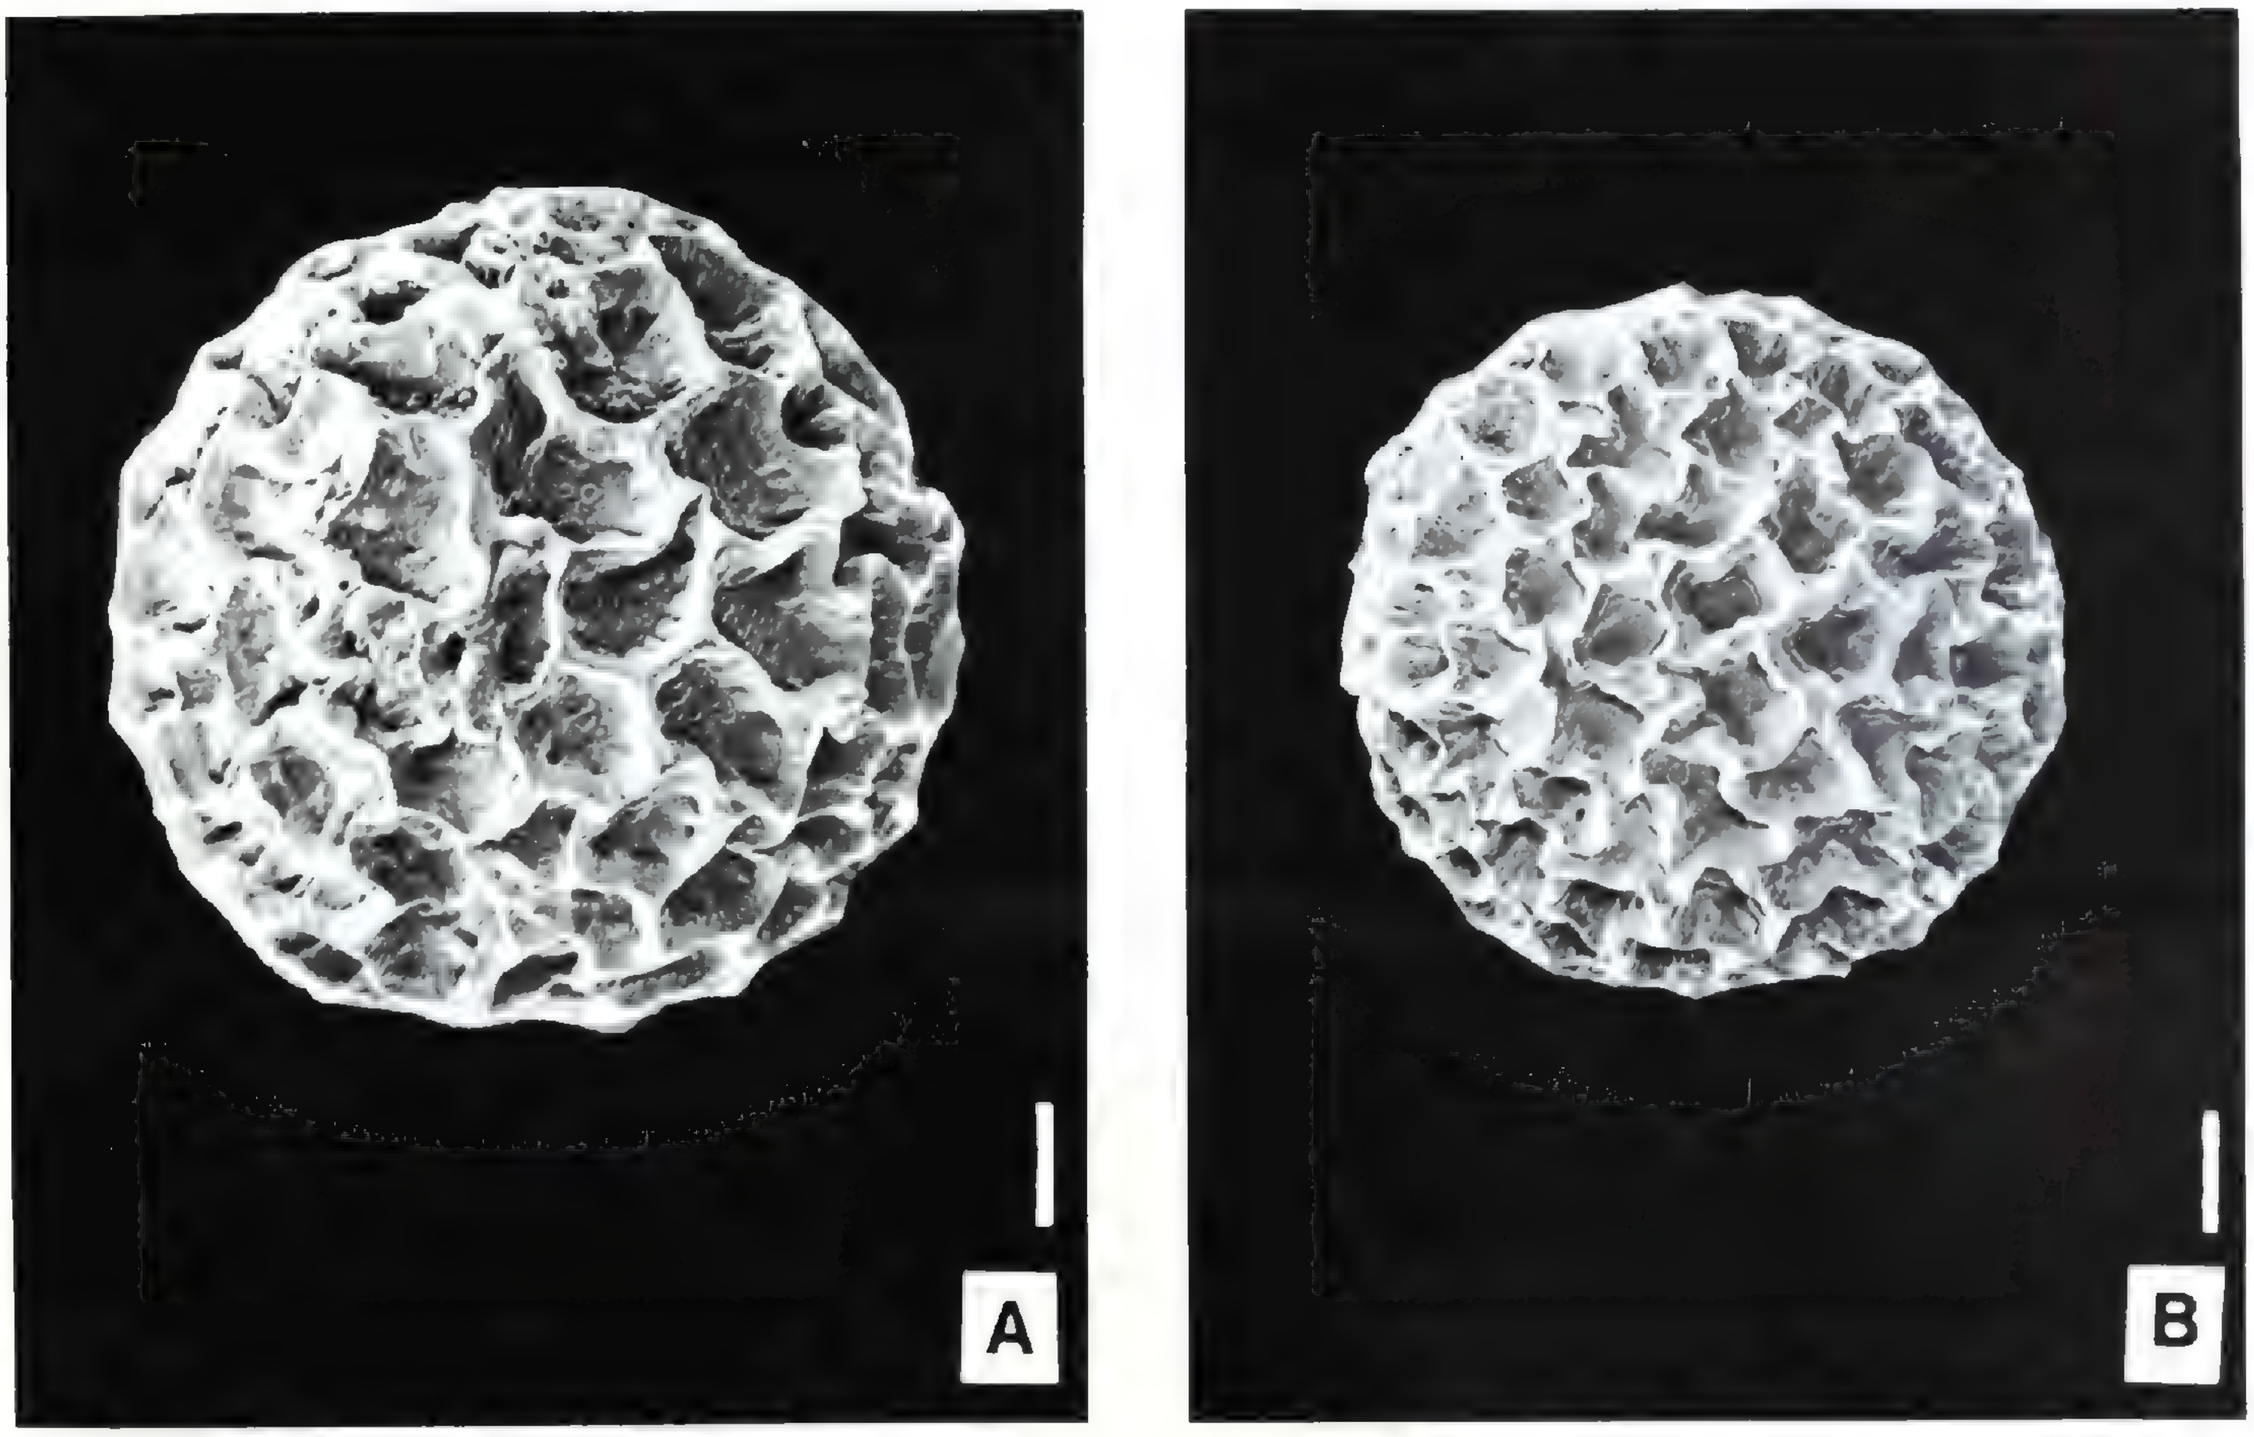

FIGURE 4. Pollen of *Ruellia*.—A. *R. coerulea* (*West 8472*).—B. *R. hypericoides* (*Zuloaga 3248*). (SEM photographs of unacetolized pollen grains. Scale bar = 10 μm.)

hawkmoths: sphingophilous) (Fig. 3G, H). The basal tube is very long, and the corollas are more or less erect, white or whitish, actinomorphic, lacking differential markings in the lobes. This type of flower appears in several unrelated groups present in southern South America, such as *Dipteracanthus*, *Ruellia*, and *Salpingacanthus* (e.g., *Ruellia multifolia*, *R. macrosolen*, *R. nobilis*), and has probably evolved independently many times within the genus.

*Blue hypocraterimorph flowers* (presumably pollinated by butterflies: psychophilous) (Fig. 3I, J). The basal tube is very narrow, and the corollas are erect, blue, and without clear differential markings in the lobes. This type appears in group *Chiloblechum* (e.g., *Ruellia hypericoides*, *R. erythropus*).

Additionally, several neotropical species present large, pale, greenish, dull-colored, campanulate flowers that have saccate corollas with a wide open throat and exserted stamens (e.g., *Ruellia petiolaris*, Daniel, 1990; *Ruellia* section *Chiropterophila*, Ramamoorthy, 1991) that appear to be pollinated by bats (chiropterophilous), but none with this syndrome reaches southern South America.

*Androecium*. In *Ruellia* there are four stamens which are generally didynamous, the two lateral being the shorter pair and the two anterior the longer, but the filaments are curved so that the anthers are placed under the posterior lobes, more or less deeply included or exserted. In ornithophilous species the stamens are sometimes all the same length. In all cases, the filaments are inserted below the throat of the corolla and are prolonged toward the interior and base of the corolla tube as two narrow protruding flaps that more or less separate the tube into a posterior (dorsal) section and an anterior (ventral) longitudinal channel.

*Pollen*. In the Acanthaceae, pollen morphology has traditionally been a useful taxonomic character in group delimitation at the generic and suprageneric level (Lindau, 1895; Petriella, 1968; Raj, 1961, 1973; Rizzini, 1949; Scotland, 1991). *Ruellia* species have spherical, porate, coarse-reticulate pollen (Fig. 4). Bremekamp & Nannega Bremekamp (1948) and Bremekamp (1969) suggested that differences in pollen morphology, such as sparsiporous grains versus three-porate ones, and differences in the constitution of the reticulum, such as size and regularity of the brochi, height of the muri, etc., could be used to separate the Old World species of *Ruellia* from the New World ones. In southern South American species the variations in size of the grains and in ornamentation of the walls

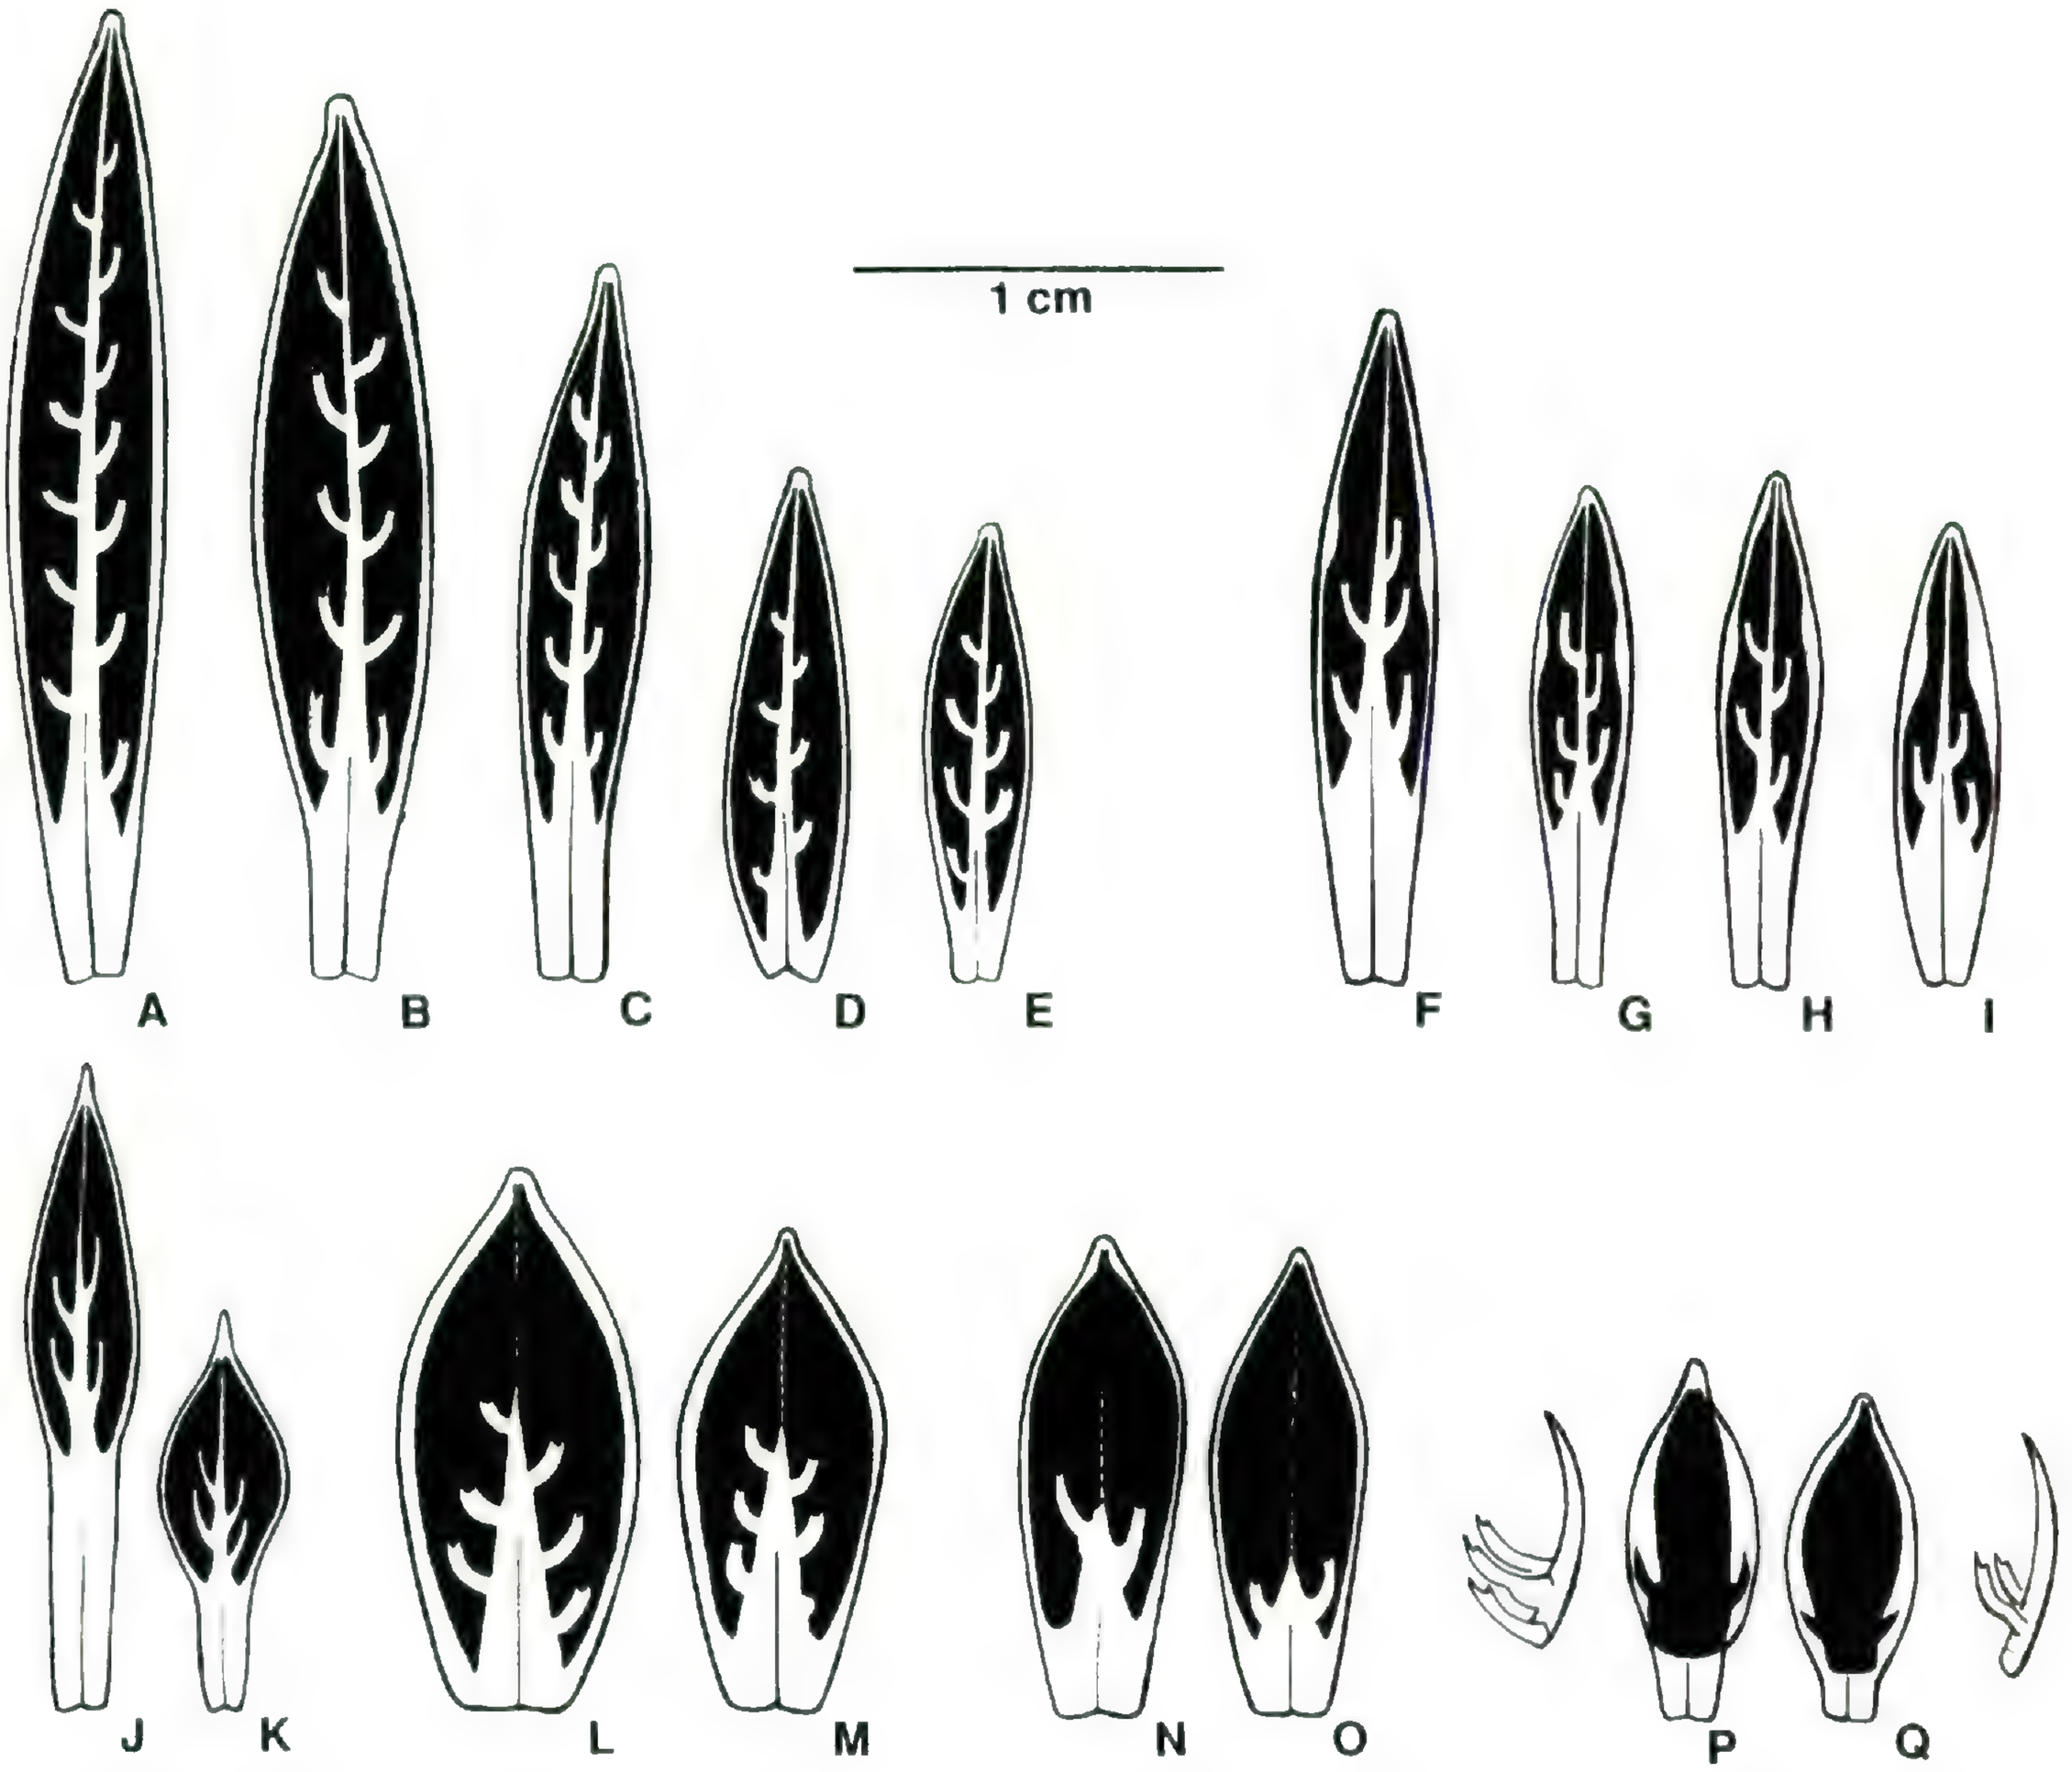

FIGURE 5. Capsule structure in *Ruellia*.—A–E. Group *Ruellia*.—F–I. Group *Physiruellia*.—J, K. Group *Hygrophiloidei*.—L, M. Group *Dipteracanthus*.—N, O. Group *Ebracteolati*.—P, Q. A, *R. coerulea*; B, *R. macrosolen*; C, *R. ciliatiflora* D, *R. morongii*; E, *R. hygrophila*; F, *R. angustiflora*; G, *R. brevifolia*; H, *R. longipedunculata*; I, *R. sanguinea*; J, *R. epallocaulos*; K, *R. kleinii*; L, *R. multifolia*; M, *R. brevicaulis*; N, *R. bulbifera*; O, *R. geminiflora*; P, *R. erythropus*; Q, *R. hypericoides*.).

do not correlate with any other morphological characters to help in the separation of groups of related species.

*Gynoecium*. The stigma is two-lobed with the lobes dorsiventrally compressed, the anterior lobe being generally larger than the posterior.

*Capsules*. In *Ruellia*, like in most Acanthaceae, the fruit is a biloculate, two-valved, loculicidal capsule. The base of the capsule is contracted and solid, and the seeds are found in the hollow upper part, subtended by hooklike retinacula. The different mechanisms by which the capsules open and the seeds are ejected are described by Sell (1969b). In some species of *Ruellia* the dehiscence is produced by the drying of the capsules (xerochasy), and in others by humidification (hydrochasy).

The structure of the capsule and the number of seeds per locule (1–14) are variable and are important taxonomic characters at a supraspecific level. Differences in the ratio between the length of the sterile, contracted, solid base, and the fertile, thicker, hollow upper part, characterize different groups of related species.

Group *Ruellia* (Fig. 5A–E) is characterized by the terete, narrowly elliptic capsules with a very short solid base (less than ¼ the length of the capsule) and numerous seeds per locule (5–14). Group *Physiruellia* (Fig. 5F–I) has a longer solid base in relation to the hollow part (⅓), and fewer seeds per locule (3–7). Group *Hygrophiloidei* (Fig. 5J–K) has clavate capsules with a short, rounded, apiculate hollow head of nearly the same length as the solid base, with very few seeds per locule (3–

4). Group *Dipteracanthus* (Fig. 5L, M) has terete, robust, thick-walled capsules with a short solid base (⅓ the length), and 3–6 seeds per locule. Group *Salpingacanthus* has a similar structure, with very large capsules. Group *Ebracteolati* (Fig. 5N, O) has an extremely reduced capsule with a very short solid base and only (1–)2 seeds per locule. Group *Chiloblechum* (Fig. 5P, Q) has small capsules with thin walls, a solid base ¼ the length, and 2–4 seeds per locule.

This last group differs markedly from the rest of the genus because on dehiscence, the protruding placentae with the retinacula and the seeds break away from the inner walls of each valve, separating elastically from the lower part of the capsule toward the top, and at the same time breaking the lateral walls. This type of dehiscence of the capsule has already been described for several unrelated genera within the family (e.g., *Dicliptera, Micranthus, Tetramerium, Blechum*) (Daniel, 1986; Sell, 1969b), but it is the first time it has been reported for *Ruellia*.

*Seeds.* The seeds are always flat and more or less orbicular in outline, with a slight notch at the chalazal end. The surface of the seed toward the outside of the capsule is usually convex, and the one toward the interior flat or concave. The seeds are more or less covered with appressed hairs that extend and turn mucilaginous on contact with water. This makes them extremely adhesive when wet, and in this way they can be dispersed by animals (ectozoochory). These hairs possess annular or spiral thickenings in their walls which strengthen their structure; the annular and spiral shape of the thickenings allows the hairs to lengthen on contact with water. In many species of group *Physiruellia* the hairs are condensed principally on the margins of the seeds, but otherwise the structure of the surface is quite constant. The mucilage the hairs secrete could also have a protective function, as it has shown high resistance to enzyme action (Lester & Ezcurra, 1991).

## Chromosome Numbers

The chromosome numbers of only less than 20% of the species of *Ruellia* have been studied, but they appear to be fairly uniform: more than 85% of the species are $2n = 34$ (Piovano & Bernardello, 1991). As Daniel et al. (1984) suggested, this constancy of chromosome number in all species of *Ruellia*, in contrast to the wide chromosomic variation that has been encountered in *Justicia*, the largest genus of the family, may be reflective of a more natural, though also large and morphologically diverse, taxon. The chromosome numbers of only eight of the species present in southern South America have been reported: *Ruellia brevifolia* (as *R. graecizans*) and *R. ciliatiflora* (as *R. lorentziana*) (Grant, 1955); *R. macrosolen* (Ezcurra & de Azkue, 1989); *R. bulbifera, R. coerulea* (as *R. tweediana*), *R. geminiflora, R. multifolia* var. *multifolia* (as *R.* aff. *dissitifolia*), and *R. longipedunculata* (Piovano & Bernardello, 1991).

Most *Ruellia* species have one pair of satellite chromosomes (Grant, 1955; Ezcurra & de Azkue, 1989; Piovano & Bernardello, 1991), and chromosome size seems quite variable (from 0.60 to 3.60 $\mu$m as reported by Piovano & Bernardello).

## Origin of Pollination Syndromes

The impressive morphological diversification of the flower in species of *Ruellia* from the New World suggests a limited set of morphological types. Distinct morphological flower types that appear recurrently within different genera and families of plants have traditionally been interpreted as representing pollination syndromes, i.e., the set of morphological, phenological, and physiological characters of flower and inflorescence that correlate with the morphology, behavior, and preferences of the effective pollinators of the species, and therefore represent adaptations to various modes of pollination (Ornduff, 1969). These different pollination syndromes have repeatedly been described for various taxonomic groups and have been summarized by Faegri & van der Pijl (1979) and Weberling (1989).

Even though Ornduff (1969) and Vogel (1991) cited several genera of gamopetalous families to exemplify complex patterns of adaptive radiation or divergence in floral morphology, few of them seem, as suggested by their morphological diversity, to have exploited such a diverse pollinator fauna as *Ruellia*. The diversity of floral form in this genus is similar to the adaptive radiation described by Grant & Grant (1965) for the Polemoniaceae and by Vogel (1991) for the Rubiaceae and Scrophulariaceae.

Cleistogamy in *Ruellia* is frequent (see Lord, 1981), and production of a great variety of floral morphs, from normal and reduced chasmogenes to semi-cleistogenes and cleistogenes, as has been described for the North American *Ruellia caroliniensis* (Long, 1971), suggests that floral morphology in the genus is labile, lacking developmental channelization. Different floral morphs within the same species have also been observed in cultivated specimens of the South American *Ruellia brevi-*

*folia* (Piovano et al., 1991), indicating developmental plasticity.

As summarized by Macnair (1989), in plant populations that are genetically variable regarding flower shape, size, coloration, or flowering time, different pollinator guilds can select different floral morphs. This can produce disruptive selection and result in the sympatric differentiation of species with different floral morphologies.

Differences in morphology related to different developmental stages can provide the variation on which selection can operate. This process has been suggested as the evolutionary origin of the corolla shape of the derived hummingbird-pollinated *Delphinium nudicaule* Torrey & Gray from a more generalized bumble-bee-pollinated species of *Delphinium*, through selection of neotenic forms by bird pollination (Guerrant, 1982).

This type of process, but through the selection of peramorphic instead of neotenic forms (as results of developmental acceleration or hypermorphosis), has been suggested to explain the evolution of *Ruellia macrosolen* (Ezcurra & de Azkue, 1989), a sphingophilous species with long, actinomorphic, white flowers, from sympatric and closely related melitophilous species, with shorter, functionally zygomorphic, blue flowers.

The heterochronic variability in development that has been observed in flower morphology within some species (expressed by the high frequency of cleistogamic and semicleistogamic or reduced forms), probably with a genetic basis, could thus be related to the wide array of floral syndromes in the genus. As has already been suggested (Ezcurra & de Azkue, 1989), the evolutionary shift from one floral syndrome to another may therefore have originated by simple heterochronic developmental changes selected by different pollinators.

## Reproduction and Dispersal

The role of cleistogamy in the reproductive biology of *Ruellia* has been discussed by Long (1971) in his detailed study of the floral polymorphy and breeding system of the North American *Ruellia caroliniensis*. Production of cleistogamic flowers has also been reported in many other genera of Acanthaceae, and Long has suggested that it is probably as important in this family as in Poaceae and Orchidaceae. Cleistogamic flowers in *Ruellia* are frequently inconspicuous structures with closed corollas of reduced size, difficult to differentiate from flower buds in herbarium material, but easily observed in live plants, where the capsules are produced without the opening of the flowers, and therefore present the closed corollas crowning the distal end, sometimes taking some time to fall off. In many cases the expression of cleistogamy has shown to have relation with external environmental factors (Uphof, 1938), like seasonality and environmental stress (Long, 1971; Piovano et al., 1991; Sell, 1977). This could explain the higher frequency of cleistogamic flower production in cultivated plants, especially in those transplanted to higher latitudes. This has been observed in plants of *Ruellia ciliatiflora* (Santos Biloni, 1963, as *R. lorentziana*) and *R. macrosolen* (Ezcurra & de Azkue, 1989) transplanted from northern Argentina (approximately 25°S) and cultivated in Buenos Aires (approximately 35°S lat.).

The combination of chasmogamic floral morphs well adapted to cross-pollination, with the production of reduced or cleistogamic ones in which autogamy is prevalent, serves as a means of assuring fertilization in cases where the efficiency of cross-fertilization decreases (Macnair, 1989). This is particularly so in cases of a single plant establishing itself in a new habitat, as is common in long-distance dispersal events, where generally one or a few seeds get introduced in a new area at a time. Moreover, colonizing plants frequently encounter a somewhat hostile environment in their new habitat, and the production of cleistogamic flowers in response to environmental stress, as is the case with *Ruellia*, ensures reproductive success with the minimum investment in flower production.

As Long (1976a) suggested, this succession of cycles of allogamy, with cycles of facultative autogamy that produce a whole series of homozygous biotypes, is probably the cause of many of the taxonomic problems present in *Ruellia*. Self-fertilization produces morphologically distinct local populations each with a low amount of diversity that can be erroneously identified as different species, and the outcrosses between different populations of this type can produce complex patterns of reticulate variation. Hence, the confused taxonomy of many *Ruellia* species groups may be related to these characteristics of the breeding system of the genus.

*Ruellia* seeds turn mucilaginous and adhesive on contact with water and in this way can be dispersed by animals (ectozoochory). Aquatic birds, especially migrating ones, could account for long-distance dispersal of such species as *Ruellia coerulea* and related entities of group *Ruellia* (e.g., *R. ciliatiflora*, *R. macrosolen*), which possess cylindrical capsules with numerous seeds and grow in open, disturbed, wet or seasonally flooded habitats. Although the distribution of the widespread and variable *Ruellia coerulea* is restricted to subtropical South America, there are species in south-

ern North America that seem closely related, such as *Ruellia malacosperma* and *Ruellia brittoniana* (cf. Turner, 1991). These could have originated by introductions through this process.

Stems fracture easily in the swollen regions over the nodes of many species, and this could also help in their dispersal. Decumbent stems of some species that grow in moist humus of the understory of forests root readily, and naturalized plants of *Ruellia brevifolia* in Instituto Lillo, San Miguel de Tucumán (Argentina), have been seen to reproduce in this way, resulting in dense thickets.

## Hybridization

Natural hybridization in *Ruellia* can be expected to be important in relation to two factors. First, many artificial crosses have resulted in hybrids, several with a high degree of fertility (Long, 1966, 1973, 1975, 1976a, b), suggesting that most species lack internal barriers to hybridization, especially when they are relatively closely related. Second, many species are sympatric in nature.

However, evidence for naturally occurring interspecific hybridization has been found only in a limited number of cases, and the putative hybrids (*Ruellia brevifolia* × *R. longipedunculata*, *R. brevicaulis* × *R. coerulea*) are discussed under the suspected parental species in the taxonomic section. The apparent rarity of natural hybrid production in the studied area may be due to the difficulties of recognizing them in herbarium material, especially between morphologically similar but variable species, and even in the field, when hybrid plant specimens or populations are rare and localized. Natural hybridization could therefore be underestimated, although it may have played an important role in the evolution of the genus. The existence of presumed naturally occurring hybrids between species pairs belonging to widely separated species groups (e.g., *Ruellia brevicaulis* × *R. coerulea*) suggests evolutionary reticulation, which could explain the taxonomic difficulties in delimiting supraspecific taxa within the genus.

It is also possible that sympatric species remain separated by external barriers, such as different pollinators, as has been suggested between *Ruellia macrosolen* and *R. ciliatiflora* (Ezcurra & de Azkue, 1989), or different ecological preferences in habitat, such as those between *Ruellia ciliatiflora* and *Ruellia coerulea*.

## Geographic Distribution and Habitat

*Ruellia*, being a mainly tropical genus, extends in South America to approximately 35°S and is present only in areas with floras belonging to the Amazon and Chaco floristic regions or dominions. In southern South America (from 20°S southward) these floristic regions have been subdivided into several phytogeographical provinces, each characterized by a different geography, climate, and vegetation. These provinces are frequently designated as Atlántica, Cerrado, Paranaense, and Yungas (Dominio Amazónico), and Chaco, Espinal, Monte, and Pampas (Dominio Chaqueño) (e.g., Cabrera, 1976; Cabrera & Willink, 1980). *Ruellia* species are found in all these floristic provinces, except in the dry Monte. The climate of these areas varies from hot and wet year-round, with over 2,000 mm rainfall, to warm and wet in summer and mild and dry in winter, with ca. 500 mm of rainfall especially during the summer months (from November to April).

Most of the species grow well in open and disturbed places, such as seasonally flooded areas or savannas with periodic fires, and are common in secondary growth. Even the ones that grow in the understory of forests are generally found in clearings and openings, roadcuts, and along stream or river banks. These characteristics together with their facultatively autogamous breeding system and mode of dispersal by animals (ectozoochory) make many species good colonizers and assure their success in long-distance dispersal events. This in some cases renders them important weeds in tropical and subtropical regions (e.g., *Ruellia ciliatiflora*).

Cultivation as ornamentals may have also helped to extend the natural range of some of the species, such as *Ruellia brevifolia*, which has become naturalized in many tropical places of the world (see Ezcurra, 1989).

## Economic Importance

Several species of *Ruellia* are cultivated mostly because of their showy flowers, sometimes in combination with attractive foliage. A few of the native ones from southern South America are frequently grown in warm regions all around the world, such as the red-flowered *Ruellia brevifolia* (generally known in horticulture as *R. graecizans*) and *Ruellia elegans* (syn.: *R. formosa*) (e.g., Everett, 1982). Other species of the area, such as *Ruellia angustiflora* and the blue-flowered *R. ciliatiflora* (generally reported as *R. lorentziana*), are not so common, and are cultivated more rarely (Dimitri, 1972; Ezcurra, 1989). Some of these subtropical species are probably hardier than their more tropical relatives and may adapt better to cooler regions of the world, hence they could be introduced in cultivation.

Some subtropical Acanthaceae native to north-

ern Argentina have been reported as having forage value (Burkart, 1943), especially in those areas with a seasonal climate with drier and colder periods where grasses are sometimes scarce. *Ruellia erythropus*, one of the most common and widespread species of *Ruellia* in southern South America, which is also found in southeastern Mexico, has been reported as good fodder (Burkart, 1943, erroneously as *Ruellia bahiensis*). This suggests it could be an important plant in the economy of those regions and should be investigated in relation to nutritional value.

## Taxonomic Treatment

**Ruellia** L., Sp. Pl. 634. 1753. TYPE: *R. tuberosa* L. (lectotype, selected by Britton & Brown (1913)).

*Stephanophysum* Pohl, Pl. Bras. Icon. Descr. 2: 83. 1831. TYPE: *Stephanophysum longifolium* Pohl (lectotype, selected by Bremekamp & Nannega Bremekamp (1948)).

*Dipteracanthus* Nees in Wallich, Pl. Asiat. Rar. 3: 75, 81. 1832. TYPE: *Dipteracanthus prostratus* Nees.

*Aphragmia* Nees in Lindl., Nat. Syst. Bot. ed. 2: 444. 1836. TYPE: *Aphragmia haenkei* Nees.

*Gymnacanthus* Nees in Lindl., Nat. Syst. Bot. ed. 2: 444. 1836, non Oersted 1854. TYPE: *Gymnacanthus petiolaris* Nees.

*Ulleria* Bremek. Proc. Kon. Ned. Akad. Wetensch. Ser. C, 72, 14: 423. 1969. TYPE: *Ulleria geminiflora* (HBK) Bremek. (= *Ruellia geminiflora* HBK).

Perennial herbs, shrubs or subshrubs, erect to decumbent, ± pubescent. Leaves opposite, petiolate or subsessile, the blades entire, crenate or slightly dentate, with cystoliths. Flowers sessile or pedicellate, in axillary sessile dichasia or in pedunculate multiflowered cymes; the bracts and bracteoles generally small, not imbricate. Chasmogamous flowers medium or large, showy, blue, purple, or red, to mauve, lavander, pink, and white, rarely yellowish; cleistogamous flowers small and tubular. Calyx deeply cleft, the five segments linear or lanceolate, usually subequal, sometimes the posterior longer, rarely the lateral united to the anterior ones. Corolla straight or incurved, tubiform, funnelform or salverform, the basal portion of the tube narrow, abruptly or gradually dilated to a ± obconic or campanulate throat, sometimes anteriorly inflated or more rarely saccate, the limb generally spreading and oblique, sometimes erect, the five lobes ovate or rounded, contorted in bud, equal, sometimes the two posterior ± connate, forming a posterior lip. Stamens four, generally didynamous, included or exserted, the filaments inserted below the throat of the corolla, slightly dilated at the base, the anthers bithecous, oblong-sagittate, dorsifixed, the thecae parallel, equal, muticous. Pollen spheroidal, porate, coarsely reticulate. Disc inconspicuous; style slender, subulate, bilobate, the anterior lobe recurved, the posterior lobe generally reduced or obsolete; ovules 2–14 in each locule. Capsule clavate, obovate, oblong-linear or narrowly elliptic in contour, contracted and ± stipiform at the base, terete or somewhat compressed above. Seeds 4–28, compressed and flat, obliquely ovate or suborbicular, with appressed hairs that extend and turn mucilaginous when wet, subtended by retinacula ± acute.

## Key to the Species and Species Groups of *Ruellia* in Southern South America

1a. Corollas red ..... Group I. *Physiruellia*

2a. Flowers in long-pedunculate, cymose, multiflowered inflorescences subtended by the upper leaves; basal tube of the corolla frequently of the same length or shorter than the throat.

3a. Corolla lobes 0.5–1 cm diam.; calyx segments oblanceolate or spathulate.
4a. Erect herbs 30–50 cm tall ..... 1. *R. elegans*
4b. Scandent shrubs or subshrubs to 2 m tall ..... 2. *R. reitzii*
3b. Corolla lobes less than 0.5 cm diam.; calyx segments linear or oblong, acute or obtuse but not spathulate.
5a. Throat notably ventricose; basal tube less than 8 mm long ..... 3. *R. brevifolia*
5b. Throat not ventricose; basal tube more than 10 mm long.
6a. Young stems sharply quadrangular, with acute angles; Brazil, Paraguay, northern Uruguay, and northeastern Argentina ..... 4. *R. angustiflora*
6b. Stems obtusely quadrangular, rounded in the angles; Bolivia and northern Argentina ..... 5. *R. longipedunculata*
2b. Flowers solitary and sessile or shortly pedunculate in the axils of the upper leaves; basal tube of the corolla generally longer than the throat; Bolivia and northern Argentina ..... 6. *R. sanguinea*
1b. Corollas white, mauve, or blue.
7a. Flowers always in pedunculate, cymose, multiflowered inflorescences (subsessile and solitary only in some rosette plants) ..... Group II. *Ruellia*
8a. Caulescent herbs.
9a. Corollas mauve or blue, rarely white, with basal tube less than 2 cm long; calyx lobes less than 1 cm long.
10a. Leaves ± pubescent; flowers in cymes aggregated into a terminal, pyramidal thyrse ..... 7. *R. ciliatiflora*
10b. Leaves glabrous; flowers in lateral, axillary cymes ..... 8. *R. coerulea*
9b. Corollas white, with basal tube 2.5–5 cm long; calyx lobes 1.5 2 cm long ..... 9. *R. macrosolen*
8b. Acaulescent rosette plants.
11a. Corollas bluish, in lax, elongate pseudoracemes; pedicels puberulous or glabrous ..... 10. *R. hygrophila*
11b. Corollas white, generally subsessile and solitary; pedicels hirsute-tomentose ..... 11. *R. morongii*
7b. Flowers sessile, rarely pedunculate, solitary in the axils of the upper leaves, rarely in twos or threes.
12a. Bractlets present, and as long as or longer than the calyx segments.
13a. Stems sharply quadrangular ..... Group III. *Hygrophiloidei*
14a. Flowers more than 2 cm long, purple ..... 12. *R. epallocaulos*
14b. Flowers less than 2 cm long, white ..... 13. *R. kleinii*
13b. Stems obtusely quadrangular or terete ..... Group IV. *Dipteracanthus*
15a. Basal tube of the corolla shorter than the throat.
16a. Leaves tomentose with sessile glands intermingled with simple hairs ..... 14. *R. brachysiphon*
16b. Leaves with lax, spreading, shiny hairs, without glands ..... 15. *R. brevicaulis*
15b. Basal tube of the corolla the same length as or longer than the throat.
17a. Leaves and stems velutino-tomentose or velutino-hirsute ..... 16. *R. multifolia*
17b. Leaves and stems glabrous ..... 17. *R. solitaria*
12b. Bractlets obsolete or absent.
18a. Basal tube of the corolla shorter than the throat; placentas not separating from the capsule; seeds (2–)4 ..... Group V. *Ebracteolati*
19a. Leaves glabrous and coriaceous; nodes and calyx lobes glabrous; underground xylopodium rounded and tuberculate ..... 18. *R. bulbifera*
19b. Leaves ± pubescent and not coriaceous; nodes and calyx lobes generally white-tomentose; xylopodium not markedly rounded and tuberculate.
20a. Roots fibrous; leaves elliptic or ovate, sometimes lanceolate, 2–5 cm long, corolla 3–4 cm long ..... 19. *R. geminiflora*
20b. Roots, fleshy, fusiform; leaves lanceolate, 5–9 cm long; corolla 4–6 cm long ..... 20. *R. magniflora*
18b. Basal tube of the corolla the same length as the throat or longer. Placentas separating or not from the capsule; seeds 4–8.
21a. Basal tube of the corolla more than 6 cm long; placentas not separating from the capsule; seeds 6–8 ..... Group VI. *Salpingacanthus*
21. *R. nobilis*
21b. Basal tube of the corolla less than 5 cm long; placentas separating with the retinacula and seeds from the capsule, breaking the walls; seeds 4–6 ..... Group VII. *Chiloblechum*
22a. Leaves 2–5 cm long, the ones subtending the flowers subsessile and markedly ciliate; calyx segments unequally cleft, forming a three-lobed structure ..... 22. *R. erythropus*
22b. Leaves 1.5–2 cm long, the ones subtending the flowers glabrous or puberulous. Calyx segments 5 and subequally cleft ..... 23. *R. hypericoides*

## I. Group **Physiruellia**

*Ruellia* L. sect. *Physiruellia*, Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4(3b): 311. 1895. *Ruellia* L. sect. *Physiruellia* Lindau ser. *Eglandulosae* Lindau, loc. cit.: 311. 1895. TYPE: *Ruellia acutangula* Nees (lectotype, selected here).

*Stephanophysum* Pohl, Pl. Bras. 2: 83. t. 155, 156. 1830 1831. TYPE: *Stephanophysum longifolium* Pohl (lectotype, selected by Bremekamp & Nannega Bremekamp (1948)).

*Scordoxylum* Nees in Benth., Pl. Hartw.: 236. 1846. TYPE: *Scordoxylum hartwegianum* Nees.

*Arrhostoxylon* Nees in C. Martius, Fl. Bras. 9: 57. 1847. TYPE: *Arrhostoxylon glabrum* Nees (lectotype, selected by Bremekamp & Nannega Bremekamp (1948)).

*Stemonacanthus* Nees in C. Martius, Fl. Bras. 9: 53. t. 54. 1847. TYPE: *Stemonacanthus salviaefolius* Nees (lectotype, selected by Leonard (1951–1958)).

Flowers pedicellate, borne in dichasial cymes subtended by the upper leaves, sometimes reduced to solitary flowers always pedicellate and bibracteolate. Capsules clavate, narrowly oblanceolate in contour, hollow the upper ⅔ of the total length, solid and stipitate in the base. Seeds 8–14.

Group *Physiruellia* is restricted to the New World and consists of numerous suffruticose plants that are frequent in the understory of tropical and subtropical forest. In southern South America they are important in floristic provinces of the Amazon region or dominion (see Cabrera & Willink, 1980). It is a large and very diversified assemblage which, on being studied in detail, may be divided into further gruops of closely allied species. Many of the species present handsome ornithophilous flowers, frequently red or pink.

**1. Ruellia elegans** Poiret, Encycl. Suppl. 4: 727. 1816. *Ruellia formosa* Andr. Bot. Repos. 10: tab. 610. 1810, non *Ruellia formosa* Humb. & Bonpl. 1805. *Arrhostoxylon formosum* (Andr.) Nees in C. Martius, Fl. Bras. 9: 62. 1847. *Arrhostoxylum elegans* (Poiret) Bremek. Verh. Nederl. Akad. Wet. (Tweede Sect.) 45(1): 12. 1948. TYPE: Illustrated in Andr. Bot. Repos. 10: tab. 610. 1810. Figure 6.

*Arrhostoxylon silvaccola* Nees var. *montanum* Nees in C. Martius, Fl. Bras. 9: 60. 1847. Syn. nov. SYNTYPES: Brazil. Minas Gerais: Mariana, *Langsdorf s.n.* (K), *Martinus s.n.* (M not seen, photo F 20524); *Sellow 104* (B destroyed), *263* (B destroyed; isosyntypes, K, P).

Erect suffruticose herb 30–50 cm tall, with few, sparsely branched, erect or decumbent stems, quadrangular and pubescent when young, glabrescent at maturity. Leaves on pilose petioles 0.5–3 cm long, the blade widely ovate, 4–9 cm long and 2–5 cm wide, obtuse and acuminate, widely cuneate on the base and somewhat decurrent on the petiole, the surface ± pilose when young, glabrescent at maturity, the margins ciliate. Flowers pedicellate, borne in long-pedunculate, few-flowered, lax, dichasial cymes, arising from the axils of the upper leaves; bracteoles narrowly oblong-spathulate or linear, less than 1 cm long and 2 mm wide, pubescent. Calyx ca. 1.5 cm long, the segments linear-spathulate, pubescent and glandular-ciliate. Corollas red, somewhat bilabiate, the basal tube 2–4 mm long, the throat curved, narrowly obconical, 2.5–3.5 cm long and 1 cm diam. at the orifice, the two posterior lobes erect, 1.5 cm long, united more than half their length, the three anterior spreading, ca. 1.5 cm diam. Stamens 3–4 cm long, subexserted under the posterior lobes, one pair somewhat shorter, anthers 3 mm long. Capsule elliptic-obovate, ca. 2 cm long and 5 mm thick, hollow nearly to the base, glabrous. Retinacula acute, 2 mm long. Seeds more than 12, flat, suborbicular, 2–3 mm wide, appressed-pubescent.

*Distribution.* Southeastern and central Brazil, from Minas Gerais to Paraná. It is found in disturbed, more or less open places, such as borders of Cerrado forest and mesophilous gallery forests. It flowers in spring and summer.

*Representative specimens.* BRAZIL. **Minas Gerais:** Estrada entre Araxá e Uberaba, km 381, em cerrado, 100 m.s.m., *Shepherd 7220* (MBM). **Paraná:** Mun. Cerro Azul, Cerro Azul, *Hatschbach 6401* (MBM, US).

*Ruellia elegans* is morphologically similar to some species of group *Ruellia* in the structure of the capsule and the herbaceous habit, but the calyx and corolla morphology place it close to *Ruellia sceptrum-marianum* (Vell. Conc.) Stearn, *R. acutangula* (Nees) Lindau, *R. silvaccola* (Nees) Lindau, and other related species of group *Physiruellia*. The similarities in vegetative and fruit characters to species of group *Ruellia* may just be a case of convergence within the evolution of group *Physiruellia*. It is a beautiful plant with large red flowers, sometimes cultivated as an ornamental. Human activities may have helped to extend its natural range.

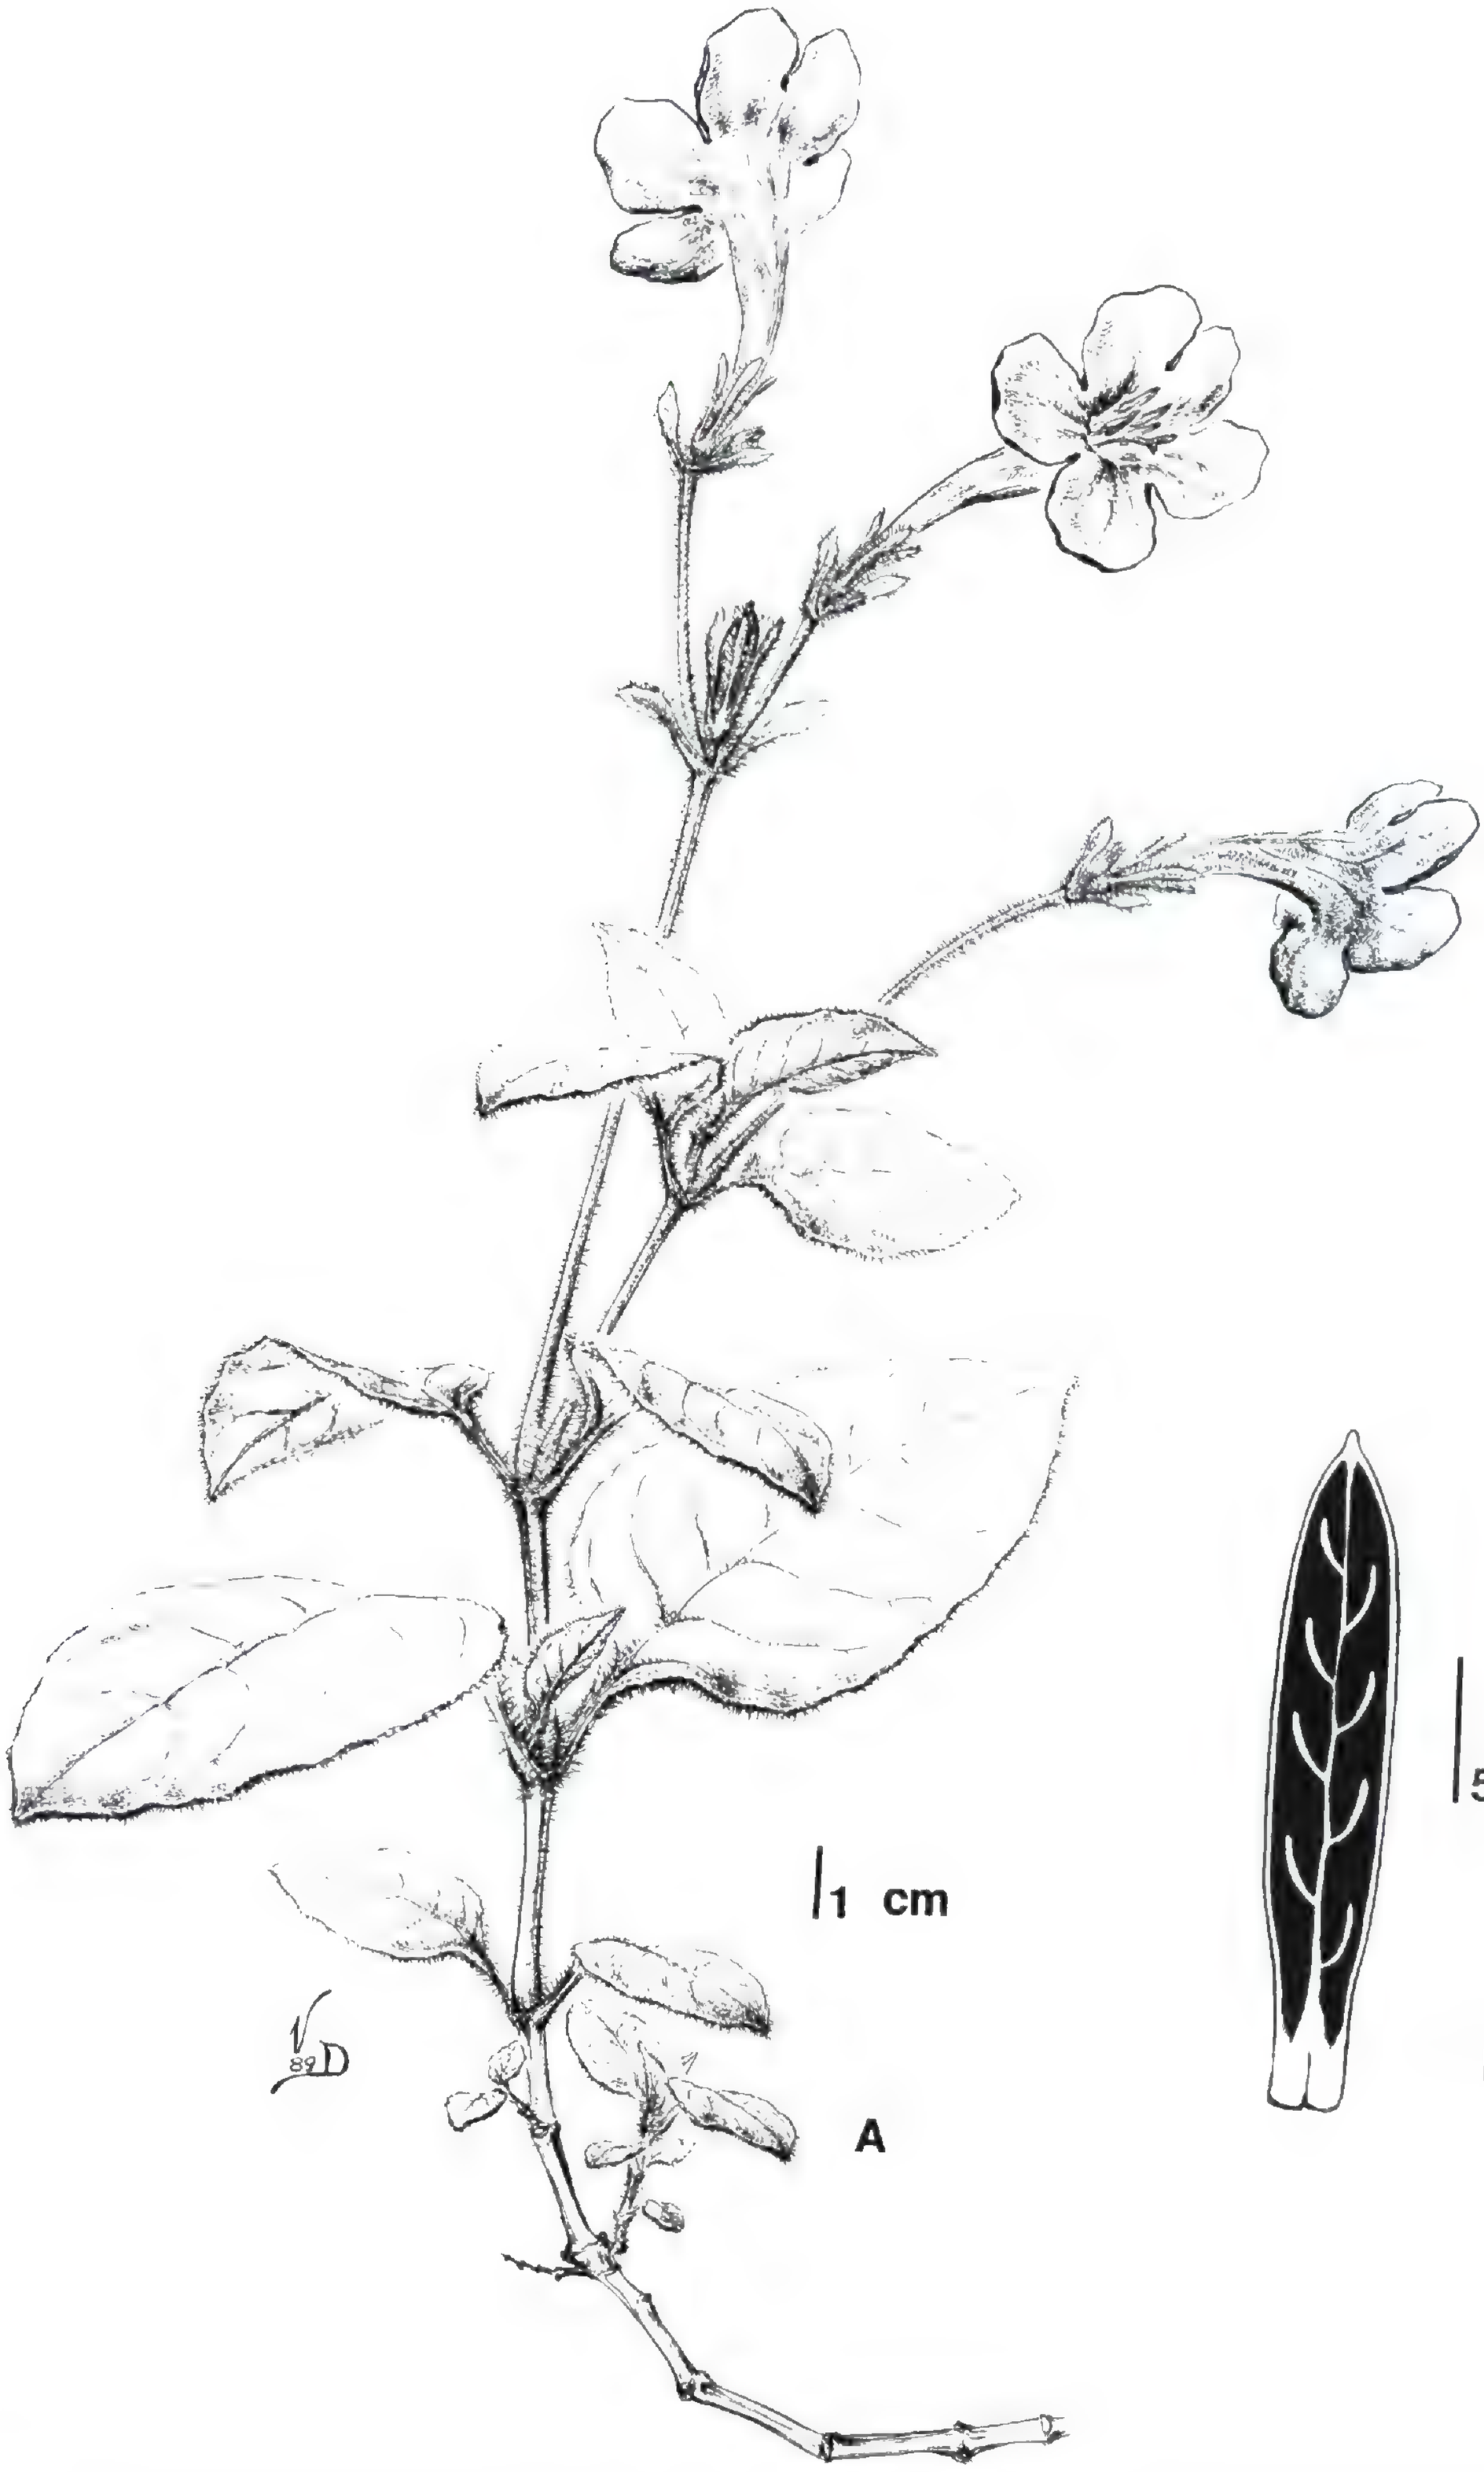

FIGURE 6. *Ruellia elegans* Poiret.—A. Flowering branch.—B. Immature capsule without seeds, schematic. (A, *Hatschbach 6401*; B, *Shepherd 7220*.)

**2. Ruellia reitzii** Wasshausen & Smith in Reitz, Fl. Illustr. Catarinense ACAN: 60. 1969. TYPE: Brazil. Santa Catarina: Luis Alves, Rio Canoas, 18 Jan. 1953, *Reitz 5154* (holotype, US).

Scandent or straggling shrub to 2 m tall, with sparsely branched stems, the younger portions markedly quadrangular, glabrous or pubescent, the older portions subterete and inflated over the nodes, becoming woody. Leaves on petioles 0.7–1.5 cm long, the blades ovate or elliptic, 3–7(–15) cm long and 1.5–3(–6) cm wide, acute or acuminate, cuneate at the base and somewhat decurrent on the petiole, irregularly and shallowly crenate, the surface glabrous to lightly velutino-puberulous, with trichomes mostly eglandular. Flowers pedicellate, in pedunculate cymes borne in the axils of the terminal leaves; peduncles 3–7 cm long; compound dichasia unevenly ramified (anisocladous), generally longer than the subtending leaves, frequently with supernumerary buds in the ramifications; bracteoles obovate, spathulate to oblanceolate, small, the lower ones generally foliaceous, more than 1 cm long. Calyx segments oblanceolate or spathulate, 12–14 mm long and 4–5 mm wide, rounded, puberulous. Corolla red, ca. 5 cm long, curved, the basal tube 1.5 cm long and 2 mm wide, opening into a cylindrical throat 1–2 cm long and 8–10 mm wide, the lobes semi-erect, rounded, 2 cm long and 1.5 cm wide, emarginate. Stamens exserted with anthers 4 mm long, laterally connate. Ovary pubescent; style exserted. Capsule unknown.

*Distribution.* Southern Brazil, in the state of Santa Catarina. In flower in January.

*Representative specimens.* BRAZIL. **Santa Catarina:** Braço Serafim, Margem de cascata, *Reitz C 2009* (HBR, US).

*Ruellia reitzii* is characterized by the large red flowers in multiflowered dichasial cymes and the spathulate or oblanceolate, pubescent calyx lobes. In these characters it shows close affinities with the group of *Ruellia acutangula* (Nees) Lindau, *R. sceptrum-marianum* (Vell. Conc.) Stearn, and related species of central and southeastern Brazil. *Ruellia reitzii* occurs more to the south and differs from these species principally by the weaker or scandent habit.

**3. Ruellia brevifolia** (Pohl) Ezcurra, Darwiniana 29: 278. 1989. *Stephanophysum brevifolium* Pohl, Pl. Bras. Icon. Descr. 2: 84, tab. 155. 1831. TYPE: Brazil. Rio de Janeiro: Rio de Janeiro, *Schott s.n.* (holotype, W not seen, photo SI). Figure 7.

Suffruticose herb or subshrub to 1 m tall, with numerous erect stems, sparsely branched, obtusely subquadrangular when young, glabrous. Leaves on petioles 1–5 cm long, the blades ovate, 4–15 cm long and 1.5–8 cm wide, acuminate at the apex, cuneate at the base, entire or shallowly crenate, the surface generally glabrous, sometimes pubescent. Flowers pedicellate, borne in axillary, lax, long-pedunculate, multiflowered cymes of compound dichasia; supernumerary buds frequent in the ramifications. Bracteoles ovate or lanceolate, foliaceous, bigger than the calyx lobes. Calyx 5–10 mm long, the segments linear and acute, less than 1 mm wide, puberulous. Corollas curved, scarlet, the basal tube 0.5–1 cm long, opening into an anteriorly inflated, ventricose throat 1–1.5 cm long and 0.5–1 cm wide, narrower toward the orifice, the lobes suberect, small, rounded, 2–3 mm long, retuse. Stamens subexserted with filaments ca. 9 mm long, and anthers 3 mm long, laterally connate, basally apiculate. Ovary puberulous; style exserted. Capsule clavate, 1–1.5 cm long and 3 mm thick, broadest above the middle, solid-stipitate to 3 mm high, glabrous. Seeds 8–12, suborbicular, 2 mm diam., with hygroscopic-viscid pilose margins; retinacula 2 mm long.

*Distribution.* Tropical and subtropical South America, from Colombia, Ecuador, Peru, and Bolivia to southern Brazil, Paraguay, and northern Argentina. It is found in the understory of open places of the forest, such as clearings, borders of roads, and water courses, from sea level to 1,500 m altitude. It prefers disturbed, humid soil; it flow-

*Ruellia brevifolia* is characterized by the small scarlet, ventricose flowers with inflated corollas in multiflowered cymes. It is one of the most widely distributed species in South America, ranging from Colombia to northern Argentina. It shows a large amount of variation over its area, sometimes presenting pubescent leaves or larger-flowered populations. It is used as an ornamental in tropical regions all over the world, where it often becomes naturalized (Ariza Espinar, 1983; Backer & Bakhuizen van den Brink, 1965; Barker, 1986). Its cultivation in South America may have helped to extend its natural range through garden escapes and establishment in new areas (Ezcurra, 1989). *Ruellia amoena* Nees and *Cyrthacanthus corymbosus* Martius ex Nees are nomina nuda that have been used for this species in herbaria (Nees, 1847b).

4. **Ruellia angustiflora** (Nees) Lindau ex Rambo, Iheringia, Bot. 12: 23. 1964. *Stephanophysum angustiflorum* Nees in C. Martius, Fl. Bras. 7: 51. 1847. SYNTYPES: Brazil. Erect or somewhat scandent shrub to 2 m tall, with sparsely branched stems, the younger portions sharply quadrangular, glabrous, the older portions subterete and inflated over the nodes, becoming woody. Leaves on petioles 0.3–1.5(–4) cm long, the blades ovate or elliptic, 3–10(–15) cm long and 1.5–4(–6) cm wide, acute or acuminate, cuneate at the base and somewhat decurrent on the petiole, irregularly and shallowly crenate, the surface glabrous to lightly velutino-puberulous, with trichomes mostly eglandular. Flowers pedicellate, in pedunculate cymes borne alternatively on one of each pair (rarely on both) of the terminal leaves; peduncles 3–7 mm long; compound dichasia unevenly ramified (anisocladous), generally longer than the subtending leaves, frequently with supernumerary buds in the ramifications; bracteoles obovate to oblanceolate, small, the lower ones generally foliaceous, more than 1 cm long. Calyx segments linear-lanceolate, 4–12 mm long and 1–2 mm wide, acute, puberulous. Corolla red, 3–4(–6) cm long, angled, the basal tube 1–2 cm long, opening into a cylindrical throat 1–2 cm long and 8 mm wide, the lobes semi-erect, rounded, 5 mm long, emarginate. Stamens subexserted with filaments 1–1.5 cm long, and anthers 4 mm long, laterally connate, obtuse, and with glandular connective. Ovary glabrous; style exserted. Capsule clavate, 1.5–2 cm long and 4 mm thick, glabrous, broadest above the middle, the base solid to 3–5 mm high. Seeds 8–12, dark brown, 2 mm diam., with pilose margins, hygroscopic-viscid when wet; retinacula 2 mm long.

*Vernacular names.* "Flor de fogo," in Santa Catarina, Brazil (Wasshausen & Smith, 1969).

*Distribution.* Southern Brazil, northern Uruguay, eastern Paraguay, and northeastern Argentina, in the hygrophilous subtropical forests of the basins of the Rivers Paraná and Uruguay (Paranaense phytogeographical province). It is found in humid places, such as borders of streams, margins of rivers, and near waterfalls, in disturbed, open and sunny locations of the forest. It flowers in winter, spring, and summer, especially from July to February.

*Ruellia angustiflora* is characterized by the markedly quadrangular stems and the bright red tubular flowers in multiflowered axillary cymes. It is frequent in the understory of gallery forests of southern Brazil, eastern Paraguay, northeastern Argentina, and northern Uruguay, and had been erroneously identified by many authors (e.g., Lindau, 1894; Wasshausen & Smith, 1969; Dawson, 1979) as *Ruellia sanguinea*, a species common in southern Bolivia and northern Argentina (see Ezcurra, 1989). It is often cultivated because of its handsome, red flowers and easy propagation. The isolated localities of the southernmost portion of its range (e.g., Entre Ríos, Federación) are probably the product of garden escapes.

5. **Ruellia longipedunculata** Lindau, Bull. Herb. Boissier 3: 365. 1895. TYPE: Bolivia. Santa Cruz: Santa Cruz, 2,600–1,000 m, *Kuntze*, May 1892 (holotype, B destroyed, photo F 18213; isotypes, NY, US). Figure 9.

*Stephanophysum brookeae* Bremek., Proc. Kon. Ned. Akad. Wetensch. Ser. C. 72, 4: 424. 1969. TYPE: Bolivia. Santa Cruz: Camiri, on Río Parapeti refinery and commencement of the pipeline, 2,500 ft., 3 Sep. 1949, *Brooke 5577* (holotype, BM; isotype, NY). Syn. nov.

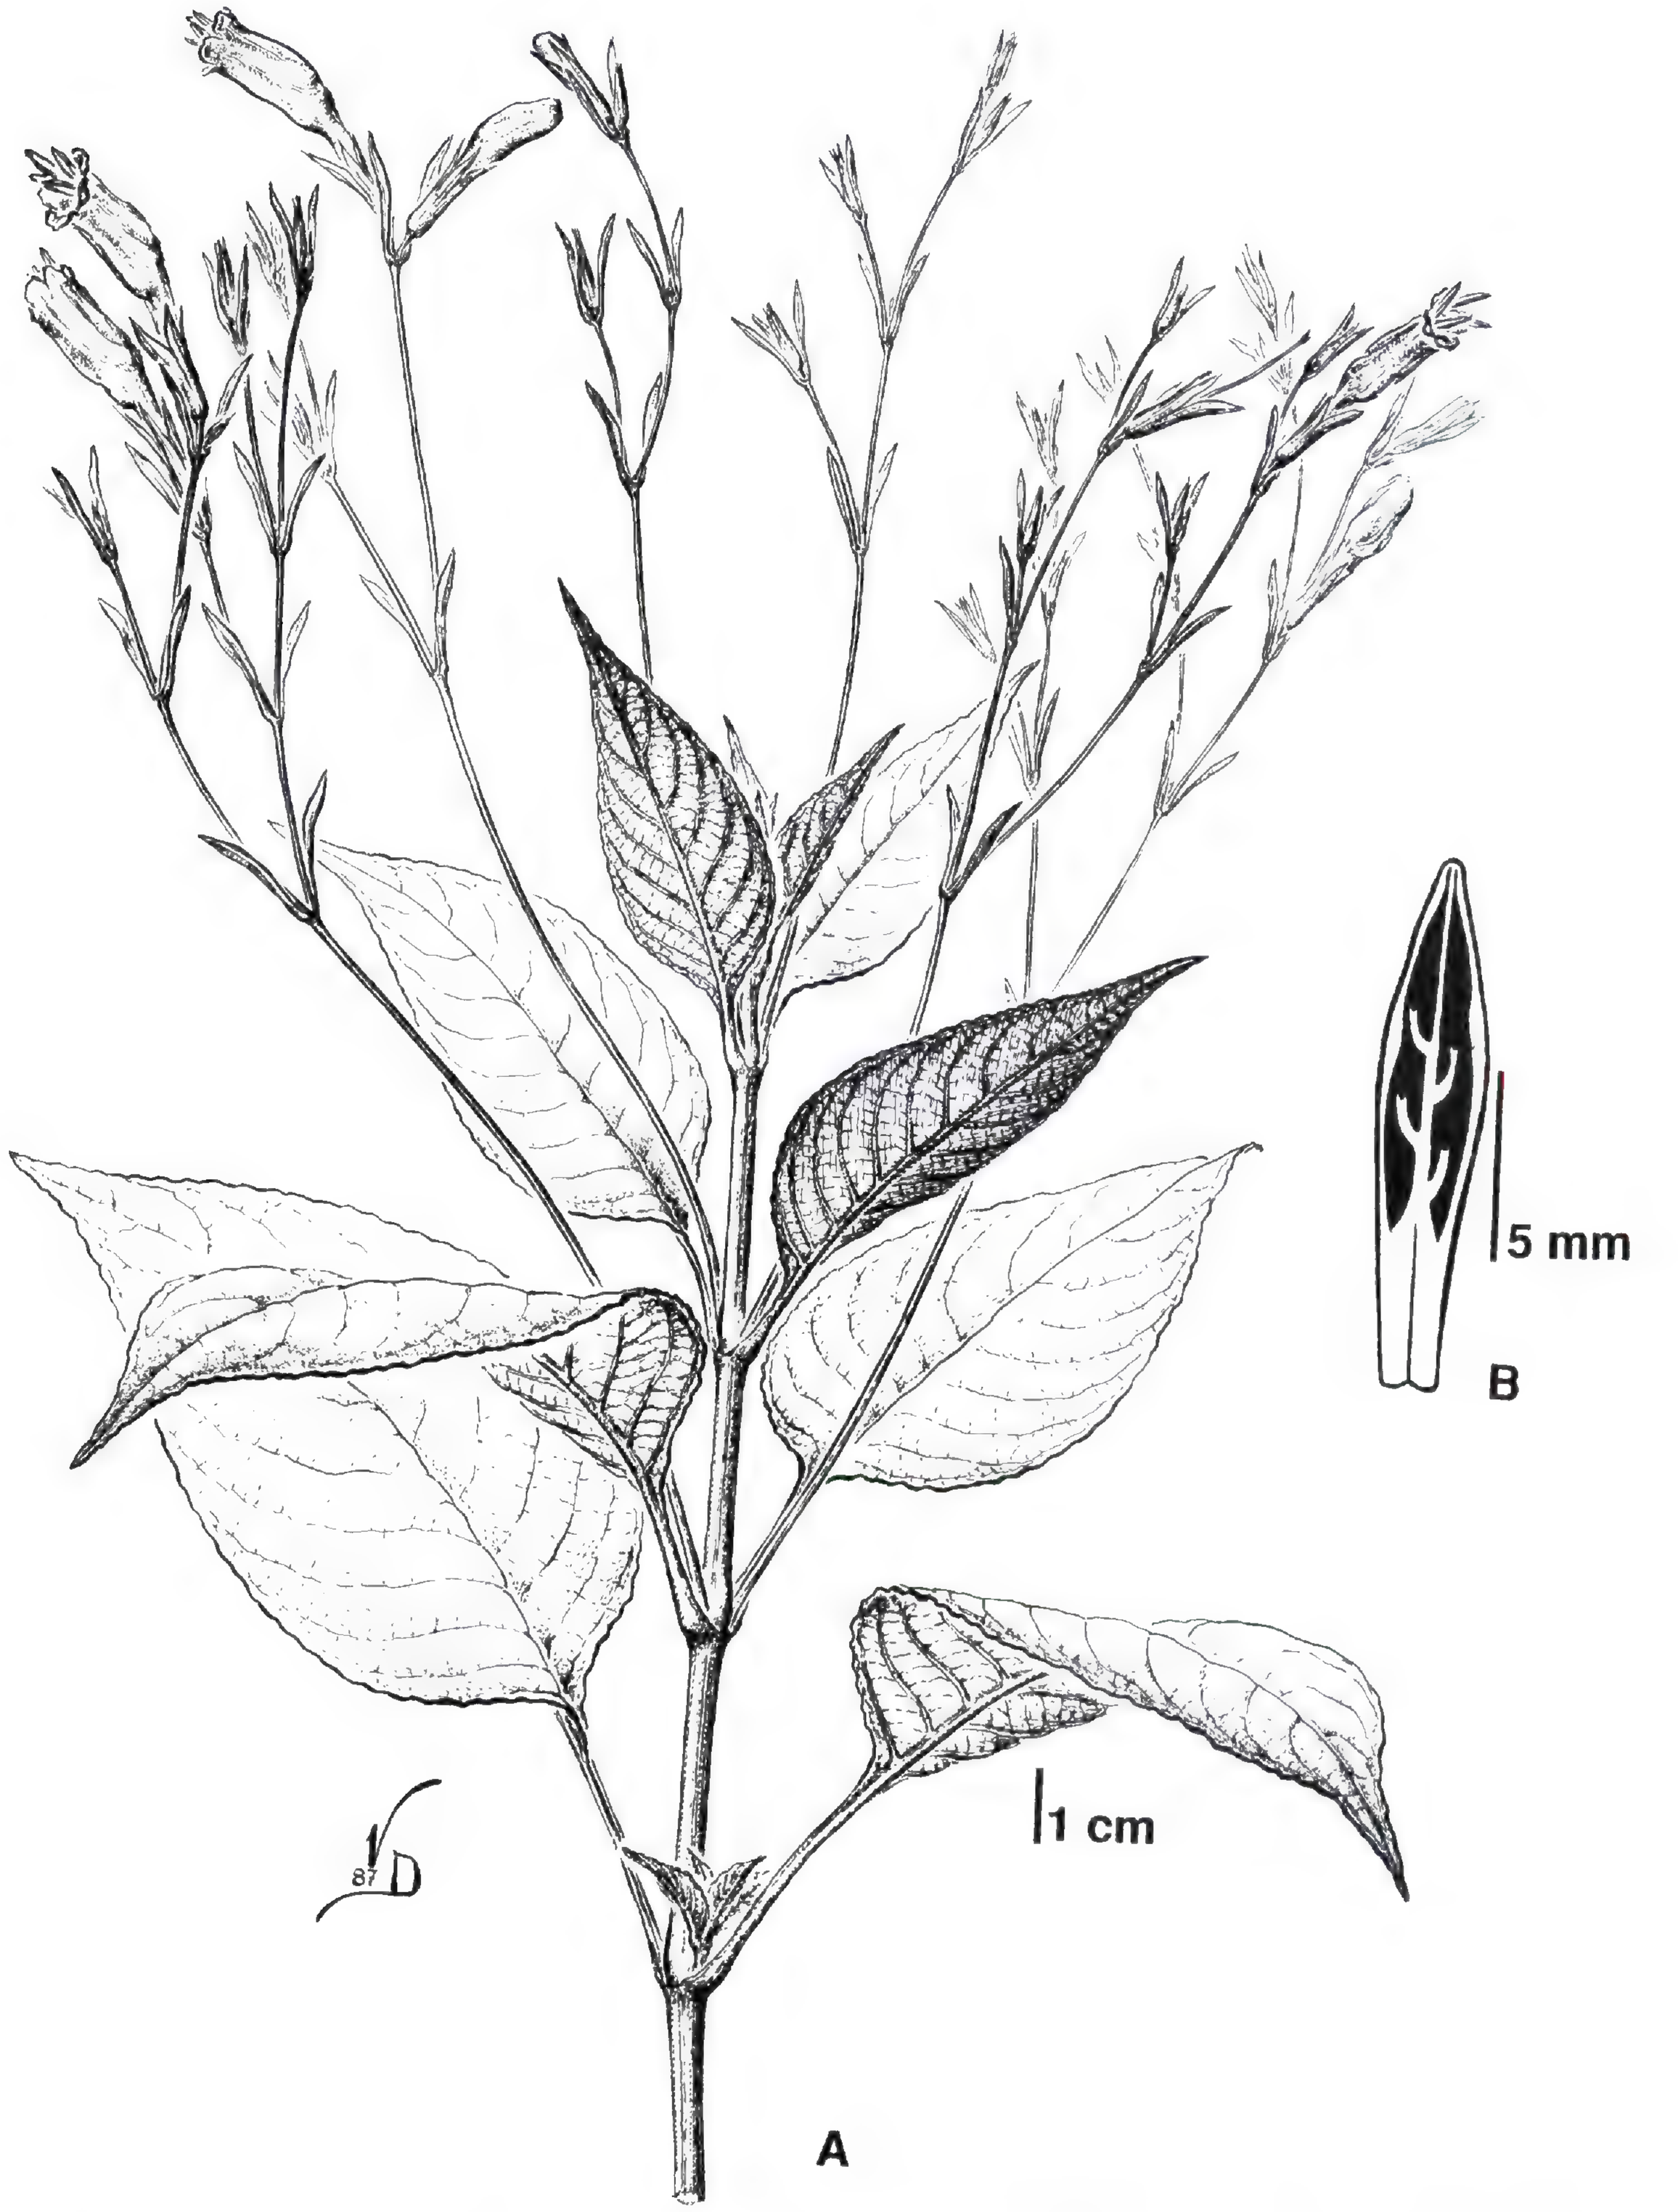

FIGURE 9. *Ruellia longipedunculata* Lindau. — A, Flowering branch. — B. Open capsule without seeds, schematic. (A, *Cabrera 26526*; B, *Cabrera 32782*.)

Stout suffruticose herb to 2 m high, the stems ascending, obtusely quadrangular, slightly hirsute-pilose when young, glabrescent at maturity. Leaves on petioles 0.5–2.5(–4) cm long, the blades ovate, 5–10(–15) cm long and 2–6(–8) cm wide, acuminate, obtuse or rounded at the base, irregularly and very shallowly crenate or dentate, the surface glabrous to lightly puberulous. Flowers pedicellate, in dichasia forming lax, long-pedunculate cymes, borne on both pairs of the terminal leaves, generally longer than the subtending leaves, frequently with supernumerary buds in the ramifications; bracteoles spathulate to oblanceolate, approximately 1.5 cm long and 1 mm wide, the lower ones generally larger and foliaceous. Calyx ca. 2 cm long, the segments oblong-lanceolate, 12–15 mm long and 2–3 mm wide, acute, glabrous, the superior somewhat larger. Corolla red, 2.5–3 cm long, the basal tube ca. 1.3 cm long, opening into a subcylindrical throat 1.5 cm long and 4–5 mm wide, the lobes semi-erect, rounded, 3–4 mm long. Stamens subexserted with filaments 13–15 mm long, and anthers 4 mm long. Ovary puberulous; style exserted. Capsule clavate, 1.5 cm long and 3 mm thick, glabrous, broadest above the middle, the base solid to 5 mm high. Seeds 6–8, dark brown, 2 mm diam., with pilose margins, hygroscopic-viscid when wetted; retinacula 2 mm long.

*Distribution.* Southeastern Bolivia and northern Argentina, in low mountain forests of the Yungas phytogeographical province, near transition to the more xerophilous Chaco forest. It is found in the underwood, in openings and borders of paths, rivers, and streams. It flowers in spring, from September to December, and could be used as an ornamental.

*Representative specimens.* ARGENTINA. **Jujuy:** Camino a Valle Grande, *Cabrera 27816* (LP, SI); Serranía de Calilegua, El Cebilar, *Fabris 4436* (LP); Mesada de Las Colmenas, *Iudica & Ramadori 5* (SI); Camino de la toma del Río Zora a Cafetales, *Zuloaga 2903* (SI). **Salta:** Agua Blanca, *Cabrera 26526* (LP, SI); Depto. Chicoana, Los Laureles, *Cabrera 32782* (SI); Quebrada de Escoipe, *Zardini 1205* (LP); Ruta Nac. 34, Dique Itiyuro, *Zuloaga 2728* (SI).

*Ruellia longipedunculata* is characterized by the long, somewhat pendulous, multiflowered inflorescences, the wide calyx lobes, and the narrow red corollas. Specimens that are morphologically intermediate with *Ruellia brevifolia* in these characters suggest natural hybridization in areas where these species are sympatric (Ezcurra, 1989).

**5a. Ruellia longipedunculata** Lindau × **Ruellia brevifolia** (Pohl) Ezcurra.

Plants similar to *Ruellia longipedunculata*, but differing by the shorter and narrower calyx lobes and the shorter and somewhat inflated corolla throats.

*Representative specimens.* ARGENTINA. **Salta:** camino a la finca Yakúlica, aprox. 5 km del Puente Agua Blanca, *Cuezzo 11718* (LIL, pro parte); Ruta Nac. 34, Dique Itiyuro, *Zuloaga 2730* (SI).

These specimens, which are morphologically intermediate between *Ruellia longipedunculata* and *R. brevifolia*, also show reduced pollen fertility, which suggests hybridization (Ezcurra, 1989).

**6. Ruellia sanguinea** Griseb., Abh. Königl. Ges. Wiss. Göttingen 24: 260. 1879. TYPE: Argentina. Salta: Orán, prope San Andrés, Rio Seco bei San Andrés, 17–24 Sep. 1873, *Lorentz & Hieronymus 269* (holotype, GOET not seen, photo SI, US; isotype, B destroyed, photo F 18209). Figure 10.

*Ruellia kuntzei* Lindau, Bull. Herb. Boissier 3: 365. 1895. *Arrhostoxylum kuntzei* (Lindau) Bremek., Proc. Kon. Ned. Akad. Wetensch. Ser. C, 72, 4: 424. 1969. TYPE: Bolivia. Without locality: 2,000 m, *Kuntze*, Apr. 1892 (holotype, B destroyed, photo F 18209; isotype, NY).

Suffruticose subshrub to 1.5 m high, the stems ascending, markedly quadrangular, slightly pubescent when young, terete and glabrescent at maturity. Leaves on petioles 2–8 cm long, the blades ovate, 6–16 cm long and 4–8 cm wide, acuminate and cuspidate, obtuse and somewhat decurrent on the petiole at the base, smooth or irregularly and very shallowly crenate or dentate, the surface glabrous to slightly puberulous. Flowers subsessile or very shortly pedunculate, solitary in the axils of reduced upper leaves, frequently with supernumerary buds in the axils of the subtending leaves; bracteoles narrowly oblanceolate or lanceolate, approximately 5 mm long and 1 mm wide. Calyx 8–10 mm long, the segments linear, 5–7 mm long and 1 mm wide, acute, ciliate. Corolla red, 3–5 cm long, puberulous, the basal tube thin and curved, 1.5–3 cm long, opening into an abconic throat 1.5–2 cm long and 5–8 mm wide, the lobes semi-erect, rounded, 3–5 mm long, somewhat retuse. Stamens subexserted with filaments 5–7 mm long, and anthers 3.5 mm long. Ovary puberulous; style exserted. Capsule clavate, 1.5 cm long and 3–4 mm thick, glabrous, broadest above the middle, the base solid to 5 mm high. Seeds 8–10, dark brown, 2–3 mm diam., with pilose margins, hygroscopic-viscid when wet; retinacula 2 mm long.

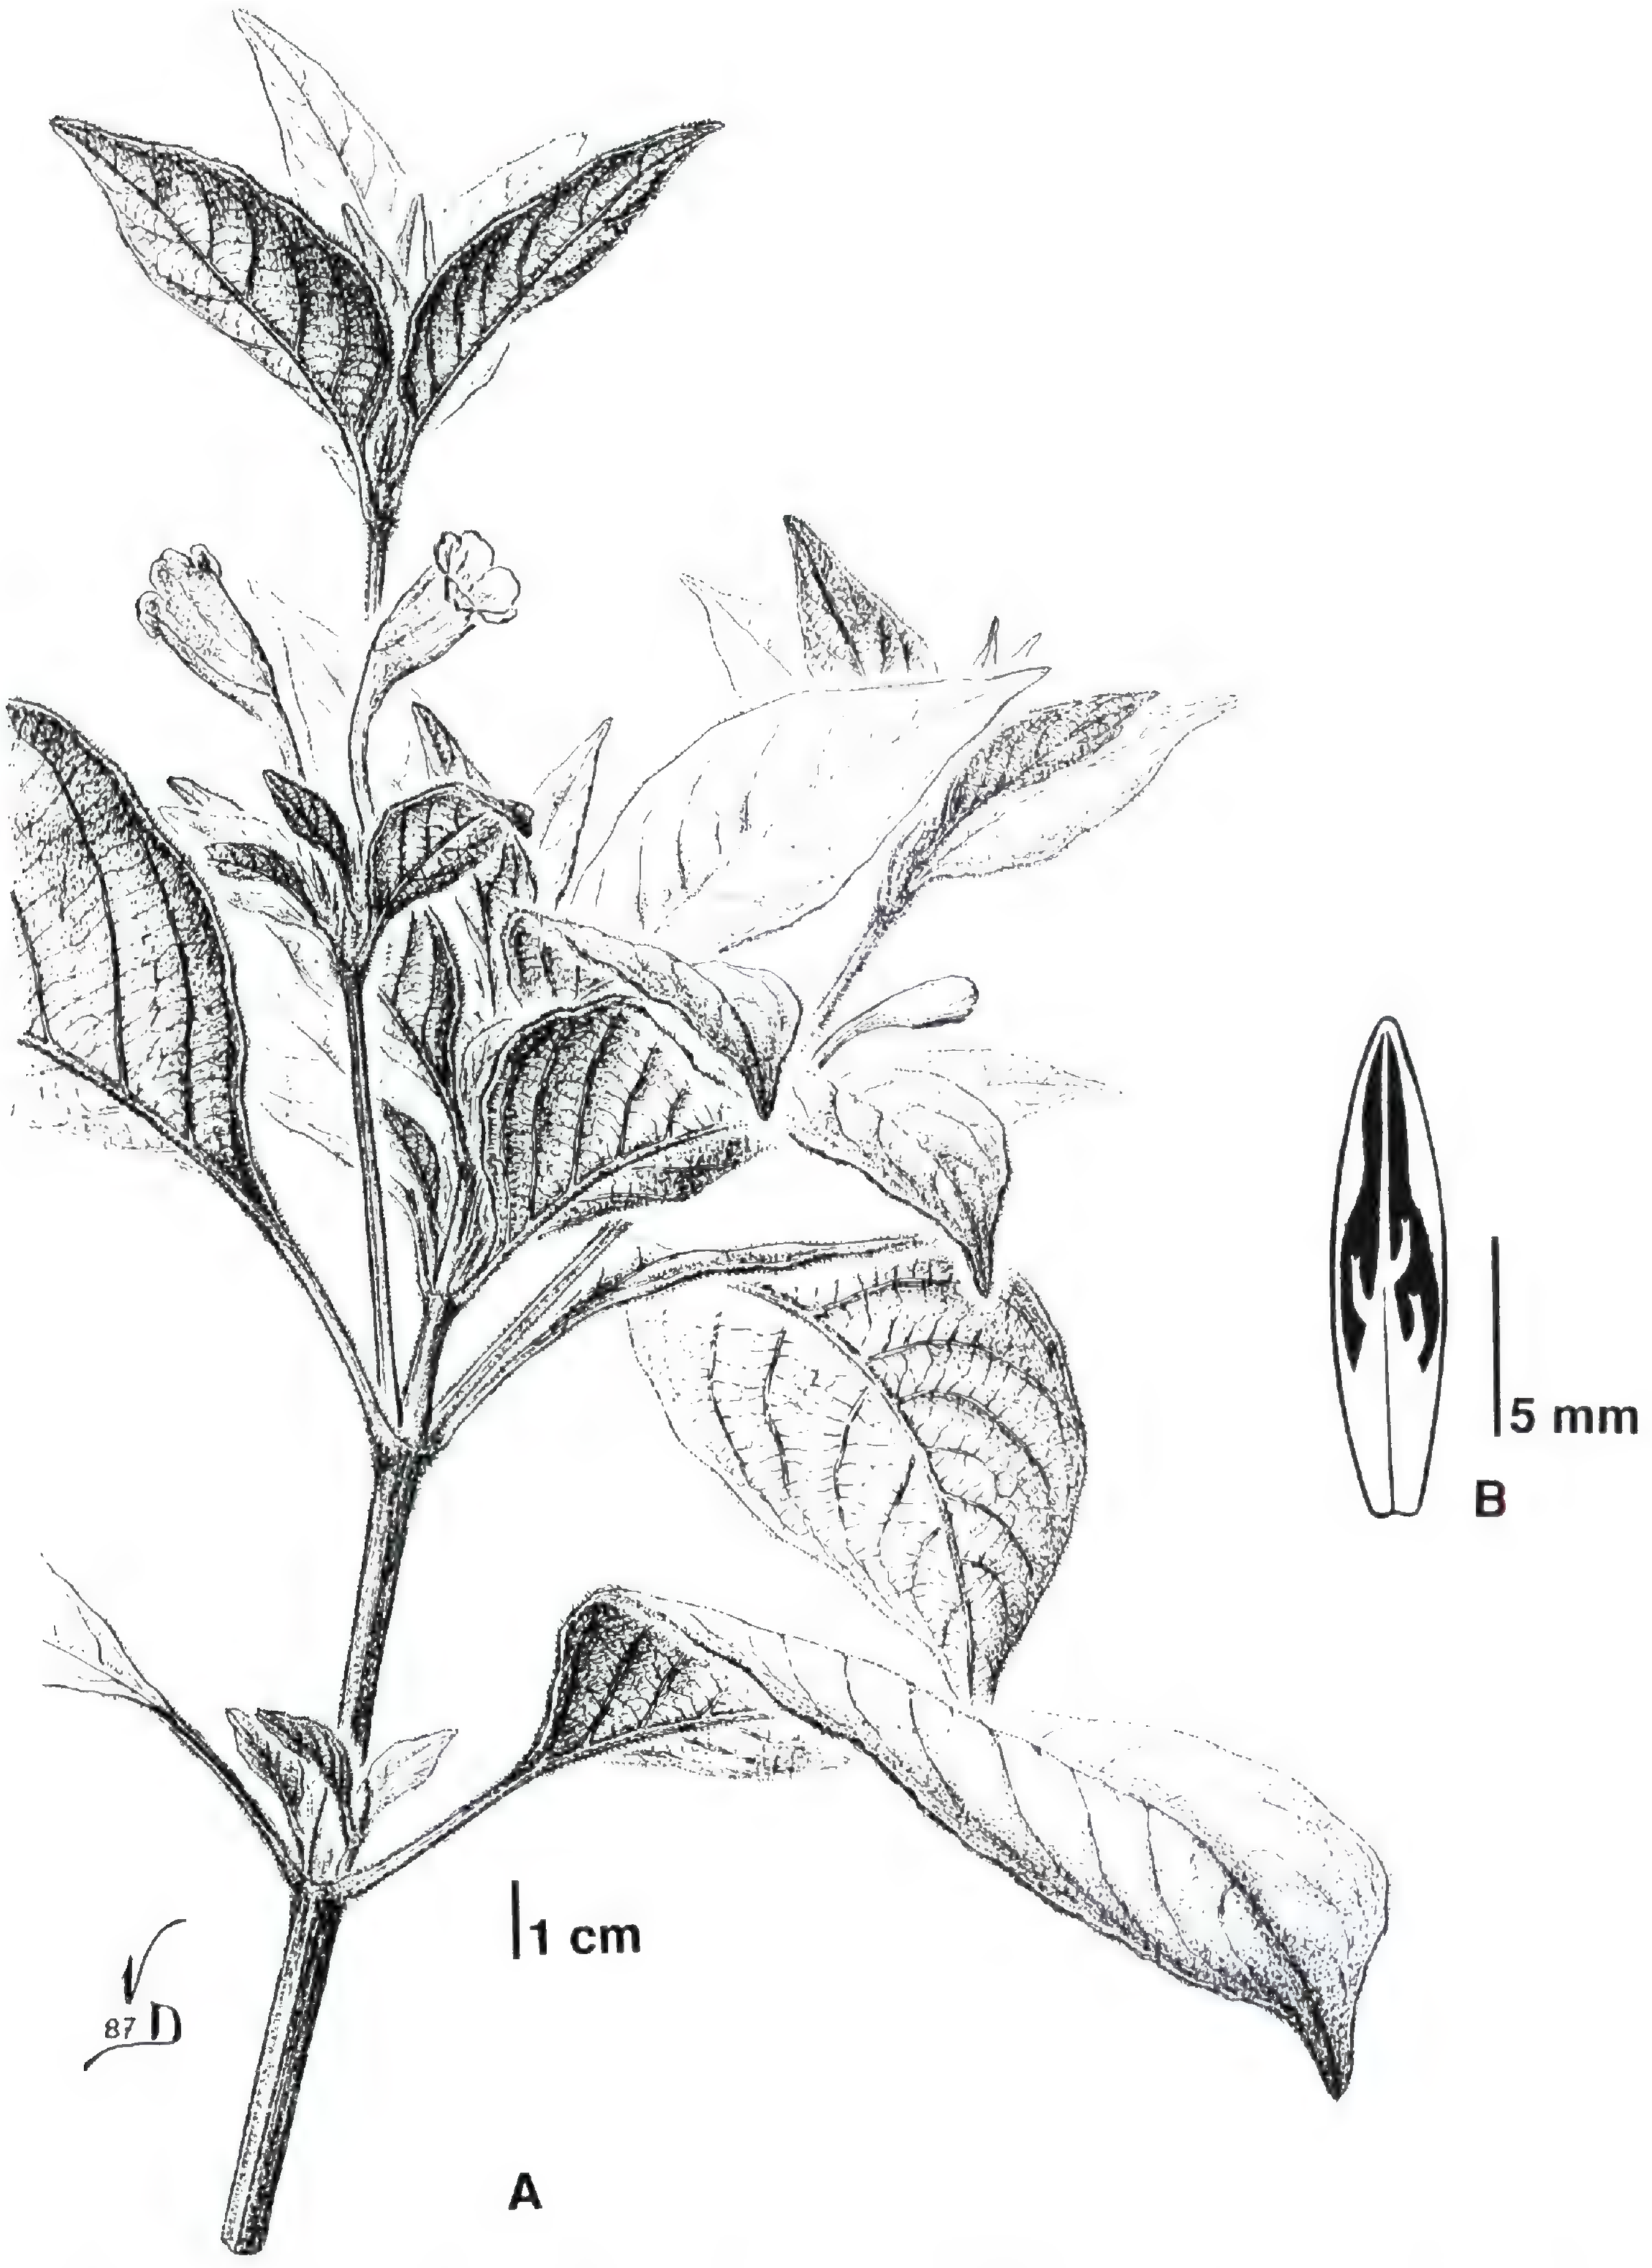

FIGURE 10. *Ruellia sanguinea* Griseb.—A. Flowering branch.—B. Open capsule without seeds, schematic. (A, *Fabris 4491*; B, *Iudica & Ramadori 355*.)

*Distribution.* Southern Bolivia and northern Argentina, in the north of Salta and east of Jujuy. It is found growing in the shade of mountain forests of the Yungas phytogeographical province, between 600 and 2,000 m altitude. It flowers in spring and autumn, especially in October and May.

*Representative specimens.* ARGENTINA. **Jujuy:** Serranía de Calilegua, *Fabris 4478, 4491* (LP); Río de Las Piedras, *Iudica & Ramadori 355* (SI). **Salta:** Depto. Orán, Río Santa María, las Juntas, *Castellanos 29* (BA, LIL); Parque Nacional Baritú, Arroyo Sidras, *Brown 2003* (SI); 8 km antes de Porongal, *Cuezzo 9213* (LIL).

*Ruellia sanguinea* is characterized by the small red corollas with a long basal tube. Though the semi-erect, small lobes and red color of the flowers suggest hummingbird pollination, the narrow, long, basal tube of the corollas and the morphology of the inflorescence separate this taxon from the other red-flowered species in the area. In these characters and in leaf morphology it is quite similar to the white-flowered, probably butterfly-pollinated, *Ruellia puri* Nees, widely distributed throughout central Brazil and western Bolivia. This suggests that the different pollination syndromes in *Ruellia* probably arose many times as parallelisms in the evolution of different lineages.

This species was originally described from northern Argentina (Salta), its name referring to the blood-colored flowers it produces. This name was erroneously used later by most modern authors for *Ruellia angustiflora*, a different red-flowered species, frequent in eastern Paraguay, northeastern Argentina, southern Brazil, and northern Uruguay (Ezcurra, 1989).

## II. Group **Ruellia**

*Ruellia* L. sect. *Euruellia* Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4(3b): 311. 1895. TYPE: *R. tuberosa* L.

*Cryphiacanthus* Nees, Index Sem. Hort. Vratisl. 1841; Linnaea 16: 298. 1842. TYPE: *C. badensis* Nees, nom. illeg. (= *R. tuberosa* L.).

Flowers pedicellate, borne in dichasial cymes subtended by the upper leaves, rarely reduced to solitary flowers, always pedicellate and bibracteolate. Capsules terete or narrowly elliptic in contour, hollow nearly to the base. Seeds 14–28.

Group *Ruellia* is important in the New World and consists of several weedy, erect or rosettiform herbs that are common in open, low, disturbed, subtropical and tropical areas. In southern South America they are principally found in floristic provinces of the Chaco region or dominion (see Cabrera & Willink, 1980). Many South American species of this group are very similar to species in Central and North America, and could be closely related. The mucilaginous viscid pubescence of the seeds when wetted allows them to be easily carried by migrating birds. This could explain the long-distance disjunctions of "vicariant" species between the Northern and Southern hemispheres.

**7. Ruellia ciliatiflora** Hook., Bot. Mag. 66: tab. 3718. 1840. *Arrhostoxylum ciliatiflorum* (Hook.) Nees, DC. Prodr. 11: 216. 1847. TYPE: Fig. in tab. 3718 of Bot. Mag. 66. 1840. Figure 11.

*Ruellia lorentziana* Griseb., Abh. Königl. Ges. Wiss. Göttingen 24: 259. 1879. SYNTYPES: Argentina. Tucumán: Tucumán, 22 Dec. 1872 *Lorentz & Hieronymus 176* (GOET not seen, photo SI); Tucumán, *Lorentz & Hieronymus*, 6–22 Dec. 1872 (GOET not seen, photo SI).

Perennial herb 30–80(–100) cm tall, sparsely branched from a subligneous base, with clustered, tough, fibrous roots. Stems erect, obtusely quadrangular, with short glandulous pubescence intermingled with longer simple hairs, glabrescent at maturity. Leaves on pilose petioles 0.5–2.5 cm long, the blade widely ovate, 4–13 cm long and 2–8 cm wide, obtuse and mucronate, widely cuneate to truncate on the base and somewhat decurrent on the petiole, markedly pubescent on the nerves, the surface ± pilose and sometimes glutinose, the margin irregularly and shallowly crenate. Flowers pedicellate, borne in dichasial cymes in the axils of small bracts or reduced apical leaves, aggregated in an ample, terminal pyramidal thyrse, sometimes enriched by lateral thyrses originating on the axils of the upper leaves, the whole appearing paniculate. Bracts foliaceous; bractlets lanceolate, small, and pubescent. Calyx ca. 10 mm long, the segments linear, to 8 mm long, glandulous-pubescent. Chasmogamous flowers tilted, blue, 3.5–4.5 cm long, the basal tube angled on top, 1–2 cm long, the throat 1.5–2 cm long and 1 cm diam., the lobes spreading, obovate, ca. 1 cm long and 1 cm wide, the margin undulate and sometimes ciliate, the anterior lobes with dark palate markings toward the orifice. Stamens included, long filaments ca. 6 mm long, short 4 mm long, the anthers 2 mm long. Ovary and style puberulous. Cleistogamous flowers frequent, reduced, tubular, and closed. Capsule elliptic, 2–3 cm long and 3–5 mm thick, hollow nearly to the base, the surface puberulous. Retinacula 2 mm long; seeds 16–24, pale-colored, 2 mm diam., appressed puberulous when dry and with mucilaginous extended hairs when wet.

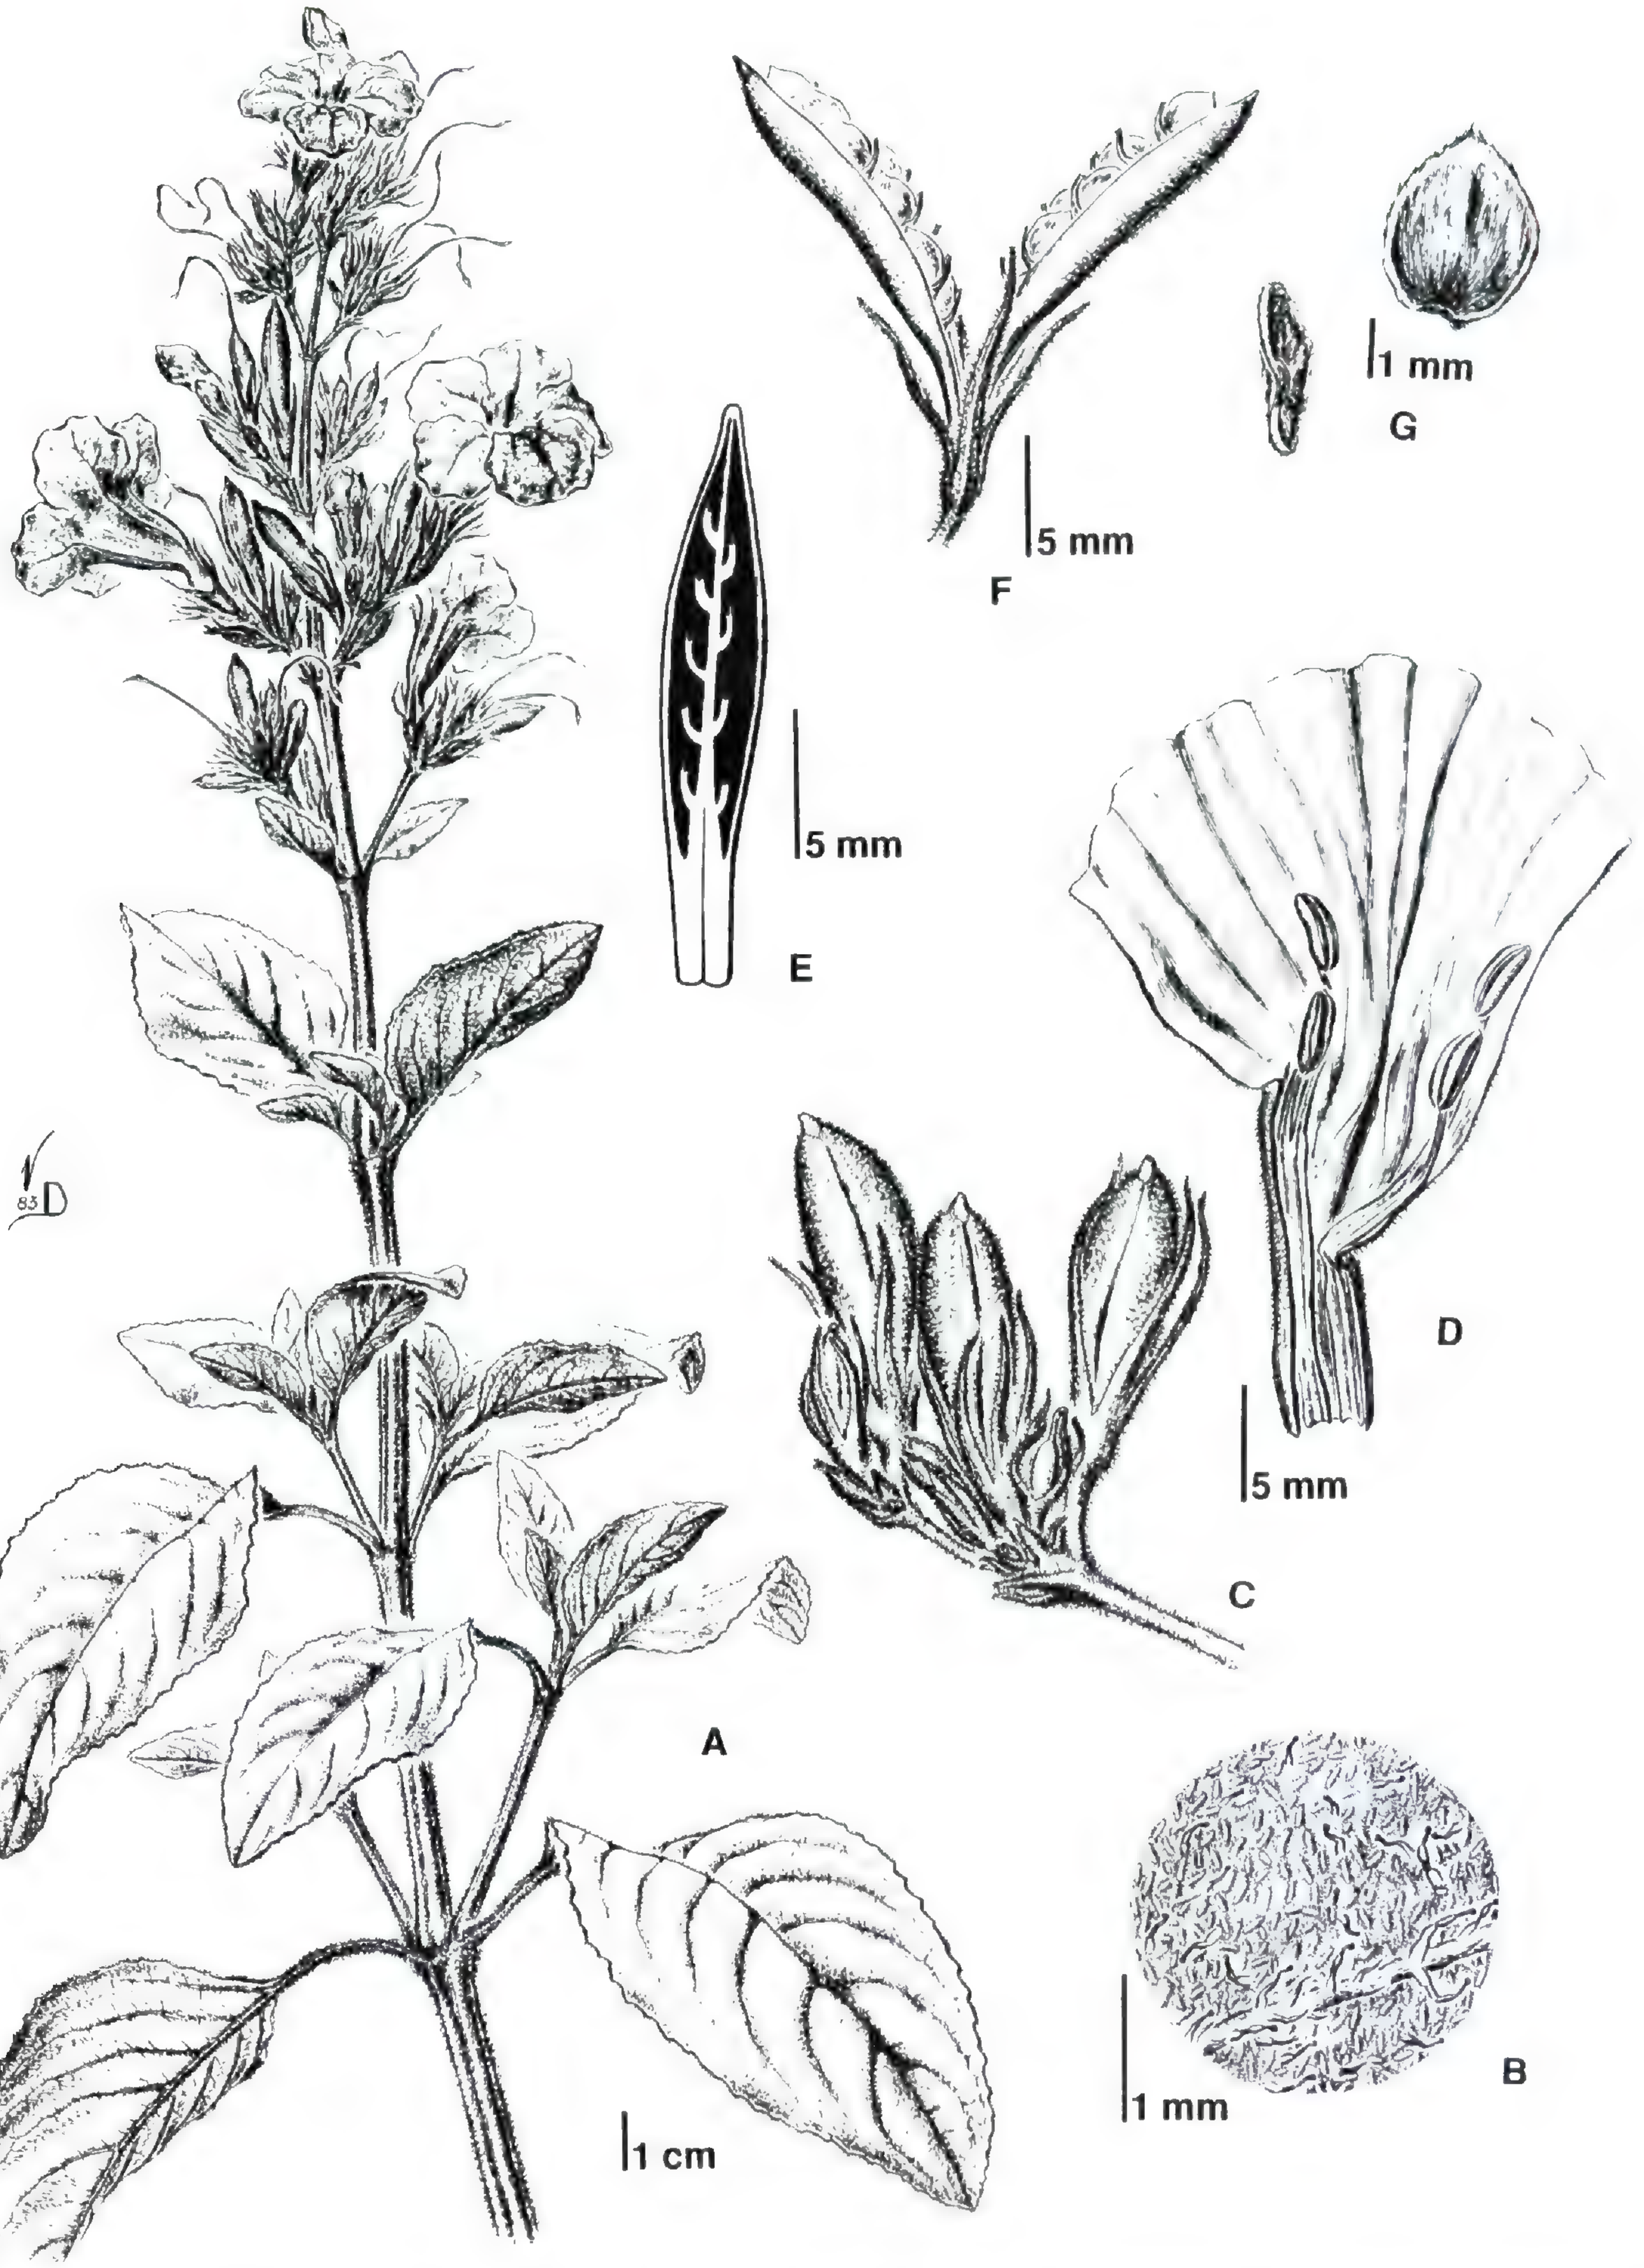

FIGURE 11. *Ruellia ciliatiflora* Hook.—A. Flowering branch.—B. Leaf abaxial surface, showing glandular and eglandular hairs and cystoliths. C. Portion of inflorescence, in fruit.—D. Corolla dorsally open, showing stamens.—E. Open capsule without seeds, schematic.—F. Dehiscent capsule, with seed. G. Seed. (A–D, F, G, *Cabrera 30998*; E, *Kiesling 5566*.)

*Distribution.* Colombia to Bolivia, Paraguay, southwestern Brazil, and northern Argentina, especially in Chaco regions. *Ruellia ciliatiflora* is commonly found growing as a weed in moist, open, disturbed places, such as roadbanks, cultivated or abandoned fields, borders of water courses, dry river beds, clearings of forests, and waste places. It is sometimes cultivated as an ornamental, and prefers sunny locations and sandy soil. It flowers in spring and summer, from October to April, and frequently presents cleistogamous flowers.

*Ruellia ciliatiflora* is a common weed in disturbed places of subtropical South America, especially in western Chaco areas and adjacent regions. This species has generally been known as *Ruellia lorentziana* in Argentina, where it ranges from Jujuy to Santiago del Estero. The name *Ruellia ciliatiflora* precedes *R. lorentziana* and was used to describe plants grown in England from seeds sent by Tweedie from Buenos Aires, Argentina. Although this species does not grow in Buenos Aires, Tweedie probably collected it during his trips to northern Argentina. The beautiful illustration and description in *Botanical Magazine* show clearly that it is the same species. It is closely related to species of the *Ruellia nudiflora* complex from North America.

**8. Ruellia coerulea** Morong in Morong & Britton, Ann. New York Acad. Sci. 7: 193. 1893. TYPE: Paraguay. Pilcomayo River, 1888–1890, *Morong 1013* (holotype, NY; isotypes, MO, US). Figure 12.

*Arrhostoxylon microphyllum* Nees in C. Martius, Fl. Bras. 9: 22. 1847. *Ruellia microphylla* (Nees) Lindau, Engl. Bot. Jahrb. 19 Beibl. 48: 16. 1894, not Cavanilles, 1801. TYPE: Uruguay. FIGURE 12. *Ruellia coerulea* Morong.—A. Flowering branch.—B. Leaf shape of a plant of another population, to show variation in this character.—C. Open capsule without seeds, schematic. (A, *Hassler 1661*; B, *Venturi 632*; C, *Krapovickas 11804*.)

Sparsely branched erect herb 30–120 cm tall, with fibrous roots from a basal rhizome; stems ascending, subtetragonous, glabrous, sometimes ciliate at the nodes. Leaves on short, ciliate petioles, the blades ovate or elliptic to narrowly oblong or lanceolate, 5–12 cm long, 0.3–1.5 cm wide, the lower ones generally shorter and wider than the upper, all obtuse at the apex, cuneate at the base, the margins entire, completely glabrous, with numerous sessile glands on the lower surface. Flowers on glabrous pedicels, borne in pedunculate, few-flowered, dichotomous cymes, in the axils of alternately one of each pair of the uppermost leaves, rarely on both; bracteoles glabrous, linear, and small. Calyx of chasmogamous flowers 0.7–1.5 cm long, the segments linear-lanceolate, acute, glandulose-puberulous. Chasmogamous corollas tilted, blue or whitish, 3–4 cm long, the basal tube 0.5–1 cm long, the throat obconic, 1.5–2 cm long and ca. 8 mm wide in the orifice, with palate markings in the lower side, the lobes suborbicular, ca. 1 cm diam. Cleistogamous corollas reduced and closed. Stamens included. Ovary and style glabrous. Capsule narrowly elliptic or oblong, 2–2.5 cm long and 4 mm thick, hollow nearly to the base, glabrous; retinacula acute. Seeds 16–24, 2–3 mm

wide, appressed pilose when dry and viscid when wet.

*Distribution.* Western Bolivia, Paraguay, Uruguay, and northeastern Argentina, and limiting areas of southern Brazil, in open areas of eastern Chaco and adjacent phytogeographical regions. It is found in wet or periodically flooded, sunny places, such as ditches, streams, riverside lawns, or temporarily inundated areas. It flowers in spring and summer, from September to February.

*Ruellia coerulea* is characterized by the blue-flowered axillary cymes and glabrous habit, and is common in seasonally inundated areas of subtropical South America. It appears clearly related to *Ruellia brittoniana* and *Ruellia malacosperma* of southern North America. Like many semiaquatic plants, it shows much variation in leaf shape and leaf area, probably subject to environmental influence. This variation may also be the result of introgression with the common *Ruellia ciliatiflora* in areas where they grow sympatrically.

*Ruellia coerulea* shows an extended range in subtropical South America and also varies in habit. The plants from the northern portions of its range (eastern Bolivia, northwestern Paraguay, and western Brazil) generally have larger and more woody stems, and present a more fruticose habit. The plants from the southernmost portion of its range (Uruguay) are frequently small, delicate herbs. This may be related to climatic variations associated with latitude and seasonality, especially temperature and photoperiod.

Fernald discussed part of the nomenclatural problems of this species when he validated the name *Ruellia tweediana*. This name has been the one most used for this species (e.g., Dawson, 1979; Piovano & Bernardello, 1991), but the epithet *coerulea* precedes it. *Ruellia microphylla* has also been used for the identification of material from Paraguay. Although the type of *Arrhostoxylon microphyllum*, its basionym, was destroyed at Berlin and no isotypes have been found, the original description by Nees of the material from Montevideo, Uruguay, clearly depicts a plant of the weaker, southernmost form of *Ruellia coerulea*.

A few specimens collected in Paraguay show morphological intermediacy with *Ruellia brevicaulis*, suggesting hybridization.

**8a. Ruellia coerulea** Morong × **Ruellia brevicaulis** (Nees) Lindau.

Plants resembling *Ruellia coerulea*, with pedunculate axillary inflorescences, the flowers pedicellate and bibracteolate, but with shorter stems and wider, ovate, somewhat serrulate, pilose leaves, the trichomes shiny and extended as in *Ruellia brevicaulis*.

*Representative specimens.* PARAGUAY. **San Pedro:** Alto Paraguay, *Woolston 118* (SI); Primavera, *Woolston 989, 1252* (US). **Canendiyú:** iter ad Yerbales Sierra de Maracayú, in regione vicine San Estanislao, *Hassler 4281* (G, P, NY); Sierra de Maracayú, *Hassler 5092* pro parte (BM, NY).

These specimens are morphologically intermediate between *Ruellia coerulea* and *R. brevicaulis*, of group *Dipteracanthus*. They all have been collected in eastern Paraguay, where the areas of these species are sympatric, and appear to be the product of hybridization.

**9. Ruellia macrosolen** Lillo ex Ezcurra, Syst. Bot. 14(3): 297. 1989. TYPE: Argentina. Jujuy: San Pedro de Jujuy, 600 m, 10 Apr. 1926, *Schreiter 5211* (holotype, LIL; isotypes, BA, LP, US). Figure 13.

Low perennial herb 20–40(–60) cm tall, with fibrous, fusiform, tuberous roots; stems ascending, sparsely branched, subtetragonous, pilose and shortly glandulose-pubescent, somewhat glabrescent at maturity, growing from a short horizontal underground rhizome. Leaves on pilose petioles 0.3–2 cm long, the blades thin, ovate or elliptic, mostly 2.5–7 cm long and 1.5–4 cm wide, rounded or obtuse at the apex, cuneate at the base and somewhat decurrent on the petiole, the margins entire or slightly crenate, undulate, the surface pilose on the principal veins. Flowers on glandular pedicels, borne in terminal and axillary, lax, pedunculate, few-flowered dichotomous cymes, aggregated in thyrses and often appearing paniculate; bracts foliaceous, pilose; bracteoles glandular, linear, and small. Calyx 1.5–2 cm long, the segments linear and acute, densely glandular-pubescent. Corollas erect, white, regular, the basal tube 2.5–5 cm long, 2–3 mm diam., the throat 1.5–3 cm long, tinted with grayish mauve at the base, expanding to 1 cm wide at the orifice, the lobes rounded, ca. 1.5 cm long and wide, often emarginate, somewhat undulate in the margins, with faint grayish mauve markings toward the orifice of the throat. Cleistogamous flowers frequent, reduced, tubular, and closed. Stamens 4, included, with filaments ca. 7 mm long and anthers 5 mm long. Style 3–5 cm long, glabrous; ovary pubescent, with a few glandular hairs. Capsules elliptical, 2.5–3.5 cm long and 6–8 mm thick, broadest at or above the middle, hollow nearly to the base, densely and shortly puberulent on the surface; pedicels accrescent at maturity. Retinacula obtuse, 2 mm long. Seeds 12–22, flat, suborbicular, 3 mm long and 2.5 mm wide, appressed-pilose when dry and with hygroscopic-viscid pubescence all over their surface when wet.

*Distribution.* Southeastern Bolivia, western

Paraguay, and northern Argentina, in regions of western Chaco and adjacent transitional forests. It is found in open and often disturbed places such as sandy roadbanks, abandoned fields, borders or clearings in forests, and margins of streams, from 300 to 900 m elevation. It flowers in spring and summer, from December to February.

*Ruellia macrosolen* is characterized by the white, nocturnal, sphingophilous flowers with a long basal tube. It seems closely related to the melitophilous, diurnal, blue-flowered *Ruellia ciliatiflora*, and is partially sympatric with it. They are probably genetically isolated through different pollen vectors (Ezcurra, 1989).

*Cryphiacanthus udus* Nees in C. Martius, Fl. Bras. 9: 49. 1847. TYPE: Brazil. Mato Grosso: prope Cuiabá, *Riedel s.n.* (holotype, LE not seen, photo SI). Syn. nov.

Low perennial, acaulescent herb, with a short basal vertical rhizome, and thick, fibrous roots. Leaves clustered in a rosette, shortly petiolate, obovate, 3–9 cm long and 1–3 cm wide, obtuse and rounded in the apex, the blade decurrent on the petiole; margins entire or somewhat crenate, surface glabrous or slightly hirsute. Flowers borne on lax, multiflowered, anisocaulous, elongate dichasia, appearing somewhat racemiform. Cymes to 15 cm long; peduncles puberulous, to 8 cm long; bracteoles linear and small; pedicels puberulous. Calyx 1–1.5 cm long, the segments linear, acute, 0.8–1.3 cm long, short-pilose, ciliate in the margins. Corolla pale blue, 3–5 cm long, the basal tube 1–1.5 cm long and 2 mm wide, obconic throat 1.2–1.5 cm long and 8 mm diam., the lobes reflexed, suborbicular, 1–1.5 cm diam. Stamens included with anthers ca. 2 mm long. Capsule narrowly elliptic, approximately the same length as the calyx, 1–1.5 cm long and 3 mm diam., hollow nearly to the base. Retinacula less than 2 mm long; seeds 14–16, approximately 2 mm long, adpressed-pilose on the entire surface, the hairs extended and mucous when wet.

*Distribution.* Southeastern Bolivia, southwestern Brazil, Paraguay, northeastern Argentina, and northwestern Uruguay. It is common in borders and clearings of open Chaco xerophilous forests and in palm formations, on hard clay and perodically flooded soil. It flowers in spring and summer, from October to March.

FIGURE 15. *Ruellia morongii* Britton. —A. Habit.—B. Open capsule without seeds, schematic. (A, *Burkart 31102*; B, *Burkart 26385*.)

*Ruellia hygrophila* is characterized by a rosette habit combined with multiflowered long-pedunculate pseudoracemes of blue flowers. It differs from the closely allied short-pedunculate, pale-flowered *Ruellia morongii* also by the nearly glabrous pedicels. It is a common species in all eastern Chaco and surrounding areas, in seasonally flooded and periodically dry soil.

**11. Ruellia morongii** Britton in Morong & Britton, Ann. New York Acad. Sci. 7: 192. 1893. *Cryphiacanthus acaulis* Nees in C. Martius, Fl. Bras. 9: 49. 1847, not *Ruellia acaulis* R. Br. 1810. SYNTYPES: Brazil. River Uruguay, *Baud s.n.* (K); Brazil. Without locality, *Sellow s.n.* (isosyntype, K); Brazil. Rio Grande do Sul: River Jacuhy, 1837, *Tweedie 770* (K). Figure 15.

Low perennial herb, acaulescent, with vertical or oblique rhizome, the thick, fasciculated roots fusiform. Leaves in rosette, ovate, oblong-ovate or obovate, 3–10 cm long and 1–3 cm wide, obtuse and rounded in the apex, the blade decurrent on the petiole, margins entire or somewhat crenate, surface glabrous or slightly hirsute on the principal veins. Flowers shortly pedunculate or borne on subsessile, few-flowered dichasia, frequently reduced to a solitary flower with two bracteoles. Peduncles glabrescent, to 3 cm long; bracteoles linear and small; pedicels hirsute-tomentose under the flowers. Calyx 1.2–2.2 cm long, the segments linear, acute, 1–2 cm long and 1–2 mm wide, densely pilose and ciliate in the margins. Corolla white, sometimes with bluish or yellowish tints, 3–5 cm long, the basal tube 1–1.5 cm long and 2 mm wide, the obconic throat 1.2–1.5 cm long and 8 mm diam., the lobes reflexed, suborbicular, 1–1.5 cm diam. Stamens with anthers ca. 3 mm long. Capsule narrowly elliptic, approximately shorter than the calyx, 1.3–1.8 cm long and 3–4 mm diam., hollow nearly to the base. Retinacula less than 2 mm long; seeds 10–14, approximately 2–3 mm long, adpressed-pilose on the entire surface, the hairs extended and mucous when wet.

*Distribution.* Southern Brazil, eastern Paraguay, northeastern Argentina, and Uruguay. *Ruellia morongii* is found in open and sunny places, on rocky or sandy soil, burnt campos, and grassy savannas. It flowers in spring and summer, from October to March.

*Representative specimens.* ARGENTINA. **Corrientes:** Depto. Esquina, 47 km W de Sauce, Ruta 126, *Ahumada 1444* (CTES); Curuzú Cuatiá, *Birabén 5185* (LP), *Ibarrola 2526* (LIL), *Martínez Crovetto 8429* (BAB); La Cruz, *Burkart 7866* (SI); Depto. *Ruellia morongii* is characterized by having leaves in a rosette and white subsessile flowers. It seems morphologically related to *Ruellia hygrophila*, but is mostly allopatric with this species and inhabits an area more to the east. It is common in sandy, sunny, open areas and burnt savannas, and seems adapted to periodic fires.

## III. Group **Hygrophiloidei**

*Dipteracanthus* (*Hygrophiloidei*) Nees in C. Martius, Fl. Bras. 9: 43. 1847. TYPE: *Dipteracanthus lamiiformis* Nees (lectotype, here selected).

Flowers sessile or shortly pedunculate in the axils of the upper leaves, bibracteolate, generally solitary, sometimes in fascicles. Calyx segments narrow, united in the base, the posterior longer. Capsule obovate in contour, apiculate, with a narrow solid base ⅓ its length. Seeds 6–8.

Species of this group are characterized by their sharply quadrangular stems, frequently reduced axillary cymes, and few-seeded capsules. They are common in floristic provinces of the Amazon region or dominion (see Cabrera & Willink, 1980), at low elevations, growing in moist soil.

The name of this infrageneric group together with *Calycosi*, *Genuini*, *Inaequifolii*, *Paniculati*, and *Subspicati* were proposed by Nees (1847a, b) under *Dipteracanthus*, but without a clear indication of rank. Following article 35 of the *International Code of Botanical Nomenclature* (Greuter et al., 1988), these names are valid provided that all other requirements for valid publication are fulfilled, and may act as homonyms or serve as basionyms for subsequent combinations in definite ranks.

**12. Ruellia epallocaulos** Leonard ex Ezcurra & Wasshausen, Brittonia 44(1): 69. 1992. TYPE: Paraguay. In regione fluminis Alto Paraná, *Fiebrig 5372* (holotype, SI; isotypes, G, GH, K, LIL, US). Figure 16.

Suffruticose perennial 0.30–1 m tall, branched from a subligneous base. Stems erect or somewhat decumbent, quadrangular, glabrous, rooting at the nodes. Leaves on glabrous petioles 0.4–1 cm long, the blade ovate, 3–6(–10) cm long and 1–2(–3.5) cm wide, acute or acuminate, obtuse or rounded at the base, glabrous, the margins faintly and irregularly crenate. Flowers sessile, solitary, sometimes in twos, in reduced subsessile dichasia condensed in the axils of the upper leaves, exceptionally pedunculate. Bracteoles small, lanceolate, 3–5 mm long. Calyx 1–1.8 cm long, the segments oblong-lanceolate, rounded or obtuse, to 1.5 cm long, ± glabrous, shortly ciliate, the posterior longest. Corolla purple or blue, 4–5 cm long, the basal tube 1.8–2.5 cm long, the throat obconic, 1–1.5 cm long and ca. 1.2 cm diam., the lobes spreading, suborbicular, 0.5–1 cm wide. Stamens included,

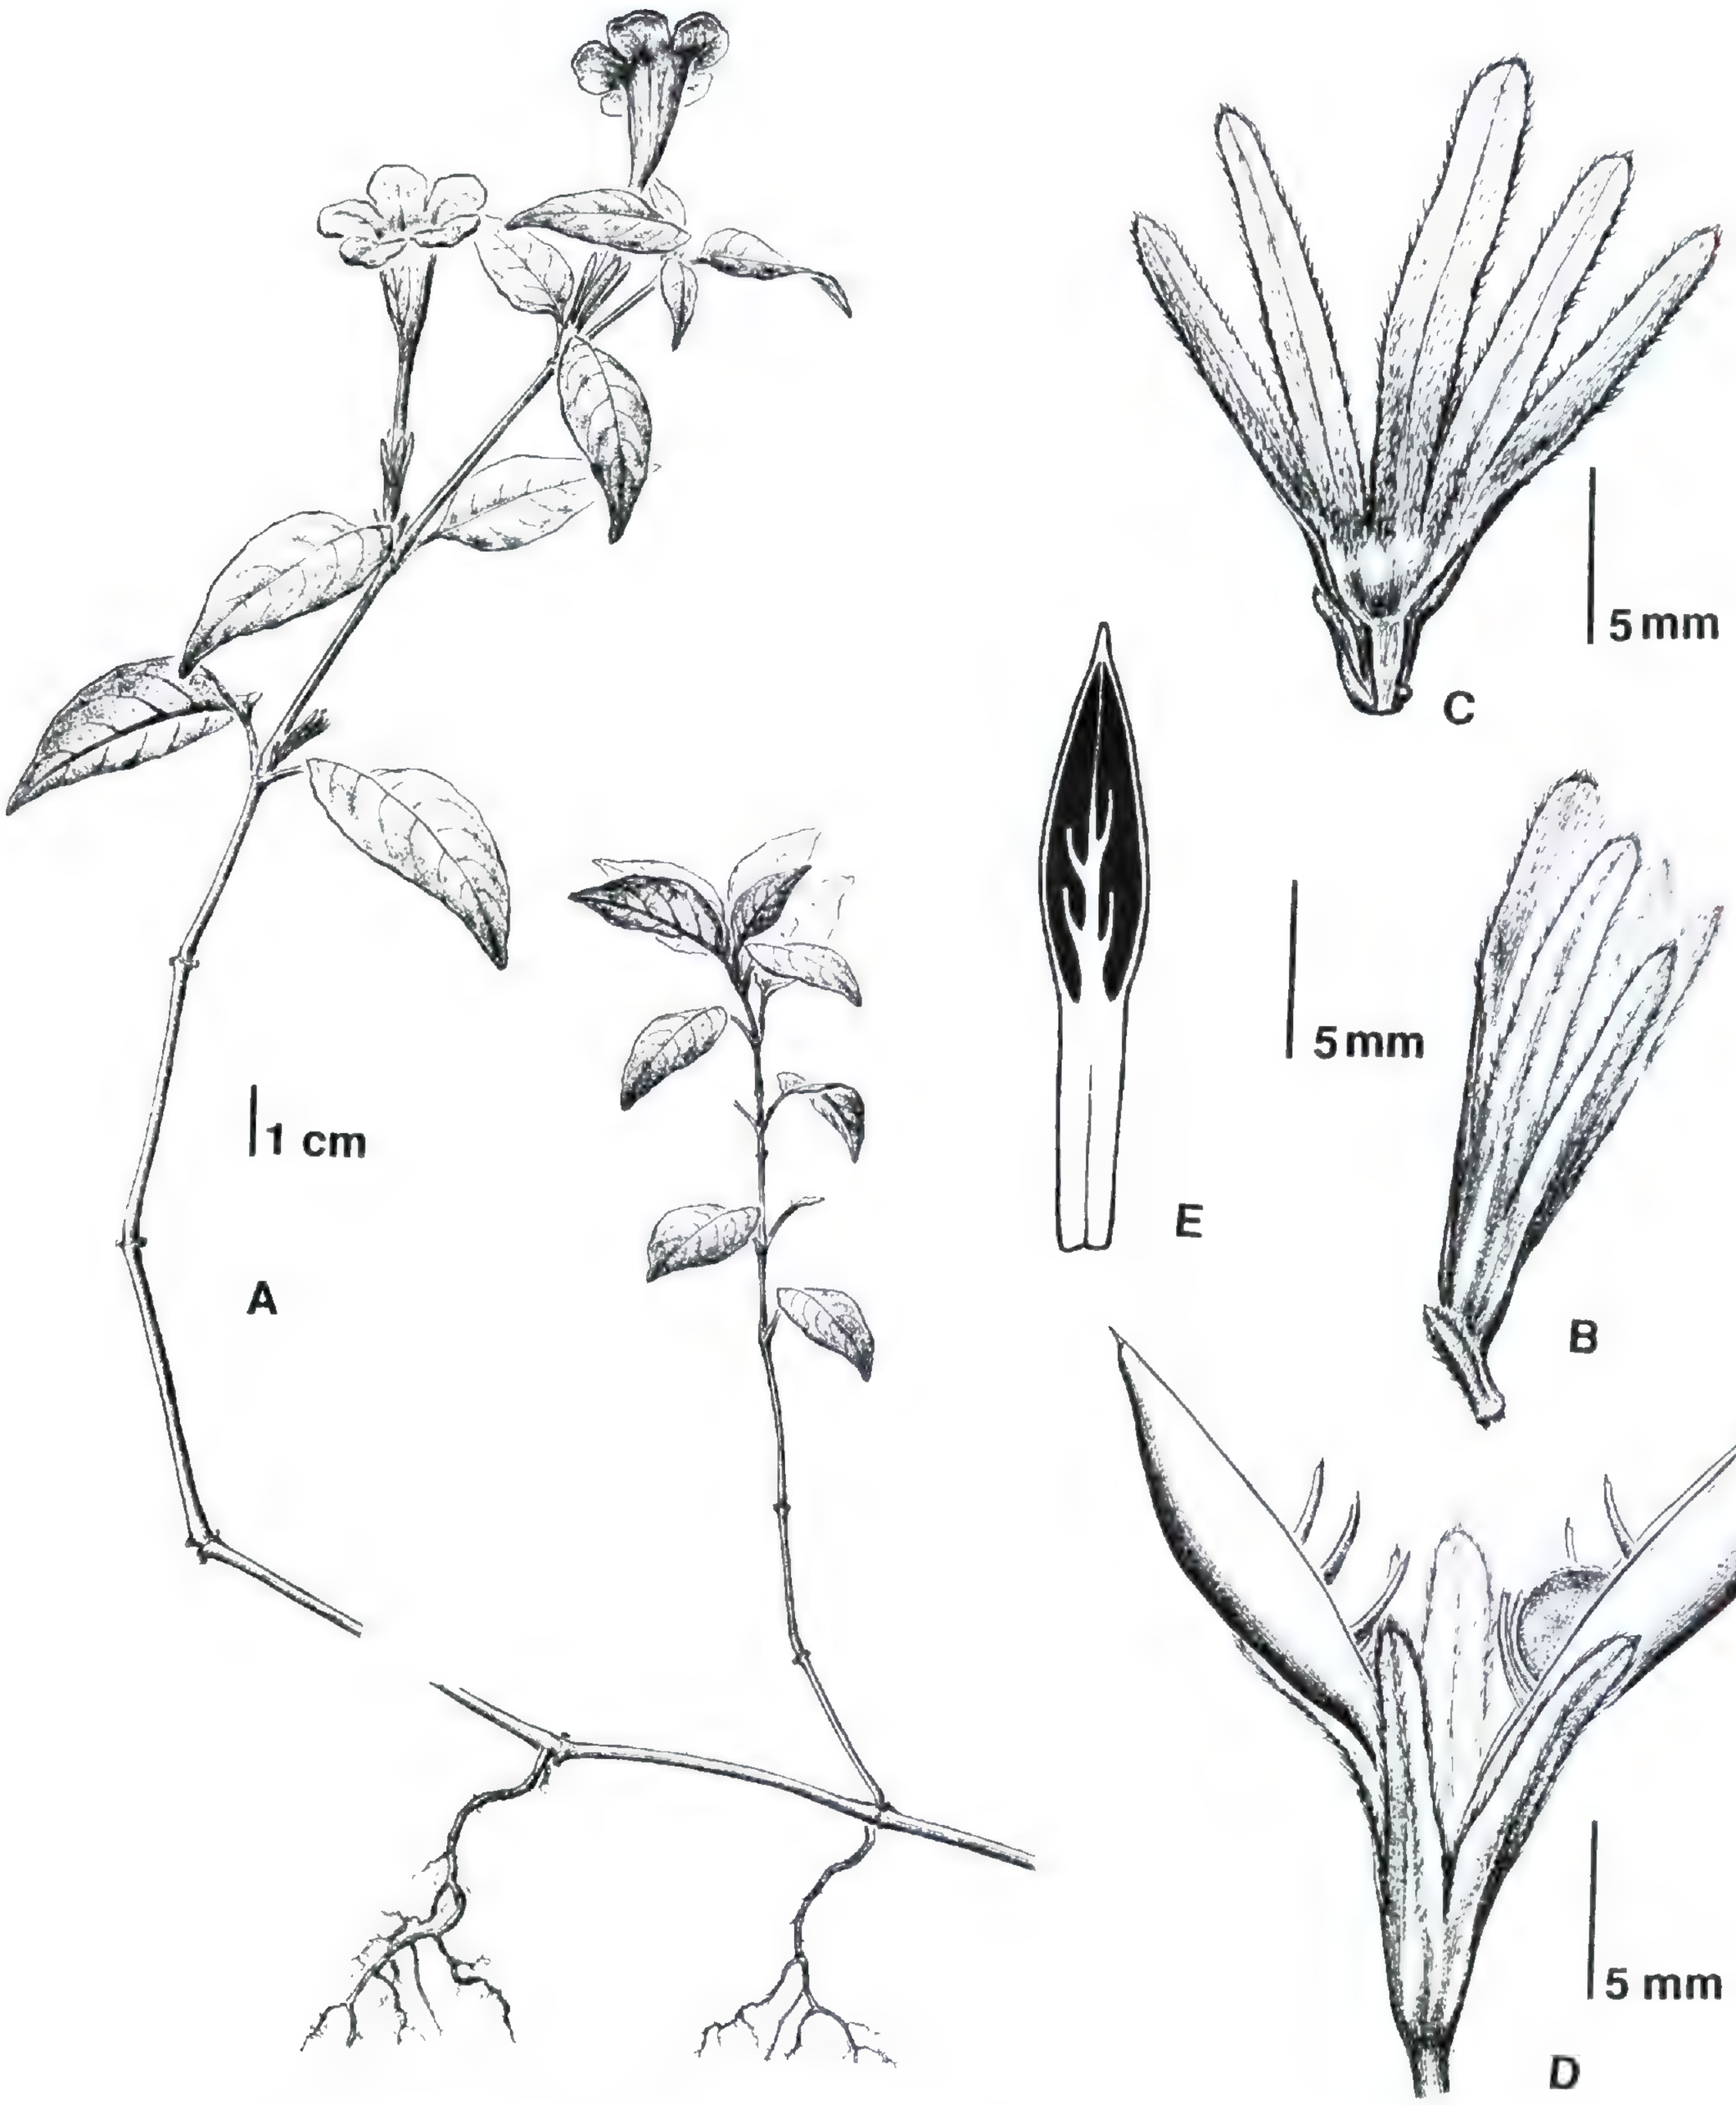

FIGURE 16. *Ruellia epallocaulos* Leonard ex Ezcurra & Wasshausen.—A. Habit.—B. Calyx with bracteoles.—C. Open calyx.—D. Dehiscent capsule.—E. Open capsule without seeds, schematic. (A–E, *Hatschbach 8322.*)

long filaments ca. 8 mm long, short 6 mm long, the anthers 2.5 mm long. Ovary and style glabrous. Capsule narrowly ovate, 1.2–1.5 cm long and 3–4 mm thick, slightly apiculate, with a solid base ca. 4 mm long, the surface glabrous. Retinacula 2 mm long; seeds 6–8, 2–2.5 mm diam., glabrous, the margins pubescent and mucilaginous when wet.

*Distribution.* Eastern Paraguay, northeastern Argentina, and southern Brazil, on the basin of the Paraná River (Paranaense phytogeographical province). It is found in the shade of the gallery forest, generally in humid places near watercourses. It flowers in spring, from August to October.

*Representative specimens.* ARGENTINA. **Misiones:** Yarupá, Arroyo Las Tranqueras, *Grondona &*

*Spegazzini 1374* (BAB); Puerto Pampa, *Kermes 197* (BAB); San Ignacio, *Quiroga s.n.* (BA 21419); Depto. Montecarlo, Arroyo Piray Guazú y ruta 12, *Schinini 19904* (CTES). BRAZIL. **Paraná:** Mun. Cerro Azul, Turvo, *Hatschbach 5025* (MBM); Mun. Cerro Azul, Cerro Azul, *Hatschbach 8322* (HBR, MBM, US); Mun. Cianorte, Fazenda Lagoa, *Hatschbach 16950* (MBM, US); Mun. Cerro Azul, Barra do Tigre, *Hatschbach 40347* (MBM, US). PARAGUAY. **Alto Paraná:** in regione fluminis Alto Paraná, *Fiebrig 5751* (G, SI); Reserva Itabó, *Itaipú Binacional 925* (MO).

*Ruellia epallocaulos* is characterized by the relatively large, solitary, bluish flowers and the markedly quadrangular stems. It is sometimes confused with the sympatric, red-flowered *Ruellia angustiflora*, because of its similar habit.

**13. Ruellia kleinii** Ezcurra & Wasshausen, Brittonia 44(1): 72. 1992. TYPE: Brazil. Santa Catarina: Florianópolis, Morro de Riberão, *Klein 7333* (holotype, US; isotypes, HBR, MBM). Figure 17.

Small suffruticose herb to 50 cm high; stems erect, markedly quadrangular. Leaves ovate, 2.5–3.3 cm long, 1.5 cm wide, acute and acuminate, cuneate, puberulous. Flowers subsessile, solitary, sometimes in sessile or pedunculate dichasia reduced to 3 flowers or less, in the axils of the upper leaves; bractlets foliaceous, less than 1 cm long and 3–4 mm broad. Calyx ca. 1 cm long, with linear segments 7–8 mm long and 1 mm broad, puberulous. Corolla white, 1.5–2 cm long, the basal tube 6–7 mm long, the throat obconic, 6 mm long, 5 mm diam., the lobes suberect, 4 mm long and 3 mm broad. Stamens included, long filaments 4 mm long, short 3 mm long, the anthers ca. 1.5 mm long. Capsule markedly stipitate, ca. 1 cm long, apiculate, few-seeded.

*Distribution.* Southern Brazil, in openings in forests, frequently on wet ground along watercourses.

*Representative specimens.* BRAZIL. **Santa Catarina:** Ilha de Santa Catarina, Florianópolis, no pasto úmido, *Klein & Bresolin 8476* (US); Ilha de Santa Catarina, Tapera, Ribeirão, orla da mata, *Klein & Bresolin 8532* (US); Ilha de Santa Catarina, Florianópolis, Lagoa do Piri, *Klein & Souza 8626* (US), *Smith & Reitz 6192* (US).

*Ruellia kleinii* is characterized by the delicate, quadrangular stems and the small flowers with ovate bracteoles. It is quite similar to some of the specimens included by Nees in the original description of *Dipteracanthus menthoides* Nees, but has smaller, ovate leaves and is found in a more southern area.

## IV. Group **Dipteracanthus**

*Dipteracanthus* (*Calycosi*) Nees in DC., Prodr. 11: 116. 1847.

*Dipteracanthus* Nees (*Genuini*: *Bracteolati*) Nees in DC., Prodr. 11: 117. 1847.

*Siphonacanthus* Nees in C. Martius, Fl. Bras. 9: 45. 1847. TYPE: *Siphonacanthus villosus* Nees.

Flowers sessile, solitary, borne in the axils of the upper leaves, bibracteolate. Capsules thick, oblong in contour, with a small solid base ¼ their length. Seeds 6–12.

Group *Dipteracanthus* is pantropical and possibly the one with the most species in the genus. The neotropical species have been separated from the Old World *Dipteracanthus* by Bremekamp (1969: 423), but the characters that supposedly differentiate them are inconsistent. Taxonomically, it is the most problematic group; in southern South America it is partly represented by the assemblage of species allied to *Ruellia dissitifolia*, which are very difficult to delimit. Most of these species are suffruticose herbs that grown in open areas of floristic provinces of Amazon region or dominion (see Cabrera & Willink, 1980).

**14. Ruellia brachysiphon** (Nees) Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4, Abt. 3b: 310. 1895. *Dipteracanthus brachysiphon* Nees in C. Martius, Fl. Bras. 7: 34. 1847. TYPE: Brazil. Rio Grande do Sul: Porto Allegre, *Sellow 68* (holotype, B destroyed, photo F 5911; isotype, K).

Erect herb to 30 cm tall, with stems subterete, ± branched, velutinous, arising from a small rhizome. Leaves shortly petiolate, the blades elliptic to widely ovate, 2–4 cm long, 1.5–3 cm wide, acute, obtuse or rounded at the apex, sometimes apiculate, cuneate at the base, ± entire, sometimes serrulate, the lower ones smaller and rounder, all softly and shortly velutine-puberulous to densely velutinous, with some hairs glandular, sometimes glutinose, the underside densely pale velutinous.

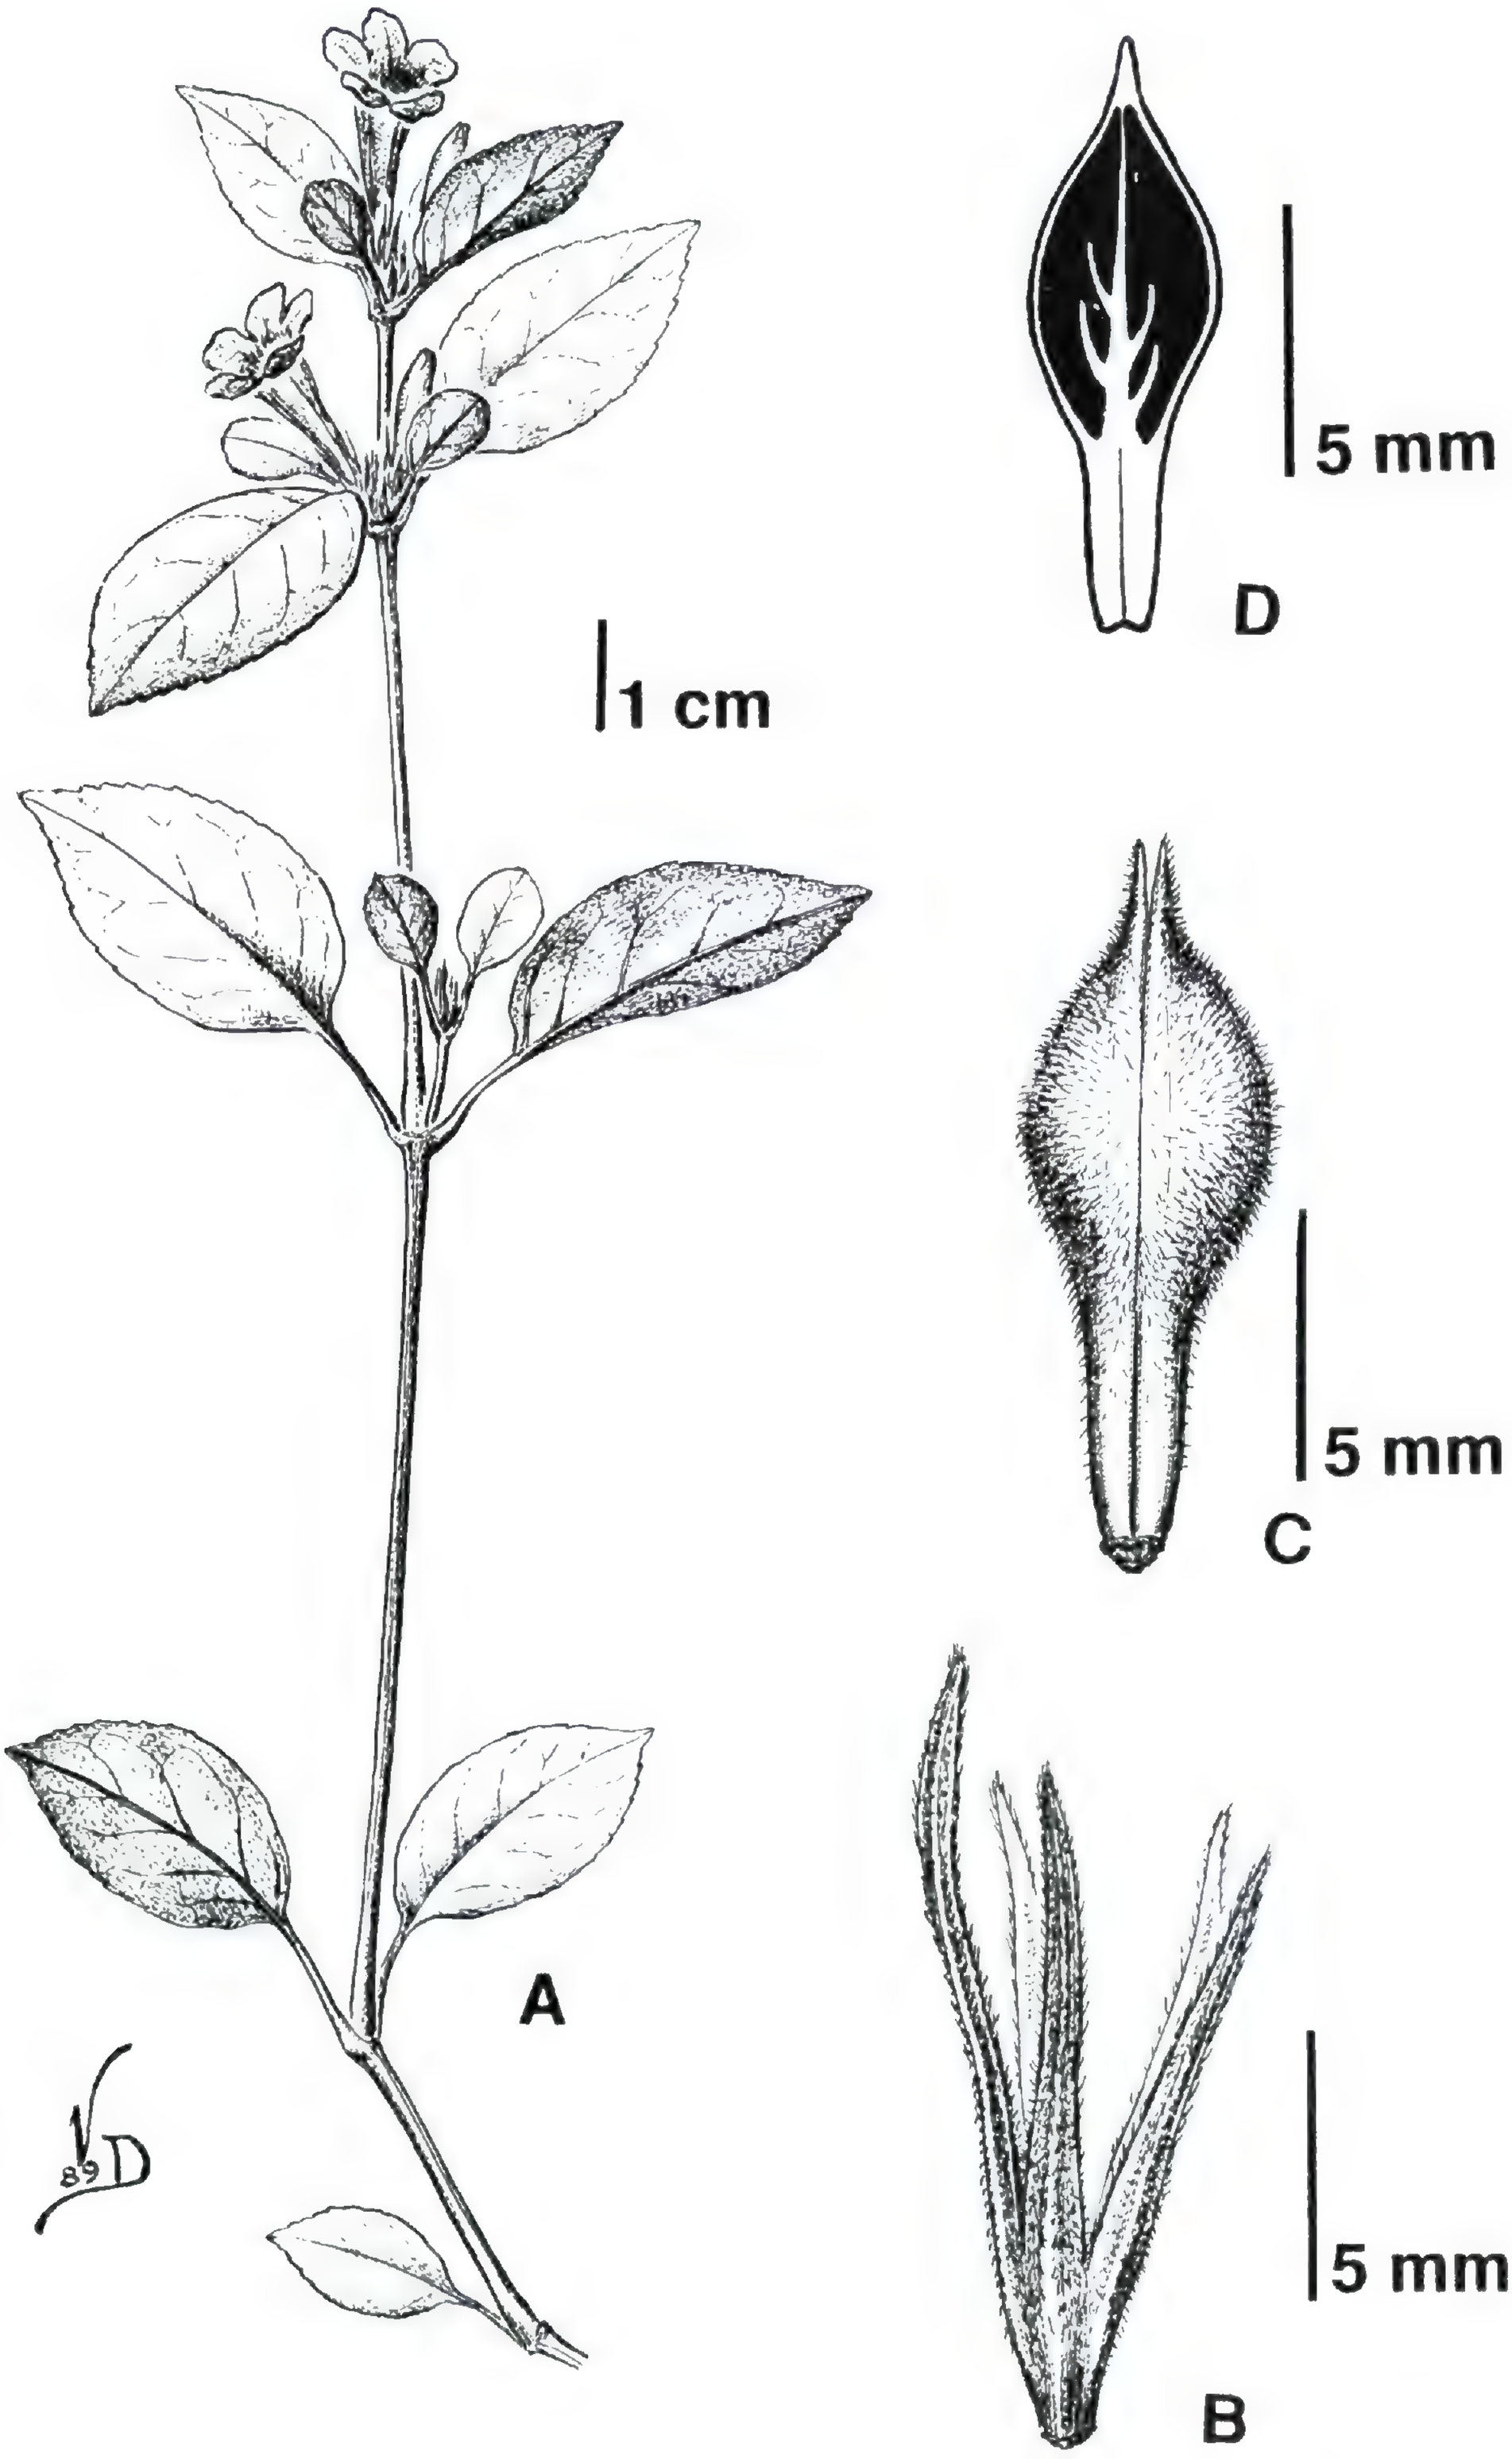

FIGURE 17. *Ruellia kleinii* Ezcurra & Wasshausen.—A. Flowering branch.—B. Calyx.—C. Capsule.—D. Open capsule without seeds, schematic. (A–C, *Klein 7333*; D, *Klein & Bresolin 8476*.)

Flowers sessile, solitary in the axils of the terminal leaves. Bractlets elliptic or lanceolate, ca. 1.5 cm long and 3–5 mm wide, acute, foliaceous, densely pubescent. Calyx 1–2 cm long, the segments ovate or lanceolate, to 1.5 cm long and 2–7 mm wide, acute, shortly puberulent to densely pubescent or velutinous, ciliate. Corolla erect, pale blue, 4–5 (–8) cm long, the basal tube less than 1(–2) cm long, the throat 2–2.5(–4) cm long, and 1.5(–2) cm wide, the lobes spreading, suborbicular, 1–1.5(–2) cm wide. Stamens included, long filaments ca. 1 cm long, short 0.5 cm long, the anthers 3 mm long. Mature capsule unknown.

*Distribution.* Eastern Paraguay, northeastern Argentina, and southern Brazil; occurring rarely in open, high campos, and flowering in spring, from September to December.

*Representative specimens.* ARGENTINA. **Corrientes:** Virasoro, *Birabén 5054* (LP); Desiderio Sosa, *Birabén 5211* (LP); Ituzaingó, sobre ruta 12, próximo al límite con Misiones, *Legname 8627, 8637* (LIL). **Misiones:** Entre Pueblo Santa Ana y cerro Santa Ana, *Alboff*, 26 Nov. 1896 (LP); Depto. *Ruellia brachysiphon* is a problematic species, variable in calyx morphology, and with a wide distribution, although apparently represented only by a relatively small number of specimens. It is characterized by the corollas with a short basal tube, the frequently wide calyx lobes, and the velutine-puberulous surface of the leaves.

**15. Ruellia brevicaulis** (Nees) Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4, Abt. 3b: 310. 1895. *Dipteracanthus brevicaulis* Nees in C. Martius, Fl. Bras. 7: 35. 1847. TYPE: Brazil. Without locality, *Sellow 3190* (holotype, B destroyed, photo F 5912). Figure 18.

*Dipteracanthus dissitifolius* Nees var. *humilior* Nees in C. Martius, Fl. Bras. 9: 35. 1847. SYNTYPES: Brazil. Minas Gerais: *Claussen 232* (P not seen); São Paulo: São Paulo, *Lund 733* (G not seen, photo herb. DC); Without state: Puerto Grosso, *Sellow s.n.* (B destroyed, photo F 5919). Syn. nov.

Erect, suffruticose herb, the stems terete, to 30 cm long, hirsute, arising from a small woody rhizome with thick, fleshy, fusiform roots. Leaves on petioles to 0.3 cm long, the blades widely ovate, 3–5 cm long and 1.5–3 cm wide, acute at the apex, cuneate at the base, serrulate, the lower ones generally smaller, all hirsute-pilose, the hairs long, white, shiny and spreading, sometimes also mixed with short, sericeous pubescence. Flowers sessile, solitary in the axils of the terminal leaves. Bractlets oblong, foliaceous, 1.5 cm long and 2–5 mm wide, acute, long-pilose. Calyx 1.5–2 cm long, the segments linear-lanceolate, to 1.8 cm long and 2 mm wide, acute, hirsute-ciliate. Corolla pale blue, 5–7 cm long, the basal tube 1–2 cm long, the throat longer, obconic, to 4 cm long and 2.5 cm diam., the lobes speading, suborbicular, ca. 2 cm wide. Stamens included, long filaments ca. 1 cm long, short 0.5 cm long, the anthers 3 mm long. Ovary and style glabrous. Capsule oblong in shape, 1.2–1.5 cm long and 0.5 cm thick, with a solid base ⅛ its length, the surface puberulous. Retinacula 3 mm long; seeds 6–8, lenticular, 3–4 mm diam., with margins appressed-puberulous, densely mucilaginous when wet.

*Distribution.* Southern Brazil, northeastern Argentina, and eastern Paraguay. *Ruellia brevicaulis* is common in open, high campos, to 950 m, especially on rocky or sandy ground subject to periodic fires. It flowers in spring, from September to December.

*Representative specimens.* ARGENTINA. **Corrientes:** Depto. *Ruellia brevicaulis* is characterized by the fusiform, tuberous roots, the hirsute pilosity—the hairs long, shiny and spreading—and the large, blue corollas with a short basal tube and a large throat. It is a common species in open, elevated campos of southern South America subject to periodic fires. The epithet "brevicaulis" is well applied to specimens of plants that have recently been burnt and only produce short stems before flowering. Some specimens do produce longer stems, probably when fires are less frequent.

Specimens of *Ruellia brevicaulis* have often been misidentified as *Ruellia dissitifolia* (e.g., Wasshausen & Smith, 1969), but *R. dissitifolia* is a different species only found in central Brazil (Goiás, Minas Gerais, and São Paulo), characterized by the basal obovate leaves, the dense, whitish, velutino-sericeous pubescence, and the large flowers.

*Ruellia brevicaulis* seems to hybridize with *Ruellia coerulea*, a species of group *Ruellia*, as suggested by the existence of morphologically intermediate specimens from eastern Paraguay, where both species are sympatric (see description of *R. coerulea*).

**16. Ruellia multifolia** (Nees) Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4(3b): 310. 1895. *Dipteracanthus multifolius* Nees in C. Martius, Fl. Bras. 7: 33. 1847. SYNTYPE: Brazil. *Sellow s.n.* (syntype, B destroyed, photo F 5938; isosyntype, K). Figure 19.

Erect herb or suffruticose perennial to 35 cm high, with stems subterete, ± branched, velutinous or hirsute on some sectors, arising from a horizontal rhizome with numerous, thick, fusiform roots. Leaves subsessile or shortly petiolate, the blades elliptic to widely ovate, 2–5 cm long, 1.5–3 cm wide, acute, obtuse or rounded at the apex, sometimes apiculate, cuneate or truncate at the base, ± entire, sometimes serrulate, the lower ones smaller and rounder, all softly and shortly velutine-puberulous to densely hirsute-velutinous, with many glandular hairs, sometimes glutinose, the underside with ± densely scattered sessile patelliform glands. Flowers sessile, solitary in the axils of the terminal leaves. Bractlets elliptic or lanceolate, foliaceous, ca. 1.5 cm long and 3–4 mm wide, acute, foliaceous, densely glandular-pubescent to shortly velutinous. Calyx 1–2 cm long, the segments lanceolate, to 1.5 cm long and 2 mm wide, acute, glandular-pubescent or velutinous, ciliolate. Corolla erect, pale mauve, 4–7 cm long, the basal tube 1.5–3 cm long, the throat 1.5–3 cm long and 1.5–2 cm wide, the lobes spreading, orbicular, 1.5–2 cm wide. Stamens included, long filaments ca. 1 cm long, short filaments 0.5 cm long, anthers 3 mm long. Style ± glabrous. Capsule oblong 1.5–1.8 cm long and ca. 5 mm thick, with a solid base ⅛ its length, the surface glabrous. Retinacula 3 mm long; seeds 6–12, 3 mm diam., with margins appressed-puberulous.

*Distribution.* Central and southern Brazil, eastern Paraguay, and northeastern Argentina. It is found growing in open cerrado and elevated campos, frequently on sandy soil. It flowers in spring and summer, from October to March.

**16a. Ruellia multifolia** (Nees) Lindau var. **multifolia.** Figure 19A.

This variety is characterized by the somewhat suffruticose habit, the generally unbranched stems, the densely velutinous-hirsute elliptic leaves that turn glabrescent on the upper surface at maturity, and the coriaceous blade with the nerves prominent below.

*Distribution.* Northeastern Argentina, eastern Paraguay, and central and southern Brazil.

*Representative specimens.* ARGENTINA. **Misiones:** Campo Grande, km 184, *Bertoni 623* (LIL); Depto. San Ignacio, Jardín América, *Crisci 324* (LP); San Ignacio, campo alto arenoso, *Quiroga 381* (BA); Santa Ana, *Rodríguez 769* (BA, LIL); San Ignacio, *Schulz*

*Dipteracanthus glanduloso-punctatus* Nees in C. Martius, Fl. Bras. 9: 34. 1847. *Ruellia glanduloso-punctata* (Nees) Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4, Abt. 3b: 310. 1895. SYNTYPE: Brazil. "Rio Grande do Sul": S. Ignacio, *Sellow s.n.* (B destroyed, photo F 5924). Syn. nov.

This variety differs from *Ruellia multifolia* var. *multifolia* by the more herbaceous habit, the less branched stems, the widely ovate leaves, obtuse or rounded at the apex, the shortly and softly velutinous pubescence with many glandular hairs, frequently glutinose, the underside with densely scattered sessile patelliform glands.

*Distribution.* Southeastern Paraguay and limiting areas of northeastern Argentina and southern Brazil, in campos.

*Representative specimens.* ARGENTINA. **Corrientes:** Depto. Mburucuyá, Estancia Santa Teresa, *Burkart 19512* (SI); Depto. Mburucuyá, 10 km W de Mburucuyá, *Krapovickas & Cristóbal 13618* (CTES, LP, US); Depto. Mburucuyá, Estancia Santa Teresa, *Pedersen 2995* (AA); Depto. PARAGUAY. **Alto Paraná:** Reserva Itatí Yupí, *Itaipú Binacional 170* (MO). **Caaguazú:** Caaguazú dans les campos, *Balansa 2462b* (P). **Caazapá:** Tavaí, propiedad de la familia Bogado, *Basualdo 2140* (MO); Tavaí, 3 km S del Destacamento, *Soria 3275* (MO). **Concepción:** in regione superioribus cursus fluminis Apa, *Hassler 8009* (G). **Cordillera:** in campo prope Itacurubí, *Hassler 1704* (P); in dumeto Cordillera de Altos, *Hassler 3500* (G). **Without locality:** Paraguaria centralis, *Hassler 3529* (BM, P, NY); en el campo Irupé, *Jorgensen 4307* (SI).

*Ruellia multifolia* var. *viscossisima* is closely related morphologically to *Ruellia multifolia* var. *multifolia*, with which it can often be confused. Variety *multifolia* is a generally more robust form that is quite frequent in south-central Brazil and northeastern Paraguay. Variety *viscossisima*, more common in southeastern Paraguay and limiting areas of northeastern Argentina, may just be a herbaceous, short-lived form, the product of seasonal climatic factors associated with latitude, such as photoperiod and temperature, or of edaphic conditions.

Although this variety was described from material reported to have been collected by Sellow in southern Brazil (Nees, 1847a: as *Dipteracanthus viscosissimus* and *D. glanduloso-punctatus*), I have found no other Brazilian material of this plant. The Spanish name of the only locality that appears in the type specimens ("S. Ignacio," and not the Portuguese orthography "S. Inácio") suggests that this material could have also been collected in northeastern Argentina near Brazil, in San Ignacio, Misiones, where the plant has been found relatively recently.

**17. Ruellia solitaria** Vell. Conc., Fl. Flumin.: 266. 1829. TYPE: Brazil. Rio de Janeiro: illustrated in Fl. Flumin. Icon. 6: t. 95. 1831. Figure 20.

Rio de Janeiro: Lacané, July 1839, *Gardner 805* (K; isosyntype, BM); Sebastianopolim, *Martius s.n.* (M, photo SI); Corcovado, *Riedel s.n.* (LE not seen); without locality, *Schott 6129* (W not seen, photo F 32759), *Sellow s.n.* (B destroyed, photo F 5913).

Branched, suffruticose herb 30–50 cm tall. Stems erect, obscurely quadrangular, pale whitish and terete at maturity, glabrous. Leaves on petioles 0.5–1 cm long, the blades widely elliptic or ovate, 5–12 cm long and 2–4 cm wide, obtuse or rounded at the base, glabrous on the surface, the margins entire. Flowers sessile, solitary in axils of the upper leaves, sometimes in twos. Bracteoles ovate, foliaceous, 1.5–2.5 cm long and 0.5–0.8 cm wide, glabrous. Calyx 0.8–1 cm long, the segments linear, to 0.8 cm long and 2 mm wide, acute, glabrous, ciliolate, somewhat accrescent and remaining on the stems after the shedding of the capsules. Corolla white or pale mauve, ca. 5 cm long, the basal tube 2 cm long, the throat obconic, 2.5 cm long and 1.3 cm diam., the lobes spreading, suborbicular, 1.3–1.8 cm wide. Stamens included, long filaments

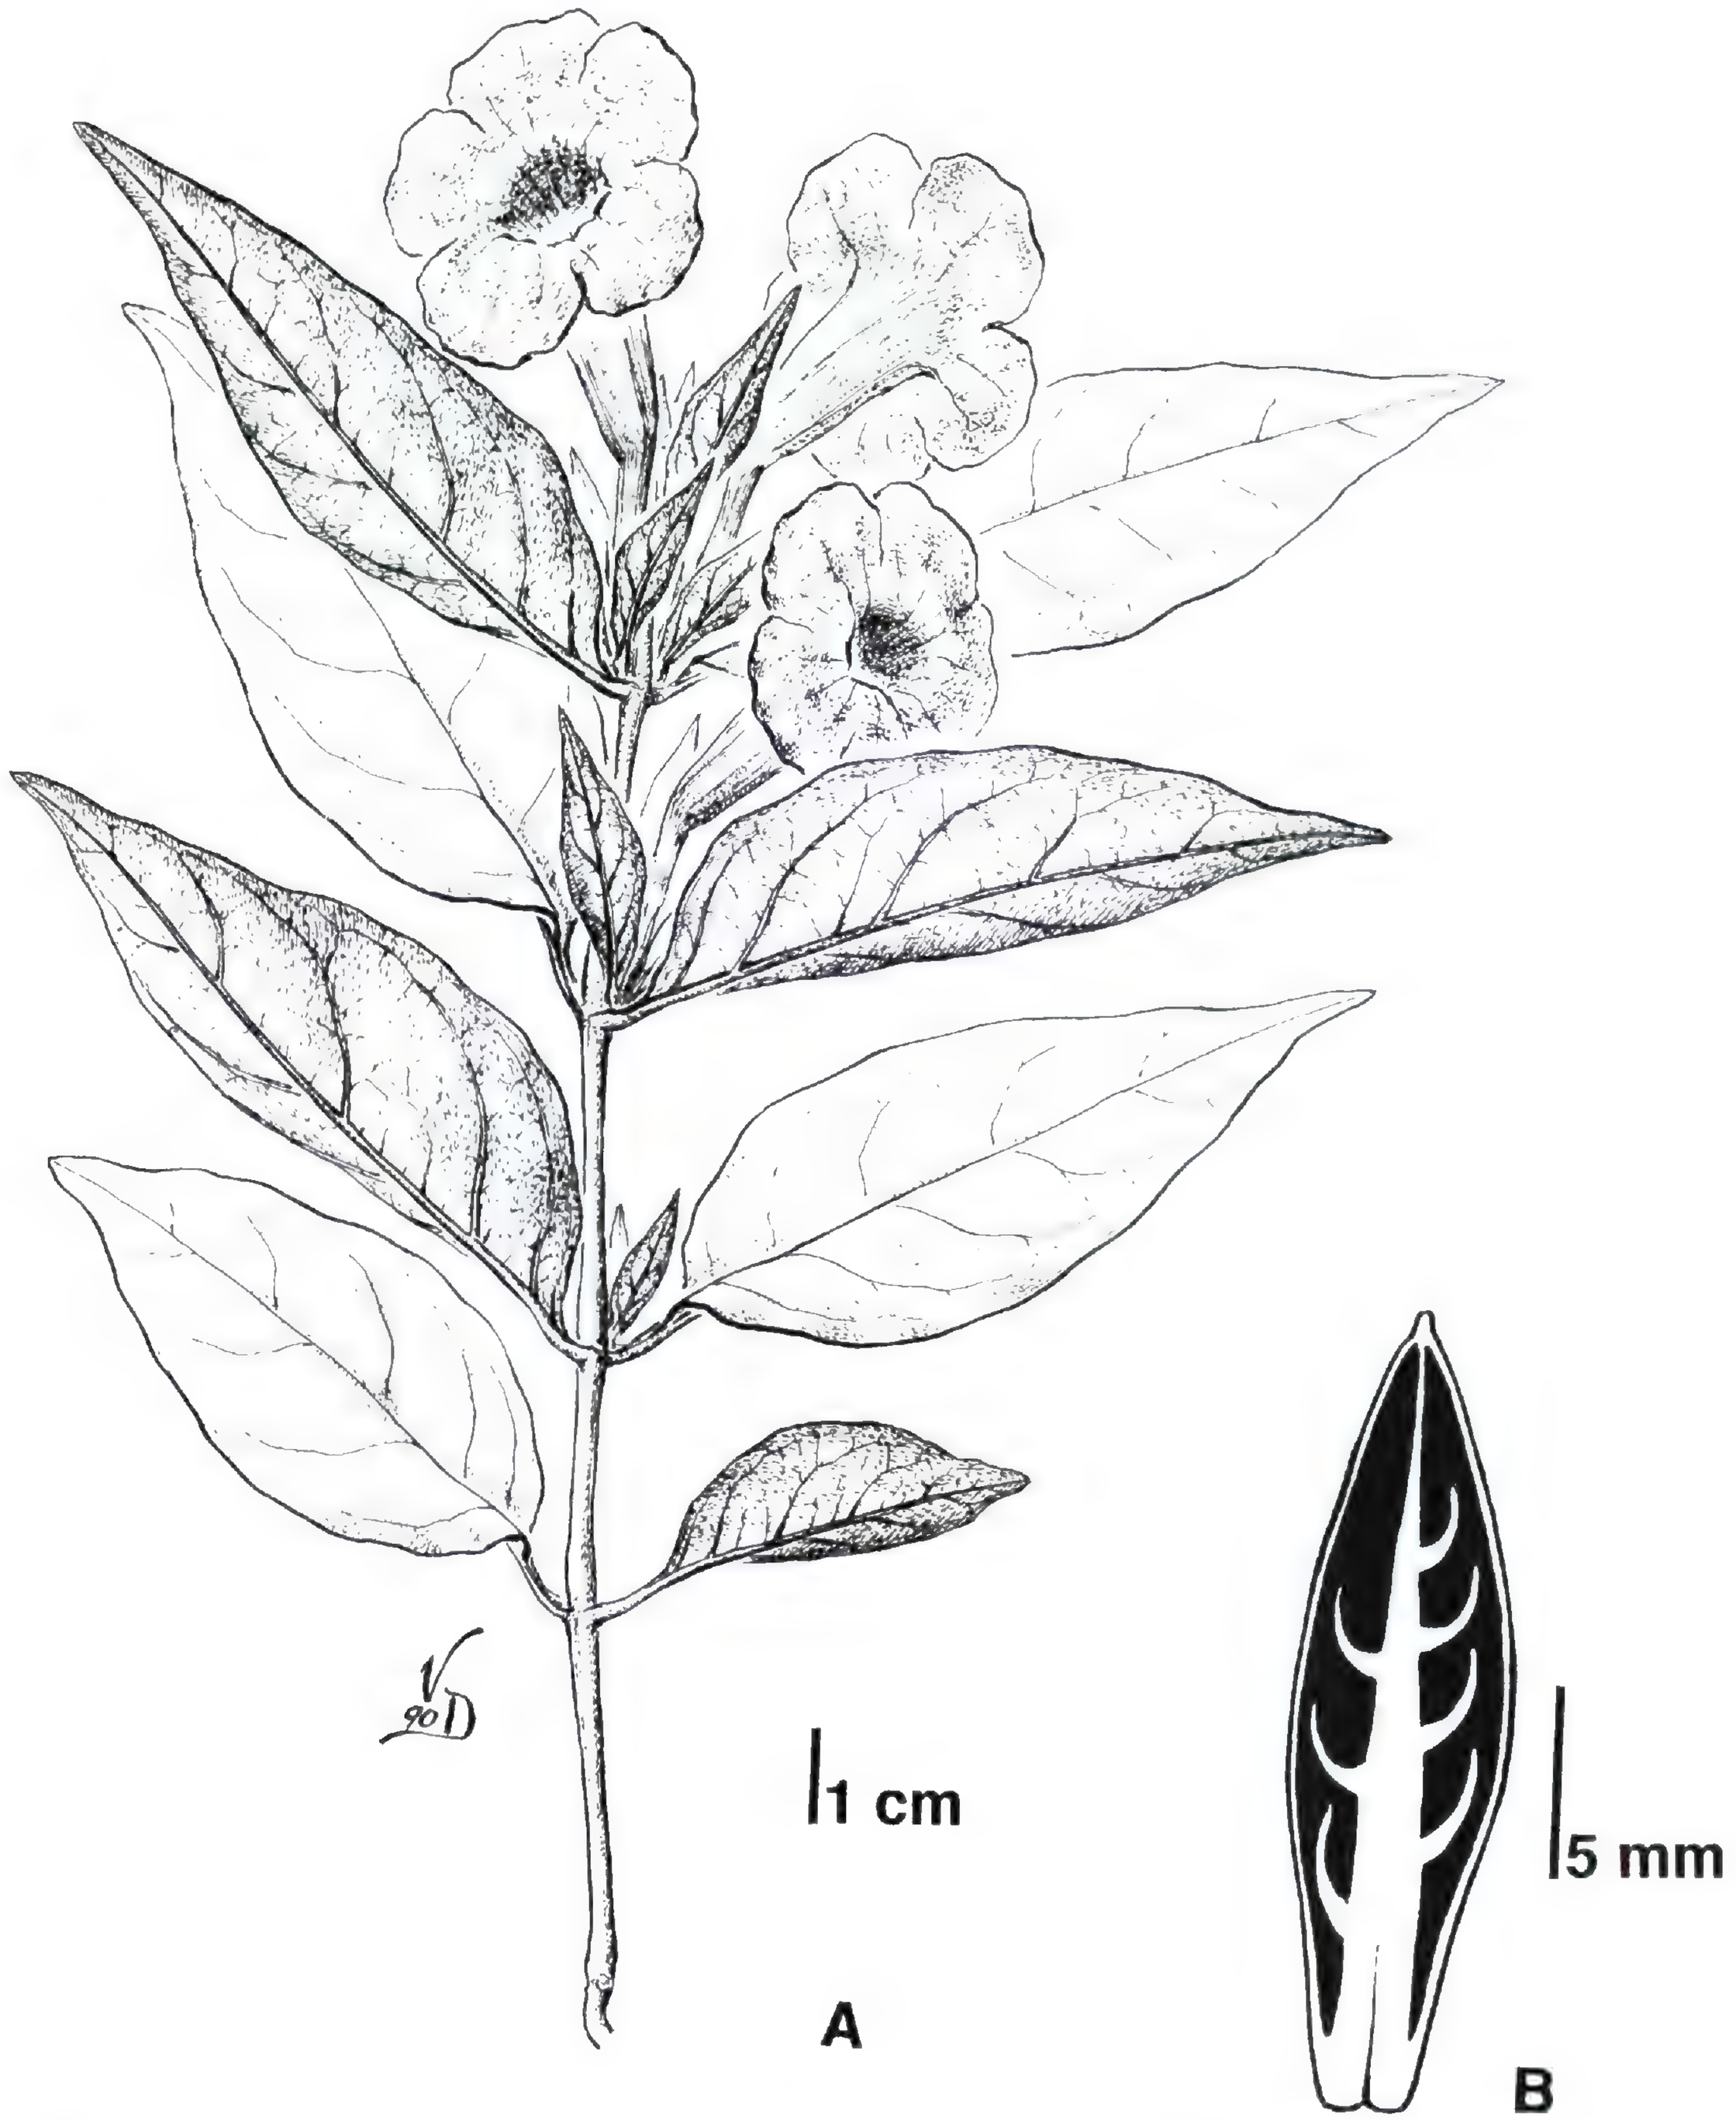

FIGURE 20. *Ruellia solitaria* Vell.—A. Flowering branch.—B. Open capsule without seeds, schematic. (A, *Hatschbach 34793*; B, *Hatschbach 14708*.)

ca. 1.2 mm long, short 0.8 mm long, the anthers 3 mm long. Ovary and style glabrous. Capsule oblong-ovate, 1.5–2 cm long and 5 mm thick, with a short solid base 3–5 mm long, the surface glabrous. Retinacula 2 mm long; seeds 12–16, 2 mm diam., glabrous, the margins pubescent and mucilaginous when wet.

*Distribution.* Southern Brazil, in the hygrophilous forest on the eastern side of the southeastern Atlantic coastal ranges, from the states of Espírito Santo and Rio de Janeiro to Paraná ("Mata Atlantica," Atlántica floristic province). It is found in the shady underwood of the forests. It flowers in winter and spring, from July to October.

*Representative specimens.* BRAZIL. **Paraná:** Mun. Morretes, Formigueiro, *Hatschbach 345* (MBM, RB); Grota Funda, *Hatschbach 4068* (MBM); Morro 7 encosta occidental, *Hatschbach 11340* (MBM); Estrada Itupava, Rio São João, *Hatschbach 14708* (MBM, NY, US); Estrada da Graciosa, Ferradura, *Hatschbach 19237* (MBM); Mun. Morretes, Estrada Graciosa, Grota Funda, *Hatschbach 34793* (MBM, US); Rio Bromado, *Hatschbach 42499* (MBM); Rio Taquaral, *Hatschbach 44983* (MBM, US); Mun. Campina Grande do Sul, Serra Capivari Grande, *Hatschbach 16209* (MBM, US). Mun. Guaraqueçaba, Rio do Cedro, *Hatschbach 19237* (MBM).

*Ruellia solitaria* is characterized by the glabrous stems and leaves, and the large, white or pale mauve, sessile, solitary flowers, with a pair of widely ovate bracteoles in the base. It is frequent in the understory of the coastal hygrophilous forest of southeastern Brazil. It is similar to *Ruellia lilacina* Hooker, a blue-flowered species of Amazonian Peru.

## V. Group **Ebracteolati**

*Dipteracanthus* Nees (Genuini: *Ebracteolati*) Nees in DC., Prodr. 11: 134. 1847.

*Gymnacanthus* Oersted, Vidensk. Meddel. Dansk Naturhist. Foren. Kjobenhavn 1854: 126. 1854, not Nees, 1836. TYPE: *Gymnacanthus geminiflorus* (HBK) Oersted (= *R. geminiflora* HBK).

*Copioglossa* Miers, Proc. Roy. Hort. Soc. London 3: 294. 1863. TYPE: *Copioglossa pilosa* Miers.

*Tremacanthus* S. Moore, J. Bot. 42: 33. 1904. TYPE: *Tremacanthus roberti* S. Moore.

*Ulleria* Bremek., Proc. Kon. Ned. Akad. Wetensch. Ser. C. 72, 14: 423. 1969. TYPE: *Ulleria geminiflora* (HBK) Bremek. (= *Ruellia geminiflora* HBK).

Flowers sessile, solitary, borne in the axils of the upper leaves, sometimes in twos by production of supernumerary buds; bracteoles obsolete or absent. Capsule obovoid, thick, with a small solid base ⅓ its length. Seeds (2–)4.

Group *Ebracteolati* is restricted to the New World and consists of several suffruticose herbs common in tropical and subtropical open areas. In South America they exist as a complex of species allied to *R. geminiflora* that is frequent in savannas and campos, in floristic provinces both of the Amazon and Chaco regions or dominions (see Cabrera & Willink, 1980). This group is characterized by a maximum reduction in the structure of the inflorescence (flowers sessile, bracteoles lacking), and by the capsule with a minimum number of seeds.

The subgeneric name *Ebracteolati* was first used by Nees (1847b) under *Dipteracanthus* (Genuini) Nees, but without clear indication of rank. Following article 35 of the *International Code of Botanical Nomenclature* (Greuter et al., 1988), this name is valid provided all other requirements for valid publication are fulfilled, in which case it may act as a homonym or serve as a basionym for future combinations in definite ranks.

**18. Ruellia bulbifera** Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4(3 b): 311. 1895. *Dipteracanthus tuberosus* Nees in C. Martius, Fl. Bras. 9: 42. 1847, not *Ruellia tuberosa* L. 1753. TYPE: Brazil. Without locality: *Sellow s.n.* (holotype, B destroyed; isotype GZU not seen, photo US). Figure 21.

*Ruellia loefgrenii* Lindau, Bull. Herb. Boissier 5: 654. 1897. TYPE: Brazil. São Paulo: in civitate São Paulo ad Feijas in campis, flor. Oct., *Loefgren 997* (holotype, B destroyed, photo F 5933; isotype, C not seen, photo US). Syn. nov.

Sprawling or decumbent herb, with stems to 30 cm long, arising from a woody, rounded or terete, tuberculate xylopodium to 2 cm diam.; stems green, obscurely quadrangular, glabrate, with nodes ± ciliate. Leaves shortly petiolate, widely elliptic, oblong or obovate, 2–4.5 cm long and 1–2 cm wide, rounded at the apex, widely cuneate at the base, the lower ones generally smaller and ± orbicular and retuse, all glabrous and coriaceous, nitidulous on top, with sessile glands and the venation prominent below. Flowers sessile, solitary in the axils of the terminal leaves. Bractlets absent or obsolete. Calyx 1.5–2 cm long, the lobes linear subulate, ca. 1.5 cm long and 2 mm wide, glabrous on the surface, ciliate. Corolla purplish white, 3.5–4.5 cm long, the basal tube ca. 1 cm long, the throat 2–2.5 cm long, the lobes orbicular, ca. 1.5 cm diam. Stamens included, longer ca. 10 mm long, shorter 5 mm long, the anthers 3 mm long. Ovary and style glabrous. Capsule ovoid, 1–1.2 cm long and 7–8 mm thick, broadest at or above the middle, glabrous, the base solid to 3 mm high. Seeds 2–4, brown, ca. 4 mm diam., lightly appressed-puberulous, densely mucilaginous when wet; retinacula 3 mm long.

*Distribution.* Eastern Bolivia, southwestern and southern Brazil, and northeastern Argentina, in dry grasslands, savannas, and campos. It is common on red earth, in recently burnt areas. It flowers in spring and summer, from October to March.

*Representative specimens.* ARGENTINA. **Corrientes:** Depto. Mburucuyá, Estancia Santa Teresa, *Bur-*

*Ruellia bulbifera* is closely related to the widely distributed and variable *Ruellia geminiflora*, from which it could have been derived, but is characterized by the completely glabrous, coriaceous leaves, generally rounded at the apex, and the thick, tuberculate xylopodium. It is easy to identify in its southernmost area, but in Minas Gerais, Brazil, a few specimens with thick, rounded xylopodia do show somewhat pubescent leaves (e.g., *Duarte 4329*, RB).

This species is associated with frequently burnt, open campos and savannas.

Suffruticose erect herb, with stems to 50 cm long, from a terete woody rhizome less than 1.5 cm diam.; stems obscurely quadrangular, pubescent, densely white-arachnoid and hirsute at the nodes. Leaves shortly petiolate, widely elliptic, 2–5 cm long and 1–2.5 cm wide, acute at the apex, cuneate at the base, ± white-tomentose, sometimes densely velutinous. Flowers sessile, solitary or geminate in the axils of the terminal leaves. Bractlets absent or obsolete. Calyx 1.5–2 cm long, the lobes linear and subulate, 2 mm wide, densely pubescent. Corolla whitish tinted with purple, 3–4 cm long, the basal tube ca. 1 cm long, the throat 2–2.5 cm long, the lobes orbicular, ca. 1.5 cm diam. Longer stamens ca. 10 mm long, shorter 5 mm long, anthers 2 mm long. Ovary and style puberulous. Capsule obovoid, 1–1.2 cm long and 7–8 mm thick, puberulous, the base solid to 3 mm high. Seeds 2–4, approximately 3 mm diam., appressed puberulous, densely mucilaginous when wetted; retinacula 3 mm long.

*Distribution.* Vastly extended in open grasslands of Central America and the West Indies (Durkee, 1986), and in savannas of South America, from Colombia and Venezuela to eastern Bolivia, southwestern and southern Brazil, Paraguay and northeastern Argentina. A heliophilous species, it is generally found in open sunny places and on sandy ground, in periodically burnt areas. In southern South America it flowers in spring and summer, from October to March.

*Ruellia geminiflora* is characterized by the somewhat thick, fibrous roots, the pubescent stems, the more or less ovate, pubescent leaves, the axillary sessile flowers that lack bracteoles, and the thick, obovoid, few-seeded capsule. It is an extremely variable species with a wide distribution that presents many local forms. These have frequently been given varietal or specific status and names.

Nees recognized five varieties for Brazil (1847a, b): *procumbens, hirsutior, erectus, subacaulis,* and *angustifolius*. Several other species that have been described for South America are also obviously related to *Ruellia geminiflora*. It is sometimes difficult to decide if they should be treated as separate taxonomic entities of a wide *Ruellia geminiflora* complex, or to include them within a single species as ecotypes, without giving them formal taxonomic recognition. Here *Ruellia geminiflora* is presented in its wider sense, and the names of several local variants have been reduced to synonymy. Such is the case of populations with narrow leaves that have been described as *Dipteracanthus canescens* Nees, *Dipteracanthus geminiflorus* var. *angustifolius* Nees, *Dipteracanthus humilis* Nees, or *Dipteracanthus vindex* Nees. These small, narrow-leaved forms appear in different areas of South America (central and southern Brazil: Minas Gerais, Mato Grosso do Sul, and Rio Grande do Sul; Guyana; Venezuela) and may be the result of parallel evolution within the species, or of long-distance dispersal phenomena, probably associated with migrating birds that could carry the mucilaginous seeds from one region to another. Such is also the case of the larger, more robust and branched shrubby plants with variable coriaceous leaves that are frequent in northeastern, central, and southwestern Brazil, and have been described as *Ruellia porrigens* Nees. Some specimens of eastern Paraguay, such as *Hassler 5382* from Canendiyú, or *Schinini 20507* and *Solomon 6819* and *6820* from Amambay, fall into this category. This form could be the result of edaphic conditions or of continuous growth related to an accidental absence of periodic fires during several successive growing seasons in some areas. A similar case is that of short-stemmed, nearly acaulescent populations described as variety *subacaulis* or *Ruellia lindmaniana*, which may be the response of the plants to the shortening of the growing period by the action of burning. Although some of these forms may deserve subspecific status, to decide on this a thorough study of the morphological and ecological diversification of the species throughout Central and South America should be undertaken.

Specimens of *Ruellia geminiflora* from Paraguay have been mistakenly identified by Morong & Britton (1892–1893) as *Ruellia bahiensis* (Nees) Morong. *Ruellia bahiensis* is another species of group *Ebracteolati*, which is very similar, but inhabits a different area and differs by the markedly swollen nodes of the stems and the somewhat accrescent calyces that remain attached to the leaf axils after the shedding of the capsules. It is found in northeastern Brazil.

**20. Ruellia magniflora** Ezcurra, sp. nov. TYPE: Paraguay. Central: Villa Elisa, sandy fields, *Pedersen 6522* (holotype, LP). Figure 23.

Herbae perennes ad basim suffruticosae, radicibus fasciculatis fibrosis crassis, ramis ascendentibus 30 cm altis parce ramificatis velutino-pubescentibus. Folia subsessilia anguste oblonga vel lanceolata, 5–9 cm longa 1.5–2 cm lata, apice acuta basi cuneata, argentea, utrimque velutino-tomentosa. Flores sessiles, solitarii vel geminati, in axillis foliorum terminalium dispositae, bracteolis obsoletis. Calycis segmenta linearia ca. 2 cm longa 1.5 mm lata extus pubescentia dense ciliata. Flores caerulei 5–7 cm longi. Corollae infundibuliformis tubo faucibus breviore, lobis rotundatis. Antherae inclusae. Stylus filiformis. Capsula obovata, 1 cm longa 0.8 cm crassa, puberula, 4-sperma. Semina 3 mm longa, in siccus adpresso puberula.

Suffruticose herbs from a small, woody rhizome, with thick, fleshy, fusiform roots. Stems erect, to 30 cm long, velutine-puberulous. Leaves shortly petiolate, narrowly oblong or lanceolate, 5–9 cm long and 1.5–2 cm wide, acute and cuneate, grayish velutine-tomentose, the lowermost somewhat shorter and obtuse. Flowers sessile, solitary or in twos in the axils of the terminal leaves. Bractlets obsolete. Calyx 2 cm long, the lobes linear, ca. 1.5 mm wide, pubescent, densely ciliate. Corolla pale blue, 5–7 cm long, the basal tube 1.5–2 cm long, the throat 2.5–3.5 cm long, the lobes orbicular, ca. 2.5 cm diam. Longer stamens ca. 1 cm long, shorter stamens 0.5 cm long, anthers 3 mm long. Ovary and style glabrous. Capsule obovoid, 1 cm long and 0.8 cm thick, puberulous, 2–4-seeded, the base solid to 2.5 mm high. Seeds 3 mm diam., appressed-puberulous, densely mucilaginous when wet; retinacula 3 mm long.

*Distribution.* Common on sandy savannas of eastern Paraguay, southwestern Brazil, and northeastern Argentina. It flowers in spring and summer.

*Representative specimens.* ARGENTINA. **Corrientes:** Depto. Mburucuyá, Estancia Santa Teresa, *Pedersen 9844* (CTES); Villa Olivari, 18 km W de Ituzaingó, *Schinini 15664* (CTES); Ituzaingó, Estancia Santa Tecla, *Schwarz 8039* (LIL); Ruta 12, 20 km E de Ituzaingó, *Zuloaga 3220* (SI). BRAZIL. **Mato Grosso do Sul:** Gouveia, Fazenda, campo rupestre, *Cerati 33790* (SPF); Mun. Rio Brilhante, Rio Vacaria, *Hatschbach 25186* (MBM). PARAGUAY. **Amambay:** Parque Nacional Cerro Corá, ca. Cerro Guaiguy Hog, *Fernández Casas 4016* (G); 7 km N de la Ruta 5 limite W del Parque Nacional Cerro Corá, *Ferrucci 701* (CTES). **Concepción:** zwischen Río Apa und Río Aquidabán, Villa Sana, *Fiebrig 4843, 4882* (G). **Cordillera:** in pratis prope San Bernardino, *Hassler 110* (G); in silva Caraguatay, *Hassler 3333* (G); in dumeto prope Caraguatay, *Hassler 4592* (G); Barranca Arroyo Y-haca, *Teague 108* (BM); iter ad yerbales montium "Sierra de Maracayú," *Hassler 4238* (BM, G).

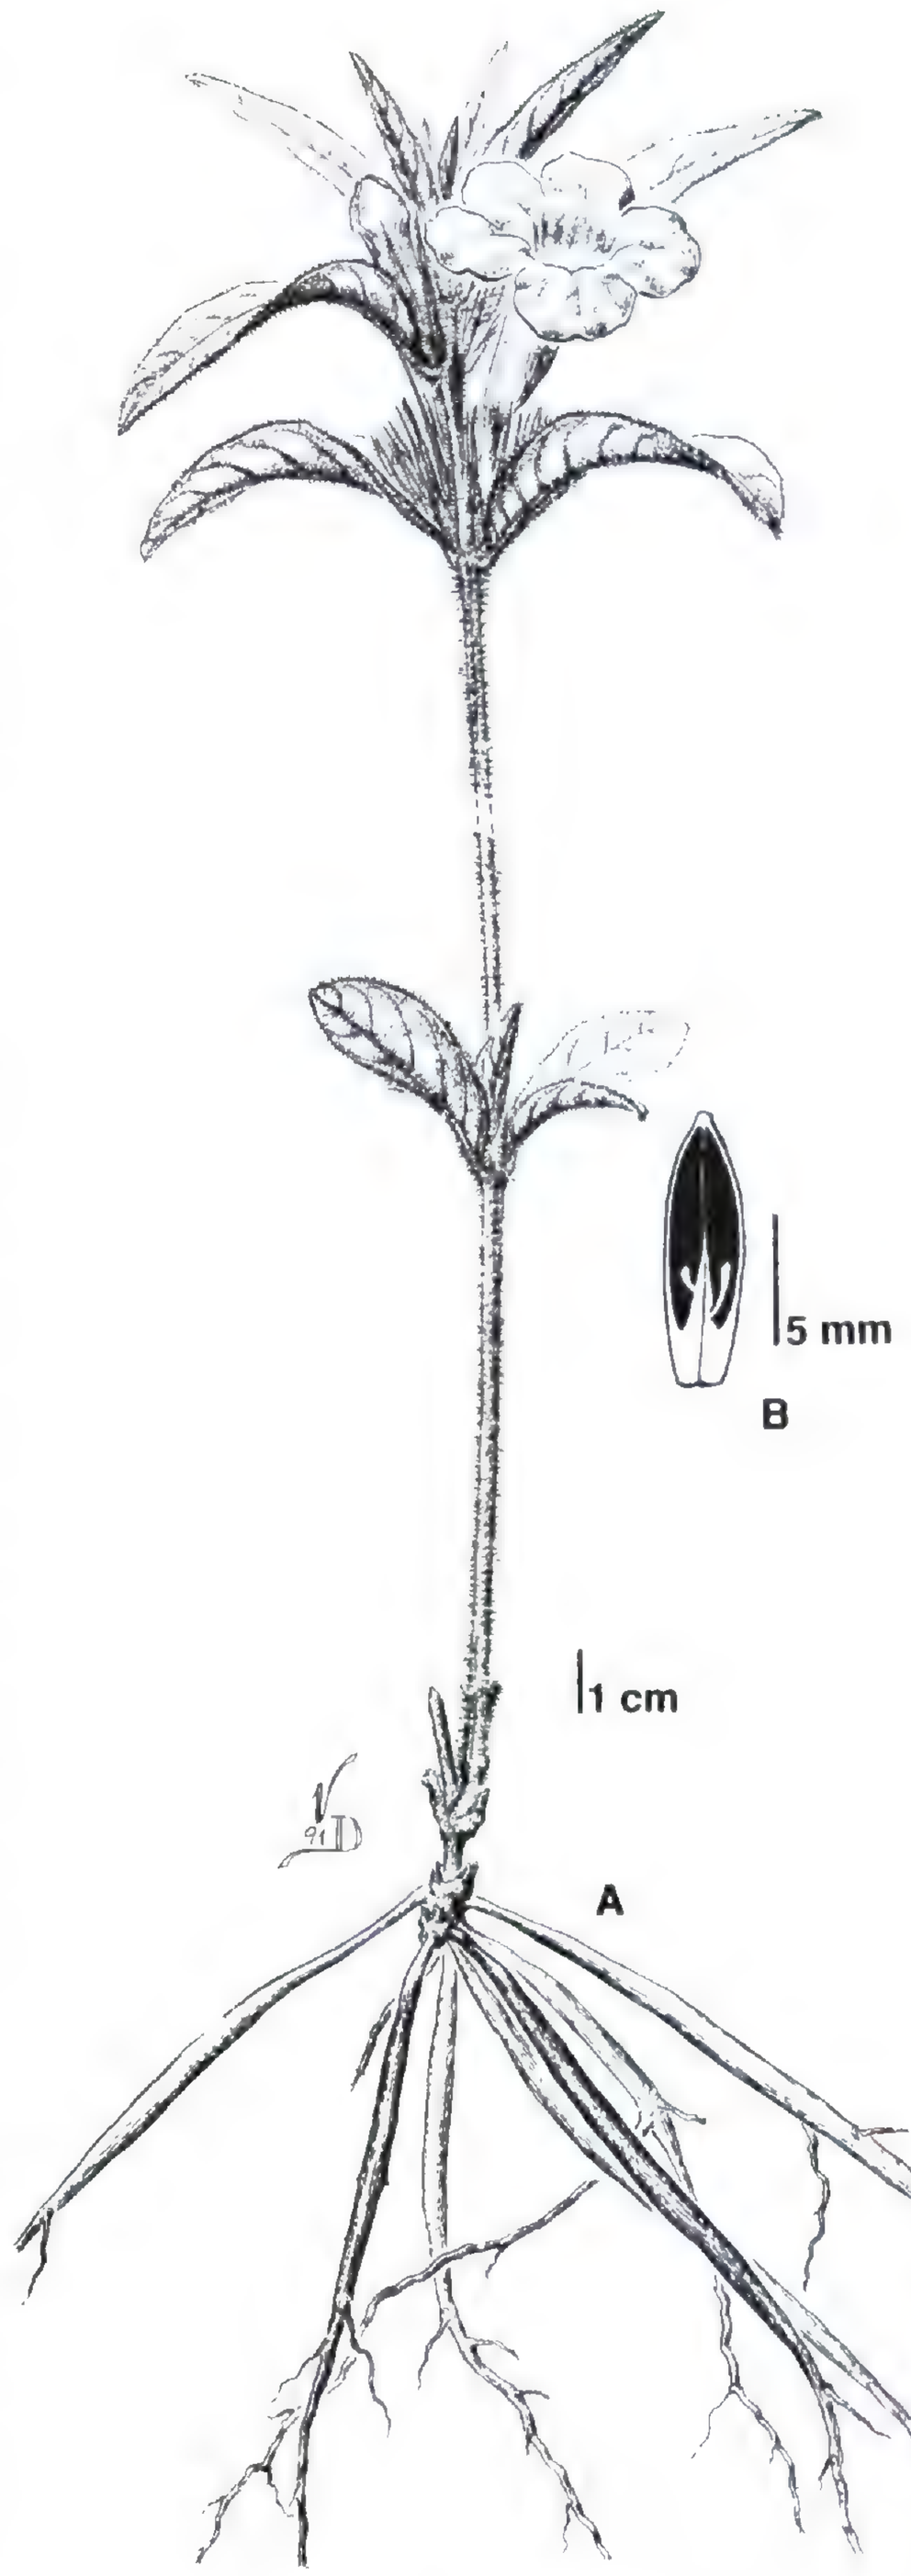

FIGURE 23. *Ruellia magniflora* Ezcurra.—A. Habit.—B. Open capsule without seeds, schematic. (A, *Pedersen 6522*; B, *Hassler 110.*)

*Ruellia magniflora* is clearly allied to *Ruellia geminiflora*; it differs by its fleshy, fusiform, tuberous roots, its narrow, lanceolate, longer leaves, and by its larger, pale-blue flowers.

## VI. Group **Salpingacanthus**

*Salpingacanthus* S. Moore, J. Bot. 42: 107. 1904. TYPE: *S. nobilis* S. Moore.

Flowers sessile, in the axils of the upper leaves; bracteoles obsolete. Calyx segments unequally cleft, forming a three-lobed structure. Capsule oblong in shape, with a small solid base ¼ its length. Seeds ca. 8.

The only species of this group is remarkable because of its large, white, sphingophilous flowers, with a long basal tube and exserted stamens. It is found in a small area of southwestern Brazil and northern Paraguay, in eastern Chaco forest.

Group *Salpingacanthus* shows no close affinities with any other groups in the area.

**21. Ruellia nobilis** (S. Moore) Lindau, Feddes Repert. 7: 67. 1909. *Salpingacanthus nobilis* S. Moore, J. Bot. 42: 107. 1904. SYNTYPES: Brazil. Mato Grosso do Sul: Corumbá, *Robert 713a*, *Robert 800* (BM; isosyntypes, NY). Figure 24.

Suffruticose herb or straggling shrub with the stems sparsely branched, terete, glabrous, pale at maturity. Leaves on petioles 0.5–1.5 cm long, the blades widely ovate, 4–10 cm long and 2.5–5 cm wide, acuminate, rounded on the base and somewhat decurrent on the petiole, the margin entire, the surface lightly velutine-puberulous, especially on the underside, the secondary veins parallel and prominent beneath. Flowers subsessile, solitary in the axils of the upper leaves. Bracteoles obsolete. Calyx 2–3 cm long, unequally cleft, lower segments united with the lateral ones, the posterior free, forming a three-lobed structure, the lobes 2 cm long and 1 cm wide, puberulous, light green in color. Corolla white, ca. 10 cm long, the basal tube 7–9 cm long, the throat obconic, 1–2 cm long and 1 cm diam., the lobes white, spreading, suborbicular, 2.5 cm wide. Stamens subexserted, filaments ca. 1.5 cm long, anthers 5 mm long. Ovary and style glabrous. Capsule oblong-elliptic in shape, 1.5–3 cm long and 4–5 mm thick, with a solid base to 0.5 cm, the surface glabrous. Retinacula 4 mm long; seeds 6–8, 3–4 mm diam., glabrous, pubescent and mucilaginous when wet.

*Distribution.* Southwestern Brazil and northern Paraguay, in eastern Chaco forest. *Ruellia nobilis* flowers in spring.

*Representative specimens.* BRAZIL. **Mato Grosso do Sul:** Corumbá, in dumetis silvulisque daris regionis calcaridis, *Malme 2747* (S); Corumbá a 200 m da divisa, Bolivia, cerrado estrada do Jacadigo, *Almeida 1713* (RB). PARAGUAY. **Alto Paraguay:** Fuerte Olimpo, Chaco Paraguayo, *Rojas 13638* (CTES, G, LIL, US).

*Ruellia nobilis* in the Acanthaceae and *Sphingiphila tetramera* (Gentry, 1990) in the Bignoniaceae appear to show convergent evolution with respect to corolla morphology. Both species, endemic to the same area (northeastern Paraguayan Chaco, and limiting areas of Brazil and Bolivia in the case of *Ruellia nobilis*), present a presumably sphingid-adapted corolla tube of the same size and proportions, attaining a length of more than 10 cm, a remarkable feature in both families. This probably reflects the selective pressure of the same type of pollinator acting in this area.

## VII. Group **Chiloblechum**

*Blechum* Nees subg. *Chiloblechum* Oersted, Vidensk. Meddel. Dansk Naturhist. Foren. Kjobenhavn 1854: 169. 1854. TYPE: *Blechum mexicanum* Oersted (lectotype, here selected).

*Penstemonacanthus* Nees in C. Martius, Fl. Bras. 9: 159. 1847. TYPE: *Penstemonacanthus modestus* Nees. Syn. nov.

Flowers sessile and solitary, ebracteolate, subtended by the upper leaves sometimes transformed into bracts, forming terminal spikes. Calyx frequently zygomorphic, the lateral lobes united with the two anterior, the posterior one free. Capsules ovate in shape, with a small solid base; placentas that separate elastically from the capsule with the retinacula and the seeds, breaking the walls. Seeds 4–8.

The species of this group occur in southern North America and subtropical South America, in a disjunct distribution. The two South American species are herbs with a suffruticose base and produce brilliant blue flowers that appear psychophilous.

Group *Chiloblechum* differs markedly from the rest of the genus in the structure of the fruit, in which the placentas, with the retinacula and the seeds, separate elastically from the walls of the capsule. This character also appears in other genera of Acanthaceae (e.g., *Blechum*, *Tetramerium*, *Dicliptera*, some *Justicia*) that do not seem to have close evolutionary relationships with *Ruellia*, and therefore could be a case of parallel evolution within the family. However, the genus *Blechum* is morphologically closely related to *Ruellia* (Bremekamp & Nannega Bremekamp, 1948), and has the same structure of the capsule correlated with the same inflorescence morphology as species of

FIGURE 24. *Ruellia nobilis* (S. Moore) Lindau. — A. Flowering branch. — B. Open capsule without seeds, schematic. (A, B, *Rojas 13638.*)

*Ruellia* sect. *Chiloblechum*, differing only in the size of the flowers and the pollen morphology. In this case, reticulate evolution could also explain the morphology of the species of group *Chiloblechum*, which have characters in common both with *Ruellia* and *Blechum*.

**22. Ruellia erythropus** (Nees) Lindau in Engl. & Prantl, Nat. Pflanzenfam. 4, Abt. 3b: 311. 1895. *Siphonacanthus erythropus* Nees in C. Martius, Fl. Bras. 9: 47. 1847. TYPE: Brazil. Rio Grande do Sul: Porto Allegre, São Lourenço, *Sellow s.n.* (holotype, B destroyed, photo F 5920; isotype, K). Figure 25.

*Penstemonacanthus modestus* Nees in C. Martius, Fl. Bras. 9: 159. 1847. TYPE: Brazil. Minas Gerais: Caatingas ad Contendas, July, *Martius s.n.* (holotype, M not seen, photo F 20573). Syn. nov.

*Blechum tweedii* Nees in DC., Prodr. 11: 466. 1847. *Ruellia tweedii* (Nees) T. Anderson ex Morong & Britton, Ann. New York Acad. Sci. 7: 192. 1893. TYPE: Argentina. Paraná? ("Panama"): without locality, *Tweedie s.n.* (holotype, K). Syn. nov.

*Blechum mexicanum* Oersted, Vidensk. Medd. Naturhist. For. Kjobenhavn 8–12: 169, tab. 5, f. 1–4, 1854. TYPE: Mexico. Vera Cruz: "Antigua og paso de Doña Juana, Hacienda de Santa Barbara, Morro de Boquilla, Rancho Nuevo," *Liebmann s.n.* (holotype, C not seen).

*Ruellia pubiflora* Griseb., Abh. Königl. Ges. Wiss. Göttingen 24: 259. 1879. TYPE: Argentina. Salta: San José, Orán, Laguna del Palmar, *Lorentz & Hieronymus 550* (holotype, GOET not seen, photo SI; isotype, NY).

*Ruellia matogrossensis* Lindau, Bull. Herb. Boissier 3: 362. 1895. TYPE: Brazil. Mato Grosso: Jacobina, *Kuntze s.n.* (holotype, B destroyed, photo F 5936; isotype, NY). Syn. nov.

*Ruellia velascana* Lindau, Bull. Herb. Boissier 3: 363. 1895. TYPE: Bolivia. Santa Cruz: prov. Velasco orientali, 200 m, *Kuntze s.n.* (holotype, B destroyed, photo F 18222; isotype, NY). Syn. nov.

Erect or straggling suffruticose perennial 20–60 cm tall, with a ligneous base and tough, fibrous roots. Stems thin, decumbent, obtusely quadrangular, somewhat woody and rooting at the lower nodes, generally glabrous. Leaves on slender petioles 0.3–1 cm long, the blade elliptic or ovate, 2–6 cm long and 1–2.5 cm wide, acute or acuminate, cuneate on the base, generally glabrous on the surface and with sessile patelliform glands beneath, the margin entire. Flowers sessile, solitary in the axils of the upper leaves, in terminal, densely foliose spikes. Bracts (upper leaves) opposite and decussate, imbricate, similar to the normal leaves but subsessile, smaller and ciliate. Bractlets obsolete. Calyx ca. 5 mm long, unequally cleft, the two lateral segments united to the two lower ones, the posterior free, forming a three-lobed structure. Corollas erect, blue, 2.5–3.5 cm long, the basal tube 1.5 cm long, the throat campanulate-obconic, 1–1.5 cm long, the lobes spreading, orbicular, ca. 8 mm long. Stamens included, long filaments ca. 8 mm, short 5 mm, the anthers 3 mm long. Ovary and style glabrous. Capsule ovate, 1 cm long and 4 mm thick, the lower 3 mm solid, puberulous, glabrescent. Placentas breaking away with the retinacula and the seeds from the dry mature capsule. Retinacula 2–3 mm long; seeds 4–8, dark, 2–3 mm diam., with mucilaginous hairs when wet.

*Distribution.* Mexico (Yucatan and Veracruz), southeastern Bolivia, Paraguay, southern, southeastern, and southwestern Brazil, and northern Argentina. In South America it is frequent in the understory of Chaco forest and adjacent brevideciduous transition forests. It flowers in winter and spring, from June to October.

*Representative specimens.* ARGENTINA. **Catamarca:** entre Los Altos y La Viña, *Morello 1160* (LIL); Depto. Paclín, Cuesta del Totoral, *Rodrigo 3184* (LP); Depto. *Ruellia erythropus* is characterized by the blue flowers in terminal spikes, with the leaves subtending the flowers subsessile and ciliate, somewhat morphologically different from those on the lower vegetative portion of the shoot, and therefore appearing like bracts. Also, the placentas separate elastically from the capsule with the retinacula and the seeds. In these characters it approaches the closely related genus *Blechum*, which differs in pollen morphology.

*Ruellia erythropus* has an extremely extended range in subtropical South America, and a curious disjunct distribution, having been described also for Veracruz and Yucatán, Mexico, as *Blechum mexicanum*. Although I have not seen the type specimen of *B. mexicanum*, I have studied material from Mexico to verify this synonymy (see list of representative specimens). The name *Ruellia erythropus* precedes the name *R. tweedii*, with which this species had been cited by most previous authors (e.g., Ariza Espinar, 1983; Dawson, 1979; Leonard, 1936; Morong & Britton, 1892–1893). The extensive synonymy of this species reflects the wide range it inhabits and its associated morphological variation. It is somewhat similar to *Ruellia bahiensis* from northeastern Brazil (of group *Ebracteolati*), but differs by the inflorescence and capsule structure. Several herbarium specimens of *Ruellia erythropus* from Paraguay and Argentina have been erroneously identified as *Ruellia bahiensis*.

Although the genus *Penstemonacanthus* was described by Nees (1847a) based on material supposedly having five stamens, it is an exception, not only in this species but in all the genus *Ruellia*, and probably a teratology. The rest of the morphological characters of the original description of *Penstemonacanthus modestus* clearly agree with those of *Ruellia erythropus*. Although I have not investigated the structure of the capsule in the photograph of the type, it has been clearly described by Nees in both the genus and species descriptions.

**23. Ruellia hypericoides** (Nees) Lindau in Engl., Bot. Jahrb. 19, Beibl. 48: 16. 1894. *Dipteracanthus hypericoides* Nees in C. Martius, Fl. Bras. 9: 39. 1847. SYNTYPES: Brazil. Rio Grande do Sul: without locality, *Sellow s.n.* (B destroyed, photo F 5931; isosyntype, K); without locality, *Gaudichaud 244* (P). Figure 26.

Delicate herb 15–25 cm tall, from a small basal rhizome with fibrous roots. Stems weak, erect or decumbent, terete, shortly appressed-pubescent, with long internodes. Leaves shortly petiolate, ovate or orbicular, 1.5–2 cm long and 0.8–1.3 cm wide, obtuse or rounded in the apex, truncate in the base, the lower ones smaller, all puberulous on top and densely dotted with sessile patelliform glands on the surface beneath, the margins entire. Flowers sessile, solitary in the axils of the upper leaves. Bracteoles obsolete. Calyx 5 mm long, the segments linear-lanceolate, 4 mm long and 1 mm wide, acute, appressed-puberulous and ciliate. Corolla erect, blue, 2–3 cm long, the basal tube 1.2–1.5 cm long, the throat campanulate-obconic, 5–6 mm long and 4–5 mm diam., the lobes spreading, suborbicular, ca.

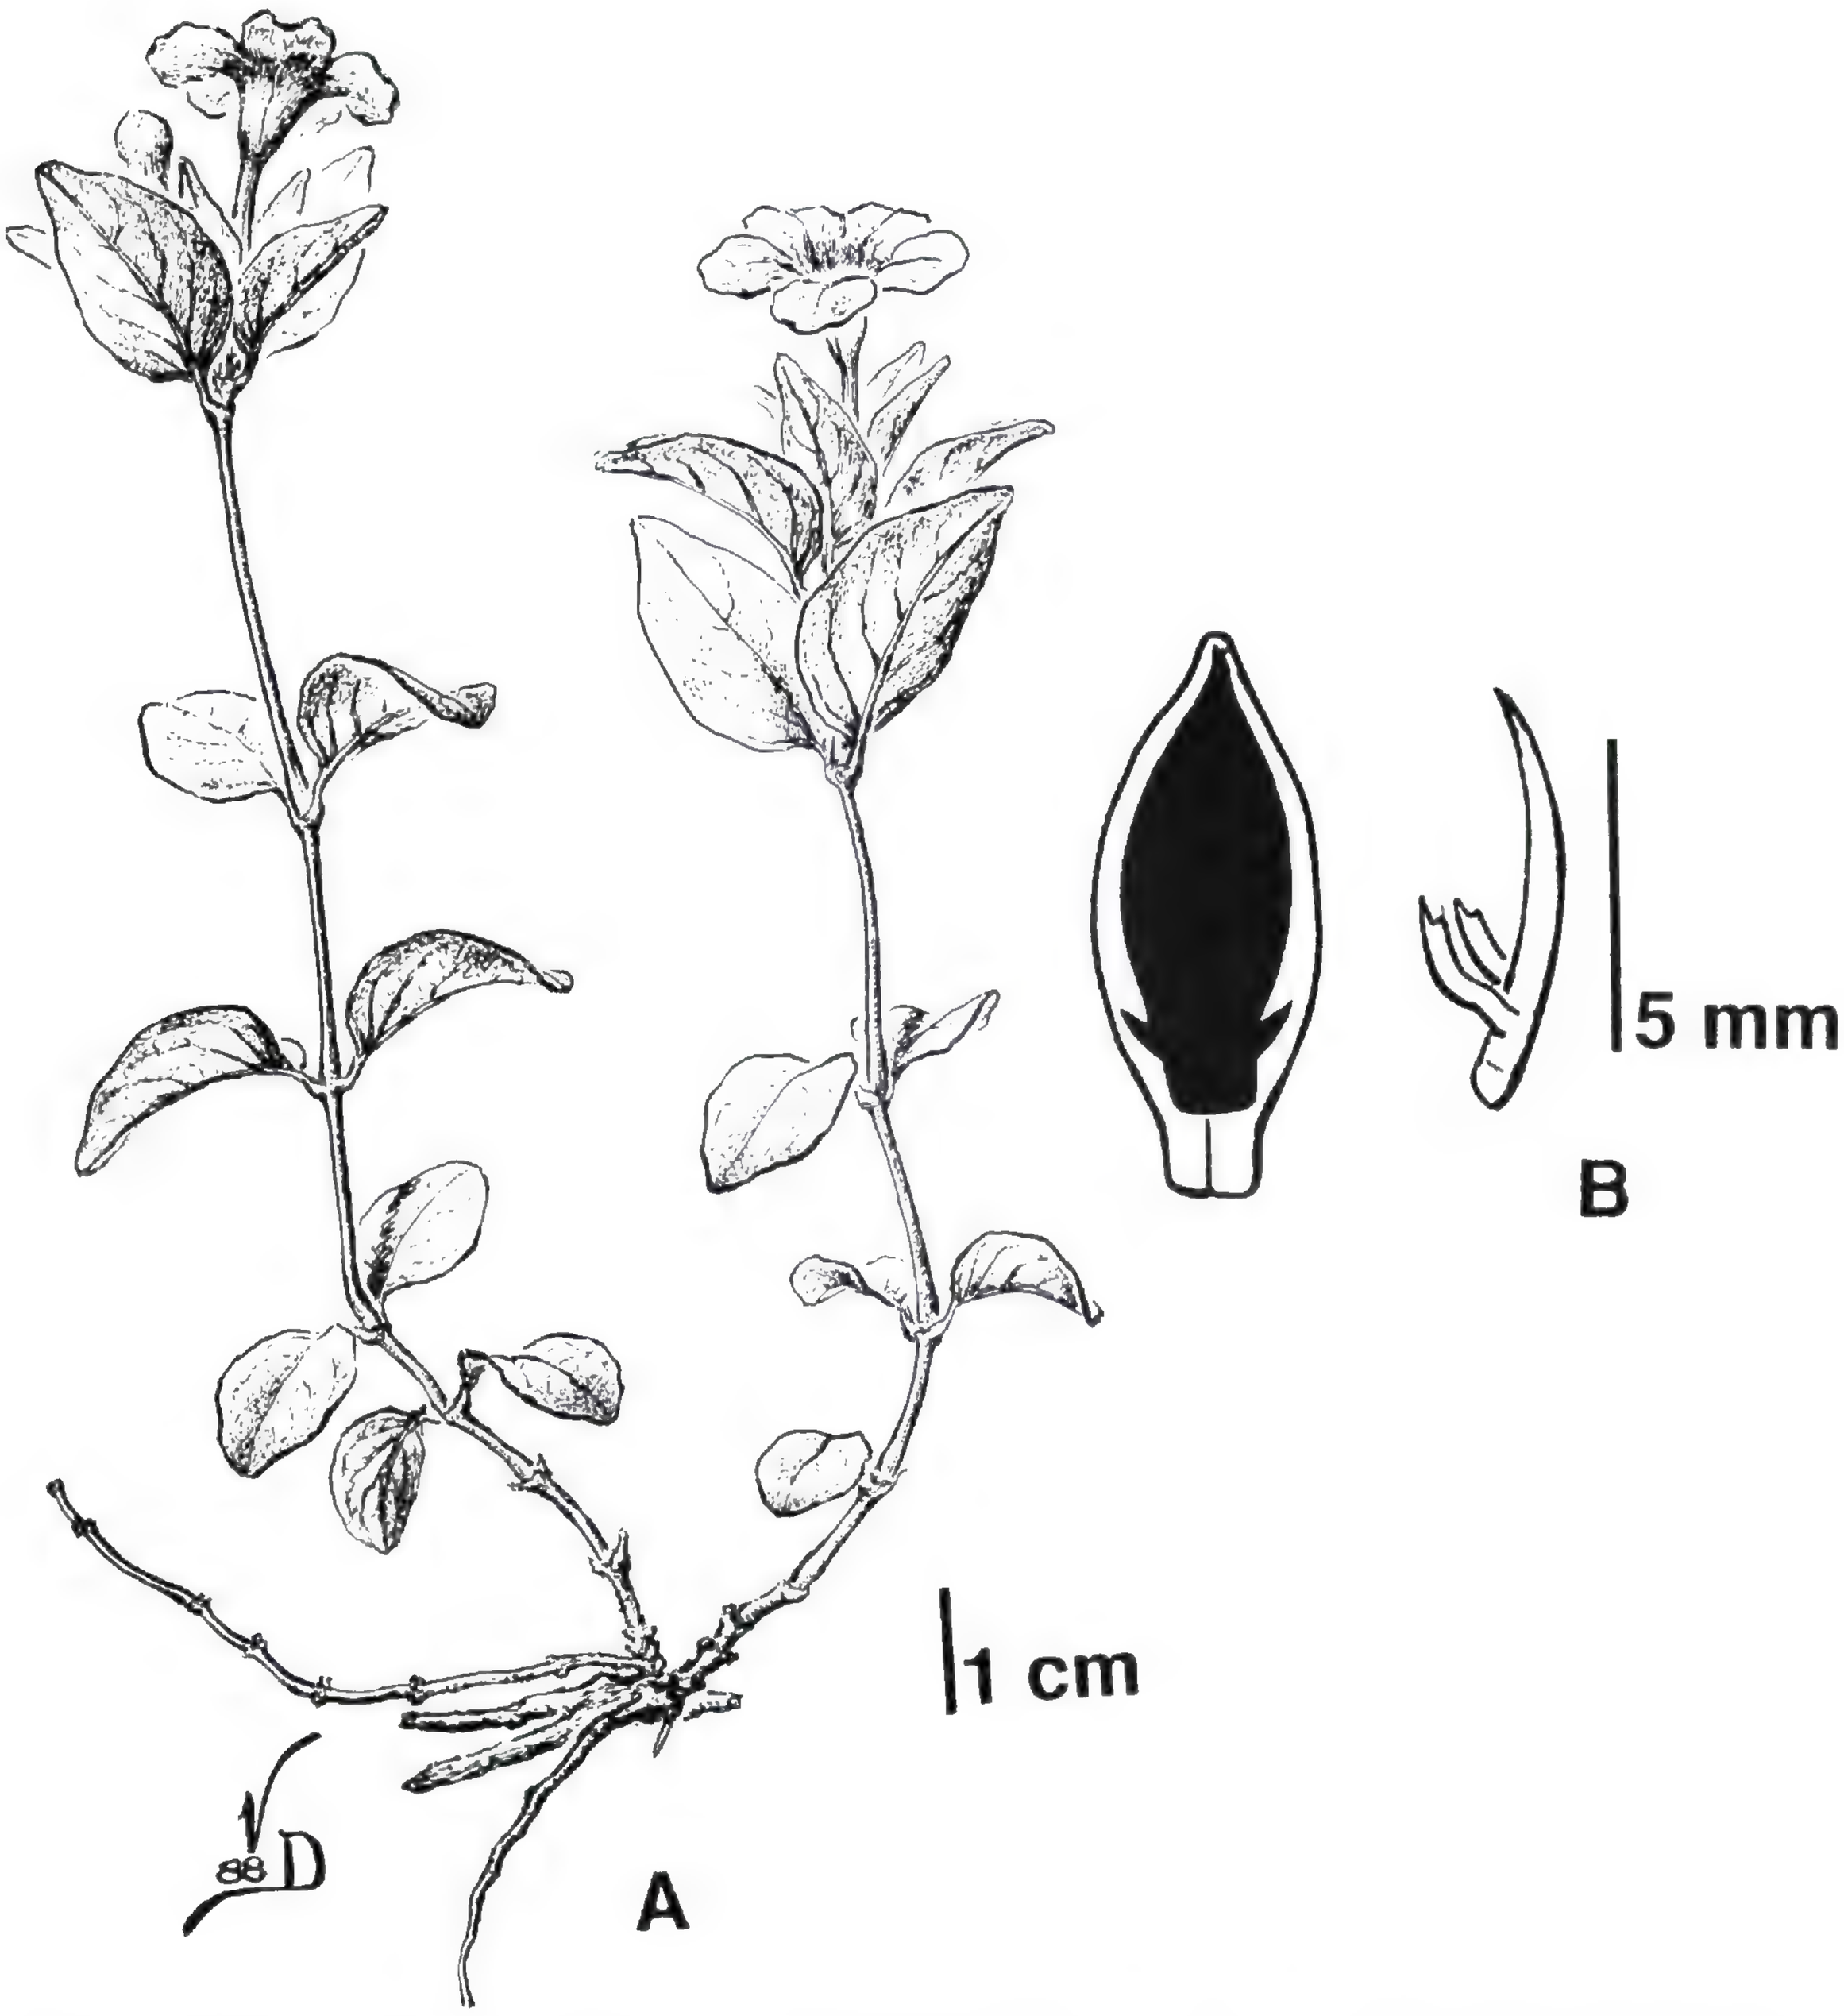

FIGURE 26. *Ruellia hypericoides* (Nees) Lindau.—A. Habit.—B. Open capsule without seeds, schematic, the placenta and the retinacula separated. (A, B, *Burkart 14181.*)

8 mm diam., somewhat emarginate. Stamens included, ca. 7 mm long, anthers 2 mm long. Ovary and style puberulous. Capsule ovate, 7–9 mm long and 4 mm thick, puberulous, the base solid. Placentas breaking away with the retinacula and the seeds from the dry mature capsule. Retinacula 1.5 mm long; seeds 4–8, brown, 2 mm diam., with mucilaginous hairs when wet.

*Distribution.* Southern Brazil, southern Paraguay, northeastern Argentina, and northern Uruguay. *Ruellia hypericoides* is found in open, grassy campos. It flowers in spring and summer, from November to February.

*Representative specimens.* ARGENTINA. **Corrientes:** Ituzaingó, Estancia San Miguelito, 20 km NE de Playadito, Ruta 39, *Carnevali 5044* (CTES); Ituzaingó, Estancia Santa Rita, *Correa 8219* (BAB); Santo Tomé, Estancia Garruchos, Cachuera, Arroyo Chirimay, *Krapovickas 21215* (US), *21216* (CTES); Santo Tomé, R.40 y Arroyo Chirimay, *Krapovickas 10682* (CTES); Santo Tomé, Estancia Garruchos, *Krapovickas 21407* (CTES);

Ituzaingó, Ruta 39, 30 km N de Virasoro, *Krapovickas 25341* (CTES); Ituzaingó, San Carlos, *Martínez Crovetto 8020* (BAB); Ituzaingó, Estancia Puerto Valle, *Partridge s.n.* (LP); Santo Tomé, Estancia Garruchos, *Pedersen 985* (AA), *5434* (AA, ICN, LP). **Misiones:** Apóstoles, Pindapoy, *Birabén 5396* (LP); Posadas, *Burkart 14181* (SI), *Martínez Crovetto 8153, 8164* (BAB); Concepción, Mártires, *Martínez Crovetto 6207* (BAB); San Ignacio, Gob. Roca, *Martínez Crovetto 8621* (BAB); Posadas, *Meyer 6010* (LIL); Frontera, San Antonio, *Montes 7074* (SI, US); San Ignacio, Santo Pipó, *Schulz 7213* (LIL); Posadas, *Spegazzini 19397* (SI); Depto. Apóstoles, Arroyo Chirimay, balneario Azara, *Tur 1927* (SI); de Apóstoles a Concepción de la Sierra, Arroyo Las Tunas, *Zuloaga 3248* (SI). BRAZIL. **Rio Grande do Sul:** Sao Luiz-Caaro, *Buck 11356* (LIL); Sao Salvador, Santo Inacio, *Henz 35695* (LIL); 20 km SE de Santa Rosa, *Lindeman 8990* (ICN); Santo Angelo, *Palacios-Cuezzo 1734* (LIL); Carazinho, *Pereira 8675* (RB); Quarai, Estancia de Jarau, *Rambo 26077* (LIL). PARAGUAY. **Misiones:** 12 km W de San Ignacio camino a Pilar, *Arbo 1885* (CTES). URUGUAY. **Artigas:** Ruta 30, Arroyo Catalán, paso Piaui, *Rosengurtt B7173* (MVFA, US).

*Ruellia hypericoides* seems closely related to *Ruellia erythropus*, but inhabits more open areas and is a more delicate herb with smaller flowers. The name *R. hypericoides* has been erroneously used by many authors to identify material of *Ruellia bulbifera* of group *Ebracteolati*. *Ruellia bulbifera* differs by the robust, tuberculate xylopodium, larger flowers with a short basal tube, and different structure of the capsule.

## Excluded Species

*Ruellia lanceolata*, *Chaetochlamys rusbyi*, and *Beloperone matthewsii* are different names for the same species, all based on different types. The genus in which this species should be placed is *Justicia*, and the correct name for it is *Justicia rusbyi*.

**Justicia rusbyi** (Lindau) V. A. W. Graham, Kew Bull. 43(4): 605. 1988, not *Justicia lanceolata* (Chapman) Small, 1933. *Chaetochlamys rusbyi* Lindau, Bull. Herb. Boissier 3: 491. 1895. TYPE: Bolivia. La Paz: Guanai, *Rusby 1117* (isosyntype, BM); Santa Cruz: without locality, 380 m, *Kuntze*, 1892 (isosyntype, NY).

*Ruellia lanceolata* Morong, Ann. New York Acad. Sci. 7: 193. 1893. TYPE: Paraguay. Paraguarí: Central Paraguay, between Pirayú and Jaguarón, 8 Apr. 1889. *Morong 667* (holotype, NY; isotype, US). Syn. nov.

*Beloperone matthewsii* Lindau, Bull. Herb. Boissier 6, App. 1: 30. 1898. SYNTYPE: Paraguay. Cordillera: in dumeto prope Cordillera de Altos, *Hassler 1936* (G; isosyntypes, K, P, NY).

# ENDEMIC HERBACEOUS BAMBOO GENERA OF CUBA (POACEAE: BAMBUSOIDEAE: OLYREAE)[1]

*Fernando O. Zuloaga,*[2] *Osvaldo Morrone,*[2] *and Emmet J. Judziewicz*[3]

ABSTRACT

A morphological, anatomical, and taxonomic study of the endemic herbaceous bamboo (Poaceae: Bambusoideae: Olyreae) genera *Ekmanochloa* and *Mniochloa* (including its new segregate *Piresiella*) is presented; the new combination *Piresiella strephioides* is proposed. An unusual feature of all three genera is the presence of inflorescences consisting of paired, conjugate racemes. Illustrations of the leaf blade anatomy show unusual features such as the absence of fusoid cells in *Ekmanochloa* and *Mniochloa* and the presence of compound epidermal papillae in *Ekmanochloa*. The three genera are compared with possible close relatives within the Olyreae.

Cuba has a rich grass (Poaceae) flora numbering at least 400 species, with 69 of these endemic (López Almiral et al., 1989). There are four endemic genera: *Lepturidium* Hitchc. & E. Ekman (Cynodonteae), *Triscenia* Griseb. (Paniceae), and the herbaceous bamboo (Bambusoideae) genera *Mniochloa* Chase and *Ekmanochloa* Hitchc. The latter two taxa are the only endemic bambusoid genera in the entire West Indies and each is known from only a few old collections. Habitats include pine woodlands, streambanks, and limestone cliffs in the provinces of Habana and Pinar del Río (one species) and Oriente (the other three species), including serpentine outcrops. In this regard, it is noteworthy that Brooks (1987) reports 511 endemic serpentine vascular plant species for Cuba. As part of a long-term project, the goal of which is to monograph all New World bamboo genera, the following study of the morphology, anatomy, and taxonomy of these endemic "dwarf bamboos" is presented.

*Mniochloa*, named for its resemblance to the moss genus *Mnium* L., was established by Chase (1908) on the basis of two species that were described in the previous century in the genera *Olyra* L. and *Digitaria* Haller. She included the group in the Paniceae, while later authors placed *Mniochloa* in the Olyreae within the Pooideae (Hubbard, 1934), or in the Phareae (along with other herbaceous bamboos) within the Panicoideae (Bews, 1929; Roshevits, 1937). Recent authors, starting with Calderón & Soderstrom (1967), have all placed *Mniochloa* (and *Ekmanochloa*) in the Olyreae within the Bambusoideae (Calderón & Soderstrom, 1980; Clayton & Renvoize, 1986; Soderstrom & Ellis, 1987; Soderstrom et al., 1988; Watson & Dalwitz, 1988). Both *M. pulchella* (Griseb.) Chase and *M. strephioides* (Griseb.) Chase are small, delicate, trailing, almost mosslike grasses that are reminiscent of the South American olyroid genus *Raddiella* Swallen, or, because of the dimorphic culms with lax, trailing flowering shoots, *Piresia* Swallen. On closer examination of the two taxa, however, we noted a number of significant differences in morphology and leaf anatomy. Except for the large, heterogeneous group *Olyra* L. (Soderstrom & Zuloaga, 1989), olyroid genera tend to have nearly identical female spikelet morphologies; however, the differences between the two *Mniochloa* species are great and include features of floret indument, stipe and apex morphology, and relative glume length. Anatomically, *M. pulchella* lacks the characteristic bambusoid fusoid cells, whereas *M. strephioides* has them. Because of these and other features (discussed in greater detail later and summarized in Tables 1 and 2), we have decided to erect the new segregate genus *Piresiella* based on *P. strephioides*. Other characters that had appeared to unite the two species are also found in more distantly related genera in the Olyreae; for

[1] We thank Vladimiro Dudás for the excellent illustrations, Tarciso Filgueiras for the Latin diagnosis, Luis Catasús Guerra for information on the recent status of these grasses in Cuba, and curators of various herbaria for the loan of specimens.

TABLE 1. Comparison of *Mniochloa* with *Piresiella*.

| Character | *Mniochloa* | *Piresiella* |
|---|---|---|
| Morphology | | |
| Leaf blade morphology | Elliptical; base cuneate, symmetrical to slightly asymmetrical | Ovate-triangular; base truncate, strongly asymmetrical |
| Flowering culm morphology | Erect, exceeding the vegetative culms | Lax, shorter than the vegetative culms |
| Female glume morphology | Shorter than the floret, obtuse to acute | Longer than the floret, usually acute |
| Internode between female upper glume and floret | Not prominent | Prominent |
| Female floret apex | Obtuse to acute | Apiculate |
| Female floret indument | Glabrous | Densely pubescent |
| Male spikelet apex | Glabrous | Short-pilose |
| Stamen number | 3 | 2 |
| Leaf blade anatomy | | |
| Fusoid cells | Absent | Present |
| Papillae | Densely papillose throughout | Weakly papillate between stomates; otherwise smooth |
| Intercostal short cells (abaxial epidermis) | Solitary | Paired |

example, paired, conjugate racemes are found in *Ekmanochloa*; leafless flowering shoots, in all species of *Piresia* and in species of *Olyra* (*O. ecaudata* Doell and others) and *Cryptochloa* Swallen (*C. decumbens* Soderstrom); corms are found in *Rehia* Fijten.

*Ekmanochloa* (two species) was also examined in morphological and anatomical detail. Based on such distinctive features as the deciduous leaf blades, long-awned female florets, the absence of leaf blade fusoid cells, and the presence of compound epidermal papillae, we decided that a thorough study of both *E. aristata* Hitchc. and *E. subaphylla* Hitchc. might shed light on their tenuous placement in the Olyreae.

Distribution maps for all four taxa treated in this paper can be found in Soderstrom et al. (1988).

## Materials and Methods

Herbarium specimens were examined from GH, MO, NY, and US (including type fragments from other herbaria). Transverse sections of dried leaf blades were prepared after desilification in 30% hydrofluoric acid (Breakwell, 1914); the sections were then stained in safranin and fast green. Abaxial epidermal scrapes of leaf blades were prepared by removing the mesophyll and vascular tissue with a scalpel and camel hair brush following the method of Metcalfe (1960). The epidermis was then stained in safranin. The standardized terminology of Ellis (1976, 1979) was used to describe the anatomical structure of the leaves. The vouchers for this study are marked with an asterisk in the specimens examined section of the taxonomic treatment.

## Leaf Anatomy

### *MNIOCHLOA PULCHELLA*

*Leaf blade in transverse section* (Fig. 1A, B). *Outline.* Expanded, flat; arms of the lamina straight, the two halves symmetrical on either side of the median vascular bundle; thickness at midlamina 32–52 μm. *Ribs and furrows.* Adaxial and abaxial ribs and furrows indistinguishable. *Median vascular bundle.* Midrib with simple, first-order vascular bundle distinguishable structurally from other first-order vascular bundles; adaxial projections inconspicuous; abaxial projections slightly convex. *Vascular bundle arrangement.* Three first-

bundle sheath present, complete, consisting of small cells with uniformly thickened walls; outer bundle sheath of third-order vascular bundles rounded, with abaxial or adaxial interruptions, without extensions, consisting of 2–4 rounded cells; chloroplasts absent; inner bundle sheath absent or with a few cells abaxially. *Sclerenchyma*. Minute, with inconspicuous adaxial and abaxial girders associated with all vascular bundles, 1–3 cells deep; fibers lignified; small sclerenchyma cap at the margin. *Mesophyll*. Chlorenchyma not radiate but adaxially cells tending to a palisade-type arrangement, with conspicuous air spaces; arm cells present but with relatively shallow invaginations; 12–25 chlorenchyma cells between consecutive vascular bundles, which are 90–170 μm apart; fusoid cells absent; colorless cells absent. *Adaxial epidermal cells*. 2–3 bulliform cells present in restricted groups between all vascular bundles, generally with a large, fan-shaped central cell occupying up to ½ of the blade thickness; epidermal cells small, regular in size, with a distinct, continuous cuticle; macrohairs not seen; prickles present, usually located opposite the vascular bundles; papillae present, usually 2 per cell, narrower than the epidermal cells, relatively broad but not much more than ½ the width of the epidermal cells. *Abaxial epidermal cells*. Bulliform cells absent, otherwise cells similar to adaxial epidermis; macrohairs not seen, but hooks present, usually located between the vascular bundles; prickles and papillae similar to adaxial epidermis.

*Abaxial epidermis in surface view* (Fig. 2A, B). *Zonation*. Costal and intercostal zones distinguishable, the costal zone 3–5 cells wide, the intercostal zone 13–18 cells wide. *Intercostal long cells*. Elongated, rectangular, more than 3 times as long as wide; anticlinal walls parallel, undulating, unthickened; end walls vertical; long cells in a file separated by a short cell, or infrequently adjoining one another and without short cells. *Intercostal short cells*. Solitary, tall and narrow in outline, transversely elongated, the cork cells with crenate or undulating walls. *Stomatal complex*. 13–17 μm long, 10–13 μm wide, with 2–4 files of stomata per intercostal zone; a single interstomatal long cell usually present between consecutive stomata; subsidiary cells dome-shaped; interstomatal cells rectangular, with anticlinal walls undulating, the end walls concave. *Microhairs*. Elongated, fingerlike, 36–46 μm long, common in the median intercostal zone; basal cell two or more times as long as the distal cell, with parallel, thickened walls; distal cells short, very thin-walled, deciduous. *Macrohairs*. Not seen. *Hooks and prickles*. Small, shortly barbed, located in the median intercostal zone; prickles with the base as long as the stomata, the barb developed, located in the costal zone over the vascular bundles. *Papillae*. Rounded, simple, small, less than ½ the vertical width of the long cells, located in the costal and intercostal zones over long and short cells, commonly arranged so as to form a ring around each stomate. *Silica bodies*. Intercostal silica bodies absent; costal silica bodies dumbbell-shaped, horizontally elongated.

*Adaxial epidermis in surface view*. Adaxial epidermal cells similar to the abaxial surface except with: stomata infrequent; frequent intercostal paired silico-suberose short cells located near the costal zones; and intercostal silica bodies tall and narrow, elongated vertically, and irregular in outline.

*PIRESIELLA STREPHIOIDES*

*Leaf blade in transverse section* (Fig. 1C, D). *Outline*. Expanded, flat, with margins slightly recurved; arms of the lamina straight, the two halves symmetrical on either side of the median vascular bundle; thickness at mid-lamina 40–65 μm. *Ribs and furrows*. Conspicuous near the midnerve, inconspicuous in the rest of the blade. *Median vascular bundle*. Midrib with a simple first-order vascular bundle structurally distinguishable from the lateral first-order vascular bundles; adaxial and abaxial projections slightly convex. *Vascular bundle arrangement*. Six first-order vascular bundles and 30–40 third-order vascular bundles in the entire blade; (3–)5–7 third-order vascular bundles between consecutive first-order vascular bundles; all vascular bundles centrally located in the blade thickness. *Vascular bundle description*. First-order vascular bundles circular in outline; phloem tissue adjoining the inner bundle sheath; metaxylem vessel elements slightly angular in outline, equal or slightly larger than the outer bundle sheath cells as seen in section; third-order vascular bundles angular in outline with xylem and phloem indistinguishable. *Vascular bundle sheath*. Outer bundle sheath of the first-order vascular bundles consisting of 6–10 inflated cells, rounded, lacking chloroplasts, abaxially or adaxially interrupted by sclerenchyma girders, without extensions; inner bundle sheath present, complete, formed by small cells with uniformly thickened walls; outer bundle sheath of the third-order vascular bundles rounded to elliptical in outline, consisting of 5–6 rounded, elliptical cells, lacking chloroplasts, with abaxial interruptions, adaxial interruptions occasionally present, without extensions; inner bundle sheath absent or with a few cells near the phloem tissue. *Sclerenchyma*. Small, with inconspicuous adaxial

and abaxial girders associated with all vascular bundles, 2–3 cells deep; fibers lignified; sclerenchyma caps absent from margins. *Mesophyll.* Chlorenchyma not radiate, with adaxial chlorenchyma cells in a palisade-like arrangement and conspicuous air spaces; arm cells present, with short invaginations; 12–15 chlorenchyma cells between consecutive vascular bundles, which are spaced 165–235 μm apart; fusoid cells present, translucent, narrowly elongated, present on either side of each vascular bundle, or occasionally absent; fusoid cells separated by numerous chlorenchyma cells; colorless cells absent. *Abaxial epidermal cells.* 3–4 bulliform cells present in discrete, fan-shaped groups between all vascular bundles, the central cell large, inflated, and occupying up to ½ of the blade thickness; epidermal cells small, regular in size, with the cuticle continuous; macrohairs present, with a sunken base, not constricted, located at the margins; prickles not seen; hooks present, located between the vascular bundles near the margin; papillae absent. *Adaxial epidermal cells.* Bulliform cells absent; epidermal cells small, with the cuticle continuous; macrohairs similar to the ones on the abaxial surface; prickles not seen; hooks small, with a short barb, located in the intercostal zones near the margin; papillae narrower than the epidermal cells, associated with the stomata.

*Abaxial epidermis in surface view* (Fig. 2D, E). *Zonation.* Costal and intercostal zones distinguishable; costal zones 1–4 cells wide; intercostal zones 13–18 cells wide. *Intercostal long cells.* Long cells in files separated by pairs of short cells, elongated, rectangular, more than 5 times as long as wide, the anticlinal walls parallel and undulating, the end walls vertical. *Intercostal short cells.* In silico-suberose pairs, tall, transversely elongated; cork cells with crenate walls. *Stomatal complex.* 19–26 μm long, 11–16 μm wide, with 4–6 files of stomata per intercostal zone; a single interstomatal long cell between consecutive stomata; subsidiary cells dome-shaped or parallel-sided; interstomatal long cells rectangular, 2–3 times as long as wide, with undulating anticlinal walls and concave end walls. *Microhairs.* Located in central intercostal zone; 49–75 μm long, elongated, fingerlike, the basal cell equal to or up to twice as long as the distal cell, with parallel, thickened walls; distal cell with very thin walls, deciduous. *Macrohairs.* Located near the margins. *Hooks and prickles.* Not seen. *Papillae.* Present, associated with intercostal long cells, arranged so as to form a ring around each stomate. *Silica bodies.* Intercostal silica bodies tall and narrow, transversely elongated, irregular in outline or cross-shaped; costal silica bodies dumbbell-shaped, horizontally elongated.

*Adaxial epidermis in surface view* (Fig. 2C). Epidermal cells similar to the abaxial surface but with paired, isolated intercostal short cells; stomata not seen; hooks small, with a short barb, located in the intercostal zones near the margins; papillae absent.

*Leaf blade in transverse section* (Fig. 1E–H). *Outline.* Open, broadly V-shaped; arms of the lamina outwardly bowed, the two halves symmetrical on either side of the median vascular bundle; thickness at mid-lamina 60–130 μm (100–130 μm in *E. aristata* and 60–80 μm in *E. subaphylla*). *Ribs and furrows.* Adaxial ribs and furrows slightly developed and abaxial ribs and furrows indistinguishable in *E. aristata*; both adaxial and abaxial ribs and furrows indistinguishable in *E. subaphylla*. *Median vascular bundle.* Midrib with simple first-order vascular bundles distinguishable structurally from lateral first-order vascular bundles; adaxial projections slightly rounded, the abaxial projections not developed. *Vascular bundle arrangement.* Three first-order vascular bundles and 7–8 third-order vascular bundles in section; 5 third-order bundles; all vascular bundles centrally located in the blade in *E. subaphylla* and slightly abaxially located in *E. aristata*. *Vascular bundle description.* First-order vascular bundles circular in outline, the phloem adjoining the inner bundle sheath; metaxylem vessels narrower than the outer bundle sheath cells as seen in section; third-order vascular bundles angular or circular in outline, the xylem and phloem indistinguishable. *Vascular bundle sheath.* Outer bundle sheath of the first-order vascular bundles rounded, with 6–9 inflated, rounded or slightly elliptical cells, without extensions, with abaxial, sometimes adaxial, sclerenchyma girders; without extensions; inner bundle sheath present, complete. Outer bundle sheath of the third-order vascular bundles rounded, with abaxial, sometimes adaxial, interruptions, without extensions, consisting of 5–7 rounded or elliptical cells; inner bundle sheath absent or present, when present with a few cells abaxially. *Sclerenchyma.* Small adaxial and abaxial girders associated with all vascular bundles, 1–3 cells deep adaxially in *E. subaphylla* and 5–10 cells deep in *E. aristata*; fibers lignified; small sclerenchyma cap at the margins. *Mesophyll.* Chlorenchyma not radiate, with ad-

axial chlorenchyma in palisadelike arrangement (*E. aristata*) or not (*E. subaphylla*), with conspicuous air spaces; arm cells present but with invaginations relatively shallow, especially in *E. subaphylla*; 9–14 chlorenchyma cells present between consecutive vascular bundles, which are spaced 100–210 μm apart; fusoid cells and colorless cells absent. *Adaxial epidermal cells.* A fan-shaped cluster of 3–6 well-developed bulliform cells present between each pair of vascular bundles, the central cell very large and inflated, occupying up to ½ of the blade thickness; epidermal cells small and regular in size in *E. subaphylla*, large and inflated in *E. aristata*; macrohairs absent in *E. aristata*, absent or present in *E. subaphylla*, when present located between the vascular bundles or above them and with a bulbous, nonconstricted base; prickles present, opposite to the vascular bundles; hooks present between vascular bundles; papillae absent. *Abaxial epidermal cells.* Bulliform cells absent; epidermal cells very large, very regular in size and shape, with a continuous cuticle; macrohairs similar to the ones of the adaxial epidermis; prickles and hooks varying considerably in their distribution; papillae one per cell, rather wide, with a bi- or multi-furcated apex.

*Abaxial epidermis in surface view* (Fig. 2F, H). *Zonation.* Costal and intercostal zones distinguishable; costal zones 1–4 cells wide, the intercostal zones 13–22 cells wide. *Intercostal long cells.* In files, usually separated by paired short cells; elongated, rectangular, more than 5 times as long as wide; side walls parallel; end walls vertical; anticlinal walls undulating. *Intercostal short cells.* In silica-suberose pairs; tall, elongated, vertical; cork cells with crenate walls. *Stomatal complex.* 19–26 μm long, 19–22 μm wide, with 4–6 files of stomata per intercostal zone; a single interstomatal cell between consecutive stomates; subsidiary cells dome-shaped, triangular or parallel-sided; interstomatal long cells rectangular, with undulating anticlinal walls and concave end walls. *Microhairs.* Located in central intercostal zones; 49–59 μm long, fingerlike in *E. subaphylla* and slightly clavate in *A. aristata*; basal cell 2–3 times longer than distal cell, with thickened and parallel walls in *E. subaphylla* but with thin walls and inflated in *E. aristata*; distal cells short, with very thin walls, deciduous. *Macrohairs.* Absent in *E. aristata*; absent or present in *E. subaphylla*, when present unicellular, hard, and with a sunken base embedded in the epidermal cells. *Hooks and prickles.* Irregularly distributed and few in number. *Papillae.* Located in both the costal and intercostal zones over both long and short cells, arranged in a single horizontal row and overarching the stomates; large, more than ½ the vertical width of the long cells, with bifurcating apices. *Silica bodies.* Intercostal silica bodies tall, elongated vertically, irregular in outline, occasionally cross- or dumbbell-shaped; costal silica bodies dumbbell-shaped, horizontally elongated in *E. subaphylla* and slightly cross-shaped in *E. aristata.*

*Adaxial epidermis in surface view* (Fig. 2G). Adaxial epidermal cells similar to the ones of the abaxial surface but without papillae and isolated stomata; costal silica bodies dumbbell-shaped in *E. aristata.*

## Discussion

*Mniochloa* and *Piresiella* are $C_3$ plants with nonradiate mesophyll, parenchyma cells without specialized chloroplasts, and adjacent vascular bundles separated by more than three chlorenchyma cells. These anatomical characters are in agreement with data previously presented by Brown (1977) concerning the $^{13}C/^{12}C$ ratio for *Piresiella* (as *Mniochloa strephioides*). Anatomically, bamboos have been characterized by their possession of arm cells and fusoid cells in the mesophyll (Metcalfe, 1960; Renvoize, 1985; Soderstrom & Ellis, 1987). Both *Mniochloa* and *Piresiella* have arm cells whose walls have shallow invaginations (Fig. 1B, D). *Piresiella* has long, narrow fusoid cells on both sides of the vascular bundles, in agreement with data presented by Renvoize (1985) and Watson & Dallwitz (1988, 1992), whereas *M. pulchella* lacks fusoids. In olyroid bamboo genera the absence of fusoid cells has been previously noted in *Ekmanochloa* and *Raddiella* Swallen (Calderón & Soderstrom, 1967; Renvoize, 1985; Watson & Dallwitz, 1988, 1992); and fusoids also appear to be absent from the leaf blades of *Parodiolyra ramossisima* (Trin.) Soderstrom & Zuloaga. Soderstrom & Ellis (1987) characterized the Olyreae as having a midrib with a first-order vascular bundle associated with an adaxial projection: in *Mniochloa* and *Piresiella* the midnerve is represented by a midrib with a solitary first-order vascular bundle and the adaxial projection is absent in *Mniochloa* and only slightly pronounced in *Piresiella.*

The epidermides of *Mniochloa* and *Piresiella* are typical of the Olyreae, having rectangular long cells with undulating walls and silica bodies of the typical olyroid type. The abaxial epidermis of *Mniochloa* has solitary short cells that are suberose and transversely elongated with crenate walls. *Piresiella* has an abaxial epidermis with pairs of silica-

suberose short cells having silica bodies of the typical olyroid type. The costal silica bodies in both genera are of the short-saddle-shaped type common in the tribe. Epidermal papillae are frequent in the Olyreae (Calderón & Soderstrom, 1967; Renvoize, 1985; Soderstrom & Ellis, 1987). *Mniochloa* has small, simple papillae distributed in longitudinal files associated with long and short cells on both epidermides and also bordering the stomatal apparatuses. Watson & Dallwitz (1988), in their description of *Mniochloa* (without citing a voucher or the species studied), noted the absence of fusoid cells; this is an obvious reference to *Mniochloa pulchella*, whereas their observation of the presence of papillae only in the vicinity of the stomates must pertain to *Piresiella strephioides*. *Piresiella* possesses small, simple papillae only on the abaxial surface concentrated in the vicinity of, and slightly overarching, the stomates. The presence of papillae restricted to the stomatal area has also been noted in the Olyreae in *Reitzia* Swallen (Calderón & Soderstrom, 1967).

*Ekmanochloa* includes $C_3$ species with nonradiate mesophyll, with cells of the outer bundle sheath lacking specialized chloroplasts, and with more than three cells between adjacent vascular bundles. In transverse section the mesophyll has chlorenchyma cells with invaginated walls, as is characteristic of the bamboos. However, fusoid cells are absent from the mesophyll, in agreement with the reports of Calderón & Soderstrom (1967), Renvoize (1985), and Watson & Dallwitz (1988, 1992). The epidermis of *Ekmanochloa* is typical of herbaceous bamboos, having rectangular long cells with undulating walls, short cells in silico-suberose pairs, and the cork cells vertically elongated with crenate walls. The silica bodies are saddle-shaped, although in *E. aristata* the costal silica bodies are slightly cruciform. The presence of cross-shaped costal silica bodies has been previously noted in *Piresia* (Calderón & Soderstrom, 1967) and in *Piresia* and *Rehia* Fijten (Watson & Dallwitz, 1988, 1992). Calderón & Soderstrom (1967) noted in *Ekmanochloa* the presence of costal silica bodies with transitional forms to silica bodies more typical of those of the Oryzeae; in the present study these transitional forms were not observed. The presence of large, compound papillae on the abaxial epidermis, distributed in a file among the long and short cells and overarching the stomatal apparatus, is characteristic of *Ekmanochloa*. The presence of compound papillae in the Olyreae has otherwise been noted only in *Piresia* (Calderón & Soderstrom, 1967) and, perhaps more weakly so, in *Maclurolyra* Calderón & Soderstrom (Calderón & Soderstrom, 1973; Renvoize, 1985).

The two species of *Ekmanochloa* have bicellular microhairs with quite different morphologies. In *E. aristata* the microhairs (barely visible in Fig. 2H) are claviform or obconic, with the walls of the basal cell not parallel, and the distal cell very short in relation to the basal cell. In *E. subaphylla* (Fig. 2F) the microhairs are narrow, fingerlike, and have the distal cell only slightly shorter than the basal cell, as in most olyroids. In comparison to *E. subaphylla*, in transverse section the blades of *E. aristata* are narrower, and the vascular bundles are slightly displaced toward the abaxial epidermis and associated with deep columns of sclerenchyma cells.

## Taxonomic Treatment

**Mniochloa** Chase, Proc. Biol. Soc. Wash. 21: 185. 1908. TYPE: *Mniochloa pulchella* (Griseb.) Chase (designated by Chase, 1908).

Delicate, tufted, monoecious perennial from small corms. Culms weak, straggling, dimorphic (vegetative and leafless flowering). Vegetative culms with several fully developed leaves per complement; ligules inconspicuous; pseudopetioles short; blades elliptical, symmetrical to slightly asymmetrical. Flowering culms erect, usually much exceeding the leaves, with only bladeless sheaths. Racemes 2, conjugate, erect, appressed, subequal, unisexual. Female racemes slightly longer than the male racemes, with several spikelets on short, slightly clavate pedicels. Female spikelets 1-flowered, narrowly ellipsoidal, falling entire; glumes delicately membranous, distinctly shorter than the floret, ovate-elliptical, 3-nerved, glabrous, obtuse to acute, the margins scabrous, the lower glume slightly shorter than the upper; internode between upper glume and floret inconspicuous; floret fusoid to narrowly ellipsoid, acute to obtuse, membranous, glabrous, pale; lemma 3-nerved; palea about as long as the lemma; lodicules 3, small; gynoecium not seen. Male racemes with several spikelets on short, slightly clavate pedicels. Male spikelets 1-flowered, much shorter than the female spikelets, lacking glumes, ellipsoid, acute; lemma 1-nerved; palea 2-nerved, with apex obtuse; stamens 3. Caryopsis fusoid; hilum linear, extending nearly the full length of the caryopsis, from slightly above the base to nearly the apex; embryo small, basal. Chromosome number unknown.

*Distribution.* A monotypic genus of limestone cliffs in lowland Oriente, Cuba.

**Mniochloa pulchella** (Griseb.) Chase, Proc. Biol. Soc. Wash. 21: 186, pl. 4. 1908. *Digitaria pulchella* Griseb., Cat. Pl. Cub. 231. 1866.

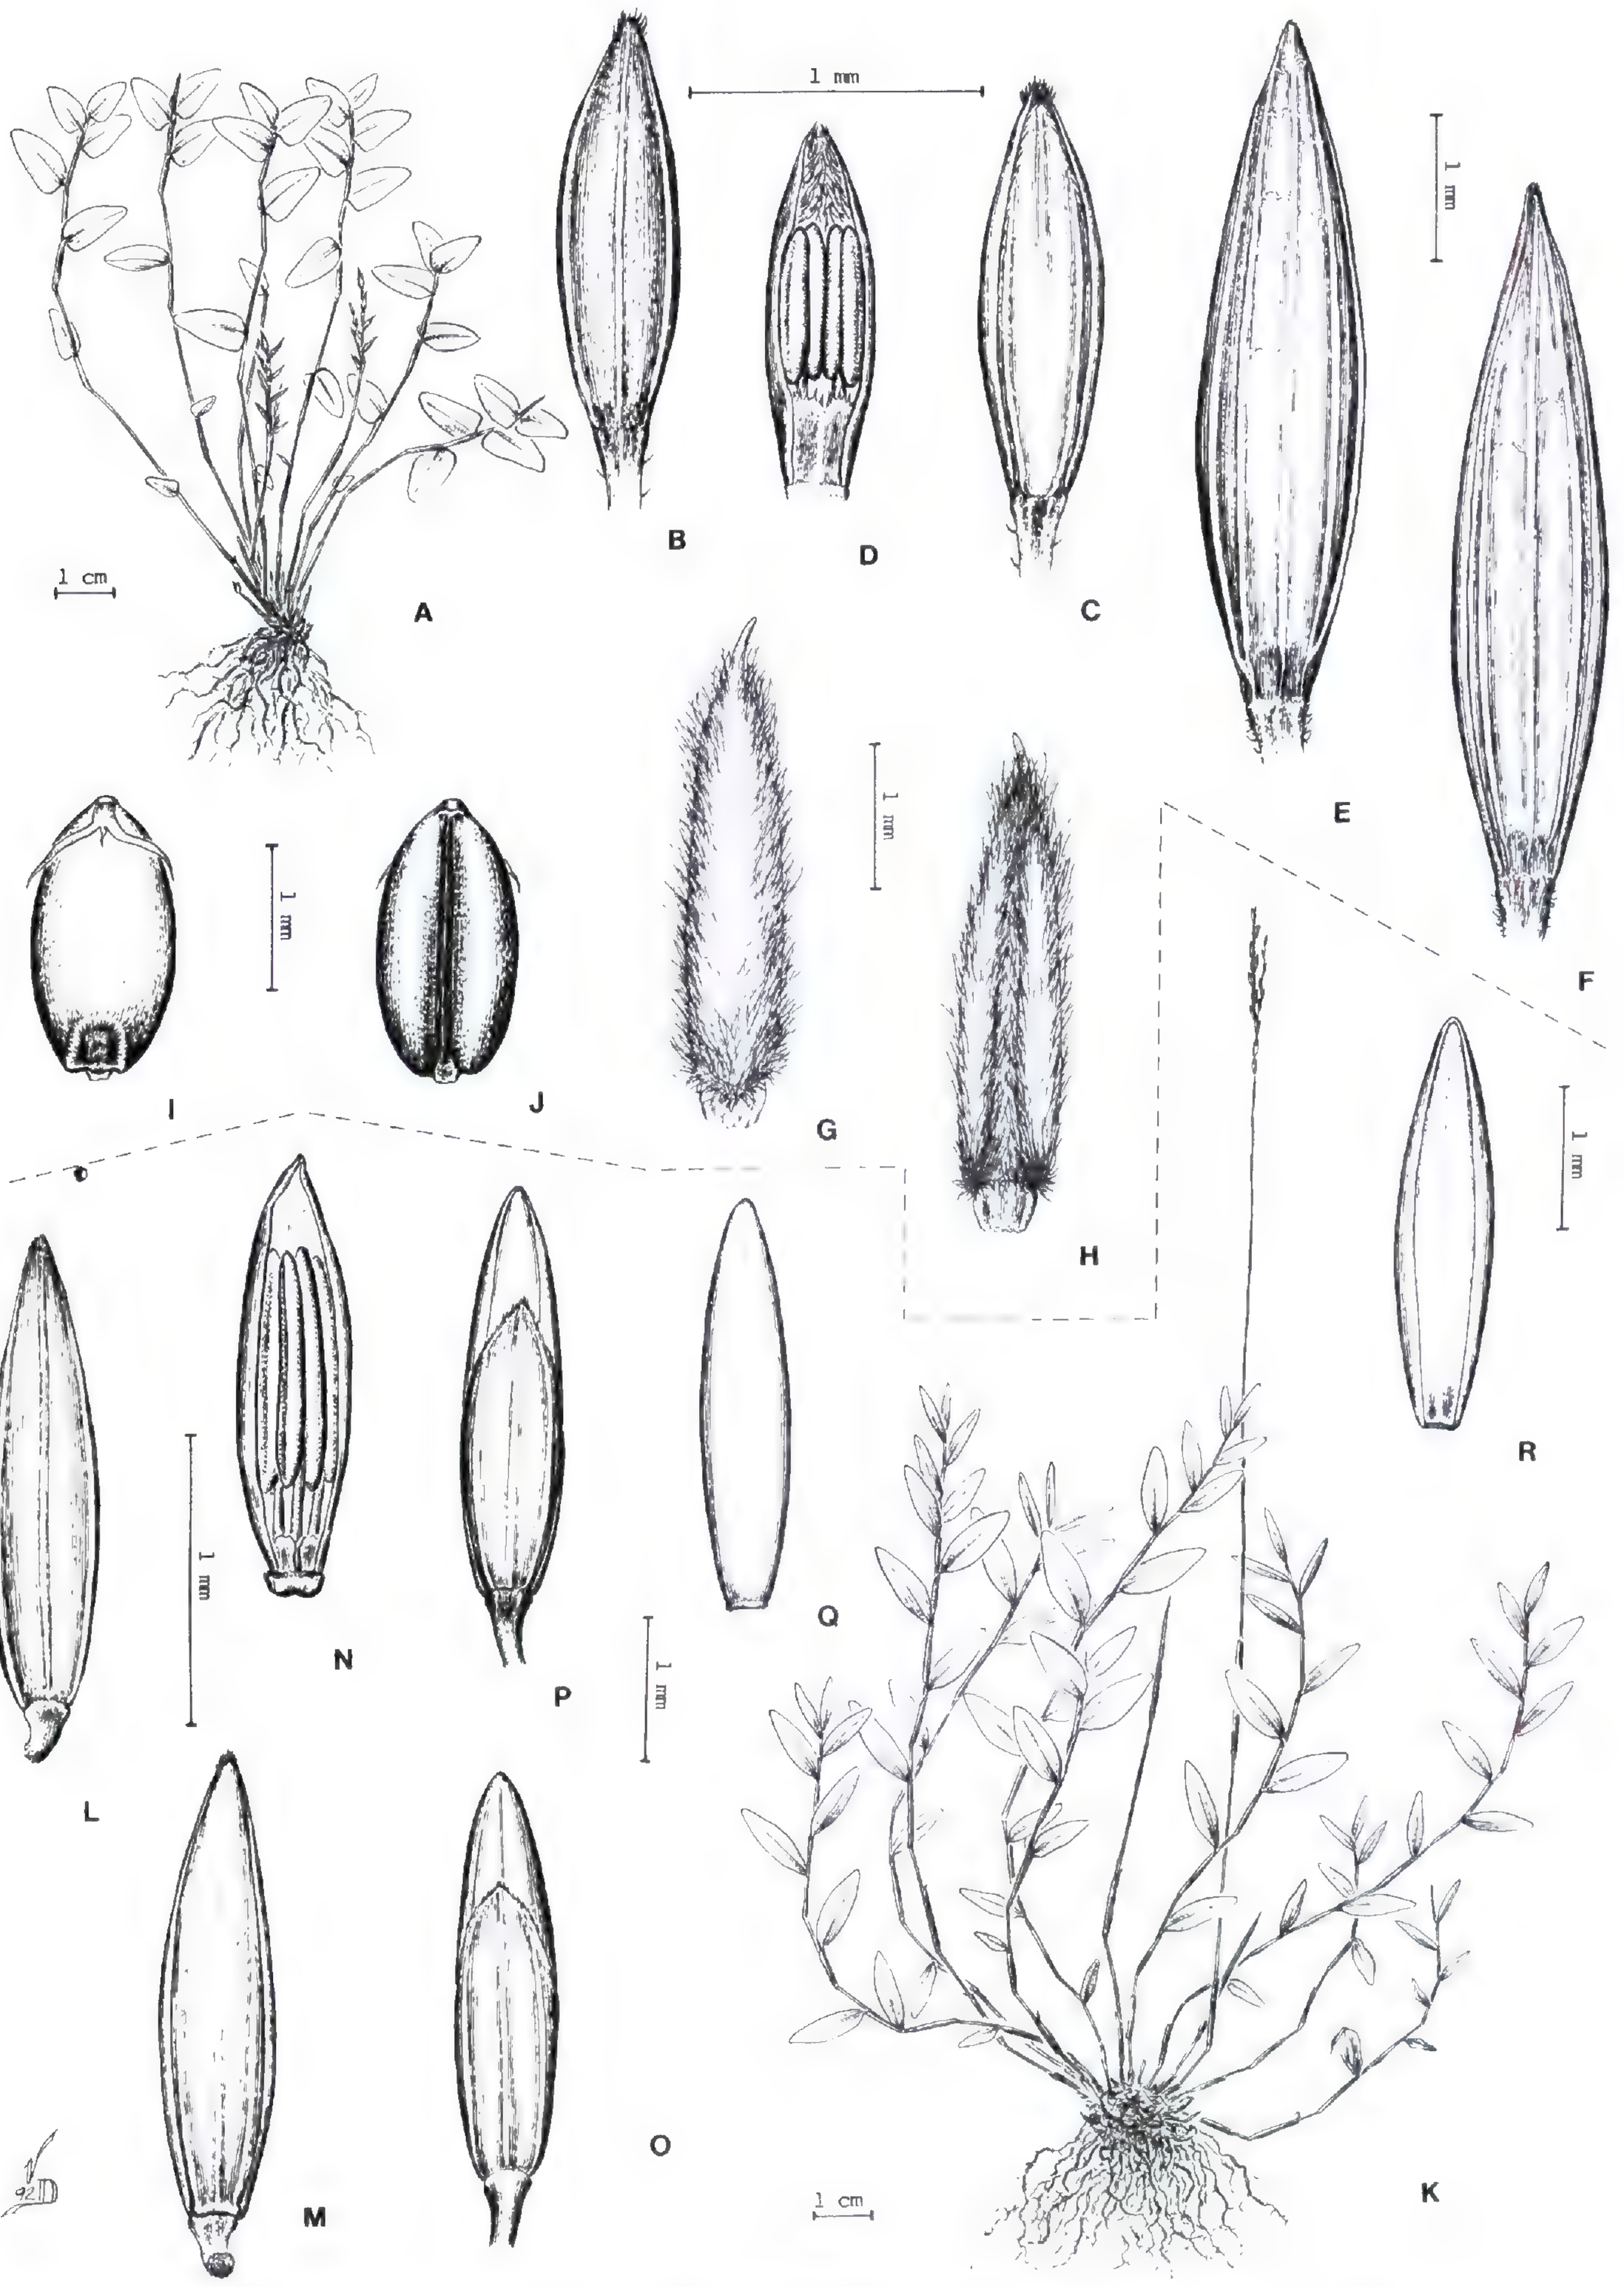

FIGURE 3. A–J, *Piresiella strephioides* (Griseb.) Judziewicz, Zuloaga, & Morrone (A, I–J from *León 4572*; B H from *Wright 3435*).—A. Habit. B–D, male spikelet: B. Lemma view.—C. Palea view. D. O–R, female spikelet:—O. Upper glume view.—P. Lower glume view. Q. Floret, lemma view.—R. Floret, palea view.

*Strephium pulchellum* (Griseb.) C. Wright, Anales Acad. Ci. Méd. Habana 8: 202. 1871. TYPE: Cuba. Oriente: Yunque de Baracoa, on vertical cliffs, 8 June 1856, *C. Wright 3448** (holotype, GOET not seen; isotypes, GH, MO). Figure 3K–R.

Corms 1.5–2.5 mm diam. Vegetative culms 3–12 cm tall, 3–9 leaves per complement; sheaths 2.5–7 mm long, usually shorter than the internodes, slightly inflated, 5–7-nerved, glabrous to pubescent, the truncate summit with a few delicate marginal cilia; ligules a hyaline, lacerate, ciliate membrane 0.1 mm long; pseudopetioles 0.1–0.4 mm long, glabrous, yellowish to brownish; blades 7–15 mm long, 2–4 mm wide, obtuse and weakly apiculate at the apex, both surfaces pubescent throughout with short, appressed hairs, less commonly nearly glabrous, or the adaxial surface often with ca. 1-mm-long, straggling hairs. Flowering culms 7–20 cm long, with 1–2 bladeless sheaths; peduncle filiform, glabrous. Racemes with the rachises slender, slightly flexuous, glabrous, scaberulous. Female inflorescences 0.8–3 cm long, with (4–)8–13 spikelets on pedicels 0.2–0.5 mm long. Female spikelets 2.2–2.8 mm long; glumes greenish, ovate-elliptical, the lower 1.7–1.9 mm long, the upper 2–2.2 mm long; floret as long as spikelet; lodicules 0.2–0.3 mm long, flabellate, hyaline. Male inflorescences 0.5–2.3 cm long, with (3–)7–12 spikelets; pedicels ca. 0.2 mm long, dark-colored. Male spikelets 1.3–1.7 mm long; anthers 0.8–1 mm long, fusoid, orangish yellow when dry. Caryopsis 1.5–2 mm long, 0.5–0.6 mm wide; embryo ca. 0.4 mm long.

*Phenology.* Apparently flowering in March, June, and December.

*Distribution.* Known only from limestone cliffs in lowland Oriente, Cuba; according to L. Catasús Guerra (17 May 1982 letter to T. R. Soderstrom), the most recent collection in the HAC herbarium was made in 1960.

*Additional material examined.* CUBA. **Oriente:** Baracoa, El Yunque, on steep, shady limestone rocks, very rare, 17–18 Dec. 1914, *Ekman 3916** (US); Sierra de Moa, Cayoguán, in crevices of rocks, 30 Mar. 1942, *León 20898* (US).

**Piresiella** Judziewicz, Zuloaga, & Morrone, gen. nov. TYPE: *Piresiella strephioides* (Griseb.) Judziewicz, Zuloaga & Morrone (= *Olyra strephioides* Griseb.).

Gramina perennia humilia caespitosa. Culmi dimorphi, floriferi laxi, decumbentes, circa dimidis culmorum vegetativorum statura. Racemi bini, ascendentes, adpressi, inaequales, unisexuales. Spiculae femineae ovoideae deciduae aut glumae deciduae poster. Glumae pariter longae ac spicula; internodium inter glumam superiorem et flosculum prominens; flosculus glumis minor, albidus, tenuis, pilis adpressis, albis, sericeis, ornatus; lemma apiculatum vel cucullatum. Spiculae masculae minores foemineis glumis expertes.

Delicate, caespitose, monoecious perennials from small corms, with delicate, elongate stolons. Culms dimorphic, either vegetative or (leafless) flowering. Vegetative culms with several fully developed leaves per complement, these all near the apex; ligules minute, membranous; pseudopetioles short; blades ovate-triangular, truncate and strongly asymmetrical at the base, acute at the apex. Flowering culms lax, decumbent, about one-half as tall as the vegetative culms. Inflorescences terminal, exerted, consisting of 2 conjugate, ascending, appressed, subequal unisexual racemes. Female racemes with narrow rachises and few spikelets. Female spikelets 1-flowered, ovoid, falling entire or the glumes tardily deciduous; glumes as long as spikelet, subequal, narrowly ovate, acute to acuminate, chartaceous, 3(–5)-nerved, sulcate, glabrous; internode between upper glume and floret prominent; floret membranous, shorter than the glumes, whitish, covered with delicate, appressed, white, silky hairs; lemma and palea equal, the lemma apex apiculate or cucullate, not evidently nerved, the margins enfolding the palea; palea 2-keeled; lodicules 3, small; gynoecium with 3 stigmas. Male racemes slightly shorter than the female racemes, with slender rachises and few spikelets on short pedicels. Male spikelets 1-flowered, shorter than female spikelets, ellipsoid, glabrous, persistent, lacking glumes; lemma as long as spikelet, lanceolate-ovate; palea nearly as long as lemma; stamens 2. Caryopsis broadly ellipsoid; hilum linear, extending the full length of the caryopsis; embryo small, basal. Chromosome number unknown.

*Distribution.* A monotypic genus of ravines, palm savannas, and streambanks in lowland Habana and Pinar del Río, Cuba.

*Discussion.* This new genus shares with *Mniochloa*, *Ekmanochloa*, *Piresia*, and some species of *Cryptochloa*, *Olyra*, and *Pariana* Fusée-Aublet inflorescences on separate culms that lack fully developed leaves. It differs from all of these genera except *Mniochloa* and one species of *Ekmanochloa* in its conjugate, unisexual racemes and spikelets with two rather than three or more stamens.

*Piresiella* differs from *Mniochloa* by eight morphological and three anatomical characters given in Table 1.

The stipe of the female floret in *Piresiella* resembles elaiosomes; these have been confirmed in *Olyra obliquifolia* Steudel, *O. fasciculata* Trin., and all species of *Cryptochloa* (Davidse, 1987). This elaiosomelike resemblance is suspected in other genera such as *Froesiochloa* G. A. Black and the non-olyroid herbaceous bamboos *Anomochloa marantoidea* Brongn. and *Puelia* Franchet.

The generic name is a diminutive of *Piresia* and was suggested by the superficial resemblance (Table 2) to a small species of that genus. *Piresiella* rivals *Raddiella minima* Judziewicz & Zuloaga as the smallest of all the bambusoid grasses; some individuals with mature inflorescences have vegetative culms only 5 cm tall, with flowering culms 3 cm long.

**Piresiella strephioides** (Griseb.) Judziewicz, Zuloaga & Morrone, comb. nov. Basionym: *Olyra strephioides* Griseb., Cat. Pl. Cub. 229. 1866. *Mniochloa strephioides* (Griseb.) Chase, Proc. Biol. Soc. Wash. 21: 186. 1908. TYPE: Cuba. Pinar del Río: Río Santa burk [? spelling of last word uncertain], among the adventitious roots of palms, river margin, 27 Aug.–5 Sep. 1865, *C. Wright 3435* (holotype, GOET not seen, fragment, US; isotypes, GH, HAC not seen, MO, NY, US). Figure 3A–J.

Corms 1–2 mm diam.; stolons up to 20 cm. Vegetative shoots (7–)10–18 cm tall, with 3–7 leaves per complement; internodes pubescent in a line, otherwise glabrous; nodes often swollen, geniculate, slightly retrorsely bearded, shrinking when dry to produce a double flange; sheaths glabrous except pubescent on one margin and with a fringe of fine, excelsiorlike cilia at the summit; ligules 0.1 mm long, membranous, ciliolate; pseudopetioles 0.2–0.6 mm long, tan, glabrous; blades 14–20 mm long, 6–10 mm wide, glabrous to puberulent on both surfaces. Flowering culms each with a single bladeless sheath, this glabrous except for one pubescent margin. Racemes with the rachises slender, angled, scabrous, slightly flexuous, glabrous to pubescent. Female inflorescenes 1.5–3 cm long, with 6–9 spikelets on pedicels 0.2–0.6 mm long; rachises 0.2–0.3 mm wide. Female spikelets 4–4.8 mm long; glumes greenish or whitish (sometimes with purplish apices), with a few faint cross-nerves, spreading up to 180° at maturity; internode between upper glume and floret 0.3–0.5 mm long; floret 3–3.5 mm long, whitish; lodicules 0.7–0.8 mm long, truncate. Male racemes with the rachis ca. 0.1 mm wide, bearing 6–8 spikelets on pedicels 0.3–1.5 mm long (longest at the base of the raceme). Male spikelets 1.3–1.8 mm long; anthers 0.5–0.7 mm long, yellowish orange when dry. Caryopsis 2 mm long, 0.8 mm wide; embryo 0.2–0.3 mm long.

*Phenology.* Apparently flowering from July through November.

*Distribution.* Palm savannas, ravines, and streambanks in lowland Habana and Pinar del Río, Cuba; reported by L. Catasús Guerra as having been collected by him as recently as 1974 (17 May 1982 letter to T. R. Soderstrom).

*Additional material examined.* CUBA. **Habana:** Loma de Coca, locis perumbrosis, 2 June 1914, *Ekman 1238* (US); banks of Río Guanabo, near Campo Florida, 10 Oct. 1943, *León 4140* (US). **Pinar del Río:** hills W of Cayajabos, in forest, 25 June 1921, *Ekman 12945* (US); Cabaños, Guabal de Lechuza, 2 July 1921, *Ekman s.n., Amer. Gr. Nat. Herb. 1029** (US); first range of hills 13 km NW of Pinar del Río, 26 Nov. 1926 (sterile), *Hitchcock 23310* (US); N of San Diego de los Baños, banks of an arroyo, 18 Aug. 1914, *León & Hiram 4391* (US); ravine near La Guira, not far from San Diego de los Baños, 26 Aug. 1914, *León 4572** (US); not far from San Diego de los Baños, banks of a rivulet, at the base of a palm, 21 Aug. 1914, *León 4593* (US).

**Ekmanochloa** Hitchc., Man. Grasses W. Ind. 374. 1936. TYPE: *Ekmanochloa subaphylla* Hitchc. (designated by Hitchcock, 1936).

Caespitose, short rhizomatous, monoecious perennials from small corms. Culms erect, simple, dimorphic. Vegetative culms with 3–6 fully developed leaves per complement. Sheaths striate, glabrous or pilose in the distal portion; ligules membranous, small; pseudopetioles short; blades linear-lanceolate, flat, glabrous or short-pilose, deciduous. Flowering culms with 2–3 bladeless leaves. Inflorescence terminal, exerted, consisting of 2 conjugate, erect, appressed, subequal unisexual racemes with filiform, slightly flexuous, glabrous, smooth rachises. Female racemes slightly longer than the male racemes, of 3–5 spikelets on clavate pedicels; male inflorescences of 3–12 spikelets on slightly clavate pedicels. Female spikelets 1-flowered, narrowly ellipsoid; glumes shorter than to as long as the floret, glabrous to sparsely pilose, the lower 5-nerved, the upper 3-nerved; internode between upper glume and floret short or up to 0.5 mm, pilose; floret fusiform, membranous, obliquely inserted above the glumes, early deciduous; lemma aristate, 3–5-nerved; palea 2-nerved, the apex not enfolded by the lemma; lodicules 3, flabellate, hy-

aline; gynoecium oblong, with 2 free styles. Male racemes of 3–12 spikelets on slightly clavate pedicels. Male spikelets 1-flowered, ellipsoid, hyaline, lacking glumes; lemma 3-nerved; palea 2-nerved; lodicules 3, hyaline; stamens 2–3. Caryopsis fusiform; hilum extending the full length of the ventral side; embryo small. Chromosome number unknown.

*Distribution.* A genus of two species endemic to ultramafic (serpentine) areas in lowland Oriente, Cuba.

*Discussion.* *Ekmanochloa* differs from most of the Olyreae in the following: (1) absence of fusoid cells (but these are also lacking in some species of *Raddiella* and *Mniochloa*); (2) presence of strongly compound papillae on the abaxial epidermis (these also present in *Piresia* and *Rehia*, but not so strongly developed); (3) deciduous leaf blades; and (4) prominently long-awned female lemmas (lemma awns are found elsewhere in the tribe only in *Agnesia* Zuloaga & Judziewicz (1993) and *Piresiella*, where they are very short and may more properly be termed apiculi).

*Ekmanochloa* also shares some characters with the doubtfully olyroid, monotypic *Buergersiochloa* Pilger of New Guinea: both of these taxa have long-awned female florets, compound epidermal papillae, and dimorphic culms. However, both have many significant morphological and anatomical differences, and it does not seem likely that they are closely related.

When both species of *Ekmanochloa* are compared with other members of the Olyreae, it appears that *E. subaphylla* is more specialized than *E. aristata*. Besides its specialized limestone cliff habitat, *E. subaphylla* differs from *E. aristata* in its two rather than three stamens; very short, emarginate rather than long and entire female glumes; leaf blades with a less well-developed adaxial palisadelike chlorenchyma layer; and slightly less well-developed arm cells. Furthermore, Clayton & Renvoize (1986) noted that the leaf blades of *E. subaphylla* are more likely to be more completely suppressed than those of *E. aristata*. Another specialized feature present in *E. aristata* is microhairs with a distinctive squat, obconic basal cell. *Ekmanochloa subaphylla* has fingerlike, typically olyroid bicellular microhairs.

KEY TO THE SPECIES OF *EKMANOCHLOA*

1a. Female spikelets with glumes about as long as the body of the floret, sparsely pilose; lemma with an awn 16–18 mm long; male inflorescence with 3–4 short-pilose spikelets 2.7–3.3 mm long; stamens 3 ..... 1. *E. aristata*

1b. Female spikelets with glumes much shorter than the body of the floret, glabrous; lemma with an awn 5–10 mm long; male inflorescence with 6–12 glabrous spikelets 1.7–2.3 mm long; stamens 2 ..... 2. *E. subaphylla*

**1. Ekmanochloa aristata** Hitchc., Man. Grasses W. Ind. 377. 1936. TYPE: Cuba. Oriente: between Taco and Nibujón, in carrascales-pinales, very rare, 4 Dec. 1914, *E. L. Ekman 3729** (holotype, US; isotype, S not seen). Figure 4A–F.

Short-rhizomatous perennial. Vegetative culms 30–50 cm tall, erect, unbranched, with 3–5 fully developed leaves per complement. Leaves with sheaths 1–4 cm long, shorter than the internodes, the margins overlapping, membranous, ciliate toward the apex, otherwise glabrous; ligules 0.1–0.2 mm long, laciniate at the apex; pseudopetioles 0.3–0.6 mm long, brownish, glabrous to short-pilose; blades apparently early deciduous, 8–55 mm long, 2–4 mm wide, linear-lanceolate, narrowed and slightly asymmetrical at the base, acute at the apex, glabrous, the margins smooth, glabrous. Flowering culms 20–50 cm tall, erect, usually exceeding the vegetative culms, unbranched, with two bladeless leaves present; peduncle up to 25 cm long, filiform, glabrous. Female inflorescence 15–20 mm long, with 3–5 spikelets at a distance of 4–8 mm from each other; pedicels clavate, 3.3–5 mm long, smooth, glabrous. Female spikelets 6–9 mm long, 0.9 mm wide; glumes as long as the body of the floret, subequal, membranous, sparsely pilose with appressed hairs; internode between upper glume and floret short, pilose; floret 5–7 mm long (excluding awn), 0.6 mm wide, fusiform, acute, scaberulous, pale; lemma 3-nerved, with an awn 16–18 mm long; palea shorter than the lemma; lodicules 0.5–0.7 mm long, brownish, apically laciniate. Male inflorescence 10–15 mm long, with 3–4 spikelets; pedicels 0.6–2.5 mm long, smooth, glabrous. Male spikelets 2.7–3.3 mm long, 0.5 mm wide, acute, sparsely pilose with short, appressed hairs between the nerves; lodicules 0.5 mm long, brownish; stamens 3, the anthers 0.8 mm long. Caryopsis 4.2 mm long, fusoid, brown, the embryo ca. 0.6 mm long.

*Phenology.* Apparently flowering in March, June, and December.

*Distribution.* Rare in pine savannas in lowland Oriente, Cuba; last collected in 1945 (L. Ca-

*Additional material examined.* CUBA. **Oriente:** Pineland not far from Moa airport, 26 June 1945, *Clement & Chrysogone 4563** (US); valley of the Río Cayoguán, near the mines, Moa, 30 Mar. 1942, *León et al. 20901* (US).

**2. Ekmanochloa subaphylla** Hitchc., Man. Grasses W. Ind. 375. 1936. TYPE: Cuba. Oriente: Sierra de Nipe, Loma Picote, on overhanging limestone rocks, 500 m, 2 Nov. 1922, *E. L. Ekman 9870* (= *Amer. Gr. Nat. Herb. 1016*) (holotype, US; isotype, US). Figure 4G–L.

Tufted perennial. Vegetative culms 50–100 cm long (the erect portion shorter), erect or geniculate at the base, unbranched, with 4–6 fully developed leaves per complement. Leaves with sheaths 0.7–2 cm long, shorter than the internodes, the margins overlapping, membranous, glabrous; ligule 0.2 mm long, laciniate at the apex; pseudopetioles 0.6–1 mm long, pale to brownish, short-pilose; blades apparently early deciduous, 10–35 mm long, 1–4 mm wide, cuneate at the base, obtuse to subacute at the apex, shortly pilose to glabrous, the margins scaberulous toward the base, otherwise smooth and glabrous. Flowering culms 33–60 cm tall, erect, usually exceeding the vegetative culms, unbranched, with 2–3 bladeless leaves; peduncle 20–30 cm long, filiform, glabrous. Female inflorescence 30–40 mm long, with 3–5 spikelets at a distance of 4–6 mm from each other; pedicels 7–12 mm long, smooth, glabrous. Female spikelets 6–6.6 mm long, 0.9 mm wide; glumes much shorter than the body of the floret, unequal, membranous, glabrous, with obtuse, truncate, or emarginate or denticulate apices; lower glume 1–2.1 mm long, the upper 2.1–4.2 mm long; internode between upper glume and floret ca. 0.5 mm long, pilose; floret as long as the spikelet, 0.6 mm wide, acute, scabrous, pale to brownish; lemma 5-nerved, with an awn 5–10 mm long; palea shorter than the lemma, greenish; lodicules 0.4 mm long. Male inflorescence 17–23 mm long, with 6–12 spikelets; pedicels ca. 0.4 mm long, smooth or scaberulous, glabrous. Male spikelets 1.7–2.3 mm long, 0.5 mm wide, ellipsoid, subacute, glabrous, greenish; lodicules 0.2 mm long, brownish; stamens 2, the anthers 1.2 mm long. Caryopsis not seen.

*Phenology.* Apparently flowering from October to November.

*Distribution.* Limestone cliffs in the Alto Songo region of Oriente, Cuba, at elevations up to 500 m; last collected in 1960 (L. Catasús Guerra, 17 May 1982 letter to T. R. Soderstrom).

*Additional material examined.* CUBA. **Oriente:** Sierra de Nipe, in limestone hills at Río Jimbambay, 13 Oct. 1919, *Ekman 9870** (same number as type collection, but different locality and date) (US).

# FENOLOGIA Y ESTRUCTURA FLORAL DE *TRICHILIA HAVANENSIS* JACQ. (MELIACEAE)[1]

*Delhy Albert Puentes,*[2] *Jesús Hernandez de Armas,*[2] y *Antonio López Almirall*[2]

## Resumen

Se realizó un estudio de fenología y estructura floral a la especie *Trichilia havanensis*. Se comprobó la dioecia de esta especie, a pesar de tener los órganos femeninos y masculinos en la misma flor. Un individuo que se había comportado como masculino durante los tres primeros años de observaciones fenológicas, fructificó posteriormente.

## Abstract

A phenological study carried out over 5 years is presented and flower morphology of *Trichilia havanensis* is given. Dioecy was confirmed in this species, despite the fact that female and male organs occur in the same flowers. A tree that behaved as male during the first 3 years of our phenological observations has fruited since 1988.

La dioecia es un fenómeno que ha sido estudiado por diferentes autores tales como Darwin (1877), Lewis (1941), Horovitz (1954). Estudios recientes han demostrado la presencia de especies dioicas que aparentan ser hermafroditas por tenor los órganos femeninos y masculinos en la misma flor.

Armstrong & Drummond (1986) señalaron que las flores estaminales y pistilares pueden adquirir aspecto similar para producir estímulo tanto visual como olfatorio al polinizador, sugiriendo que las flores pistiladas son probablemente miméticas de las flores estaminadas, mecanismo que ha sido clasificado por Little (1983) como decepción alimentaria por automimetismo. Otras hipótesis tratan de explicar la dioecia a partir del hermafroditismo; por ejemplo las de Arroyo & Raven (1975) quienes expresaron que el paso clave en la evolución de la dioecia es la reducción de los órganos femeninos en las plantas hermafroditas; y la de Lewis (1941) quien demostró la esporádica distribución de las especies dioicas en comparación con las familias hermafroditas (que se encuentran en todas partes), por lo que deduce que las especies dioicas han evolucionado a partir de representantes hermafroditas.

Luz de Armas (1985) en su estudio de las flores de *Chamissoa altissima* var. *altissima* expuso que ese taxon atravieza una fase evolutiva en la formación de una especie dioica, existiendo cuatro tipos florales en la misma. Las especies de la familia Meliaceae han sido consideradas como hermafroditas por numerosos botánicos, tales como Britton & Wilson (1923), Harms (1940), León & Alain (1951), y otros, debido a que aparentemente sus flores poseen los dos sexos.

Sin embargo, Styles (1972), de acuerdo con sus observaciones realizadas en el Suroeste y Centro de Africa, señaló que la mayoría de las especies de esta familia poseían flores unisexuales pero con rudimentos bien desarrollados del sexo no funcional. Años más tarde, este mismo autor resume el conocimiento adquirido hasta ese momento en cuanto a la biología floral de Meliaceae, lo cual fue utilizado por Pennington & Styles (1975, 1981) en el tratamiento taxonómico de la familia.

Nuestro trabajo tiene como objetivo dar a conocer los patrones de floración y fructificación de la especie *Trichilia havanensis* Jacq., perteneciente a la familia Meliaceae, en Cuba y ofrecer datos acerca de su estructura floral.

## Materiales y Metodos

Se realizaron observaciones fenológicas semanales durante cinco años (1985–1989) a 10 individuos de *Trichilia havanensis* localizados en el

[1] Queremos expresar nuestro agradecimiento al compañero Heriberto Rodriguez por la realización de los dibujos.
[2] Instituto de Ecología y Sistemática, Herbario, Academia de Ciencias de Cuba, Carretera de Varona K, 3½, Capdevile, Boyeros, Apartado 8010, Código Postal 10800, La Habana 8, CUBA.

Parque Metropolitano de La Habana. Este parque se encuentra situado a 23°6′N y a 82°26′O, presentando un suelo de rendzina negra (Obregón, com. pers.) y un bioclima termoxerochiménico con un periodo seco subhúmedo (Vilamajó et al., 1989). Los promedios mensuales de temperatura y las precipitaciones mensuales totales fueron tomadas del Instituto de Meteorología en la estación de Casa Blanca y con estos datos se confeccionaron los diagramas climáticos de Walter & Lieth (1960) (Fig. 1).

Las fenofases observadas fueron las siguientes:

Porcentaje de hojas
Botones (desde su aparición hasta la antesis)
Flores (desde el momento de la apertura hasta su desaparición)
Frutos (abarca todos los estadios de su desarrollo hasta la apertura)
Frutos abiertos (desde su apertura hasta que pierde las semillas)

Para la delimitación de las fenofases se empleó la metodología de Ramia (1981) y los datos fueron adaptados posteriormente a la escala de Fournier (1974) mediante el cual se establecen cinco rangos de aparición del caracter como sigue:

0 = ausencia del fenómeno observado
1 = presencia del fenómeno con una magnitud entre 1–25%
2 = presencia del fenómeno con una magnitud entre 26–50%
3 = presencia del fenómeno con una magnitud entre 51–75%
4 = presencia del fenómeno con una magnitud entre 76–100%

Para establecer los patrones de floración y fructificación de la especie, se compararon nuestros resultados con ejemplares localizados en los alrededores del Instituto de Ecología y Sistemática del Academia de Ciencias de Cuba, con observaciones de campo realizadas por nosotros en diferentes tipos de vegetación en la Provincia de Pinar del Río, y con 82 ejemplares de *T. havanensis* procedentes de diferentes localidades del país, ubicados en los herbarios de la Academia de Ciencias de Cuba (HAC) y Jardín Botánico Nacional (HAJB).

Para el estudio de la estructura floral, se tomaron 10 flores por cada árbol a las cuales se les midieron los siguientes indices:

A = longitud del tubo estaminal
B = longitud de la antera
C = longitud del ovario
D = ancho del ovario
E = longitud des estilo
F = longitud del estigma
G = longitud del pétalo
H = ancho del pétalo
I = longitud del disco nectarífero

TABLA 1. Relación de medias calculadas para las flores de *Trichilia havanensis*.

| Carácter | × general (mm) | × flores masculinas (mm) | × flores femeninas (mm) |
|---|---|---|---|
| A | 2.47 | 3.46 | 2.24 |
| B | 0.84 | 1.21 | 0.60 |
| C | 1.25 | 1.50 | 1.00 |
| D | 1.50 | 1.42 | 1.61 |
| E | 0.71 | 1.00 | 0.75 |
| F | 0.60 | 0.70 | 0.50 |
| G | 4.25 | 5.00 | 3.50 |
| H | 2.40 | 2.60 | 2.20 |
| I | 0.45 | 0.50 | 0.40 |

Con los datos obtenidos se confeccionaron los gráficos de Jentys-Szaferowa (1959). En este método se calculan previamente las medias aritméticas generales para cada carácter (de las plantas femeninas y masculinas tomadas como un todo) las cuales constituyen la linea unidad; posteriormente se grafican las diferencias de las medias de cada carácter con la media general (Tabla 1, Fig. 5).

Como caracteres cualitativos se observaron los tipos de apertura floral (completa o parcial) y la coloración de las anteras.

## RESULTADOS Y DISCUSION

Al analizar el porcentaje de hojas durante los cinco años observados, podemos ver que esta especie se comporta como siempreverde, ya que la pérdida en hojas no sobrepasa el 20% del total del follaje (Fig. 2).

La fenofase "botones" se ubica entre los meses de enero y marzo y "flores" a partir del mes de febrero, con un máximo en la segunda quincena de marzo, extendiendose hasta la primera semana de mayo (Fig. 2), de forma tal que puede catalogarse como una especie de floración tardía de acuerdo con la clasificación de Sarmiento & Monasterio (1983) y de floración corta según Ramirez & Brito (1987).

En los individuos más expuestos al sol se observó en todos los años mayor porcentaje de flores que en los que se encuentran en lugares mas sombreados.

En la Figura 3 están representados los promedios

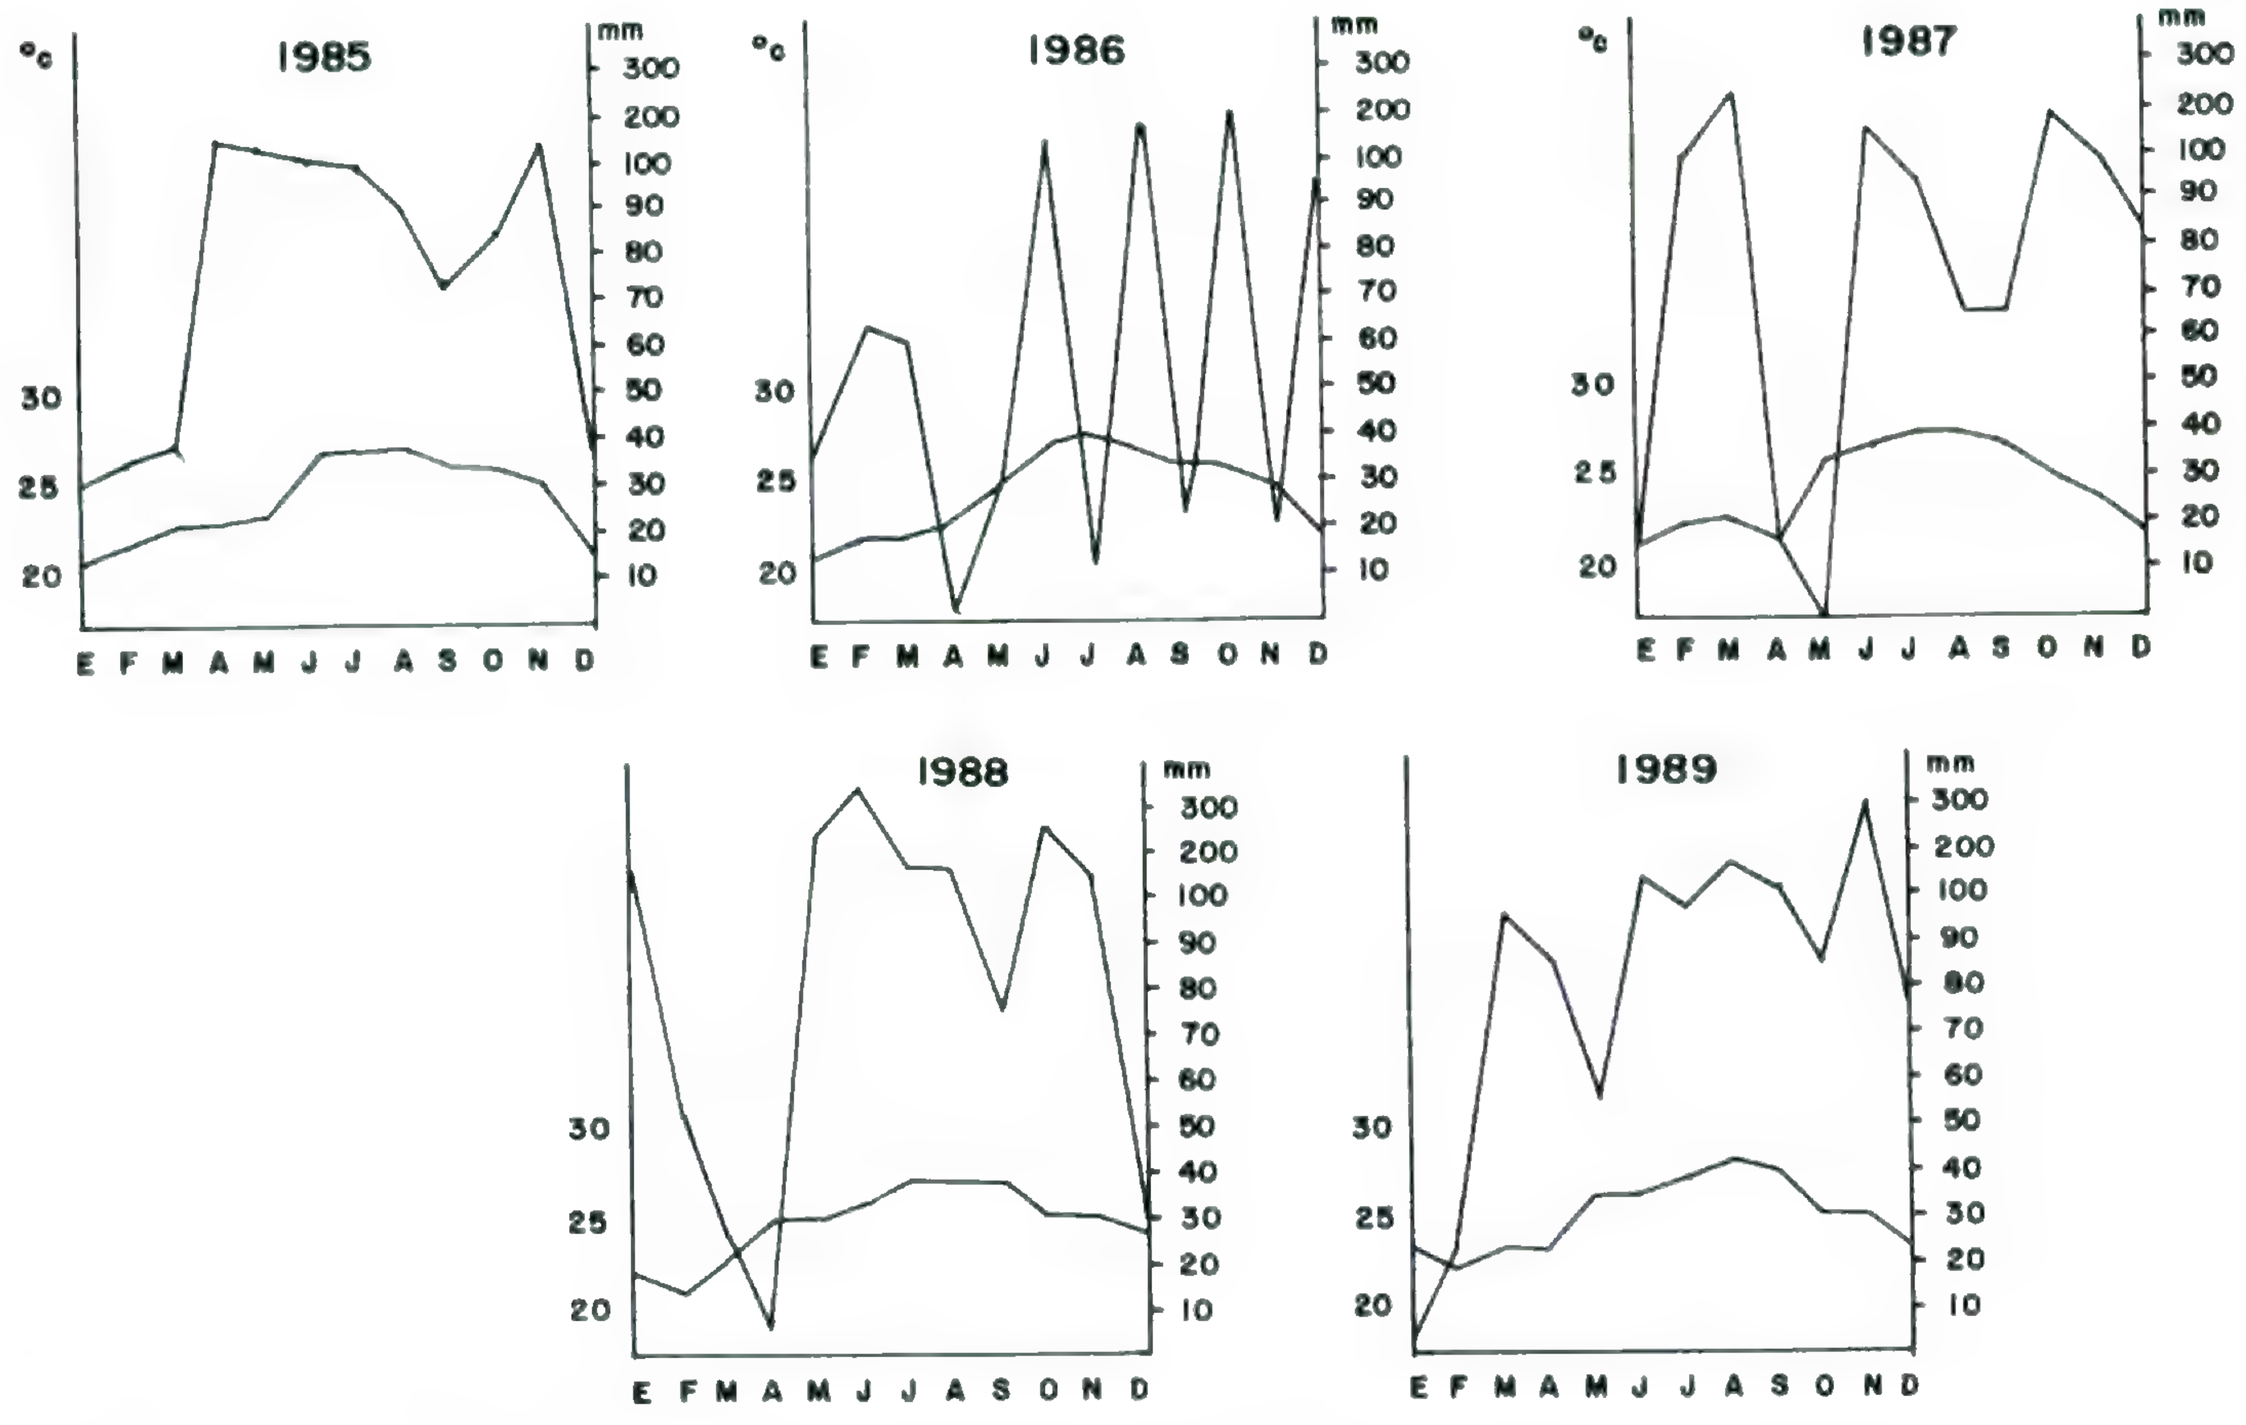

FIGURA 1. Diagramas climáticos del Parque Metropolitano de La Habana durante los años 1985–1989.

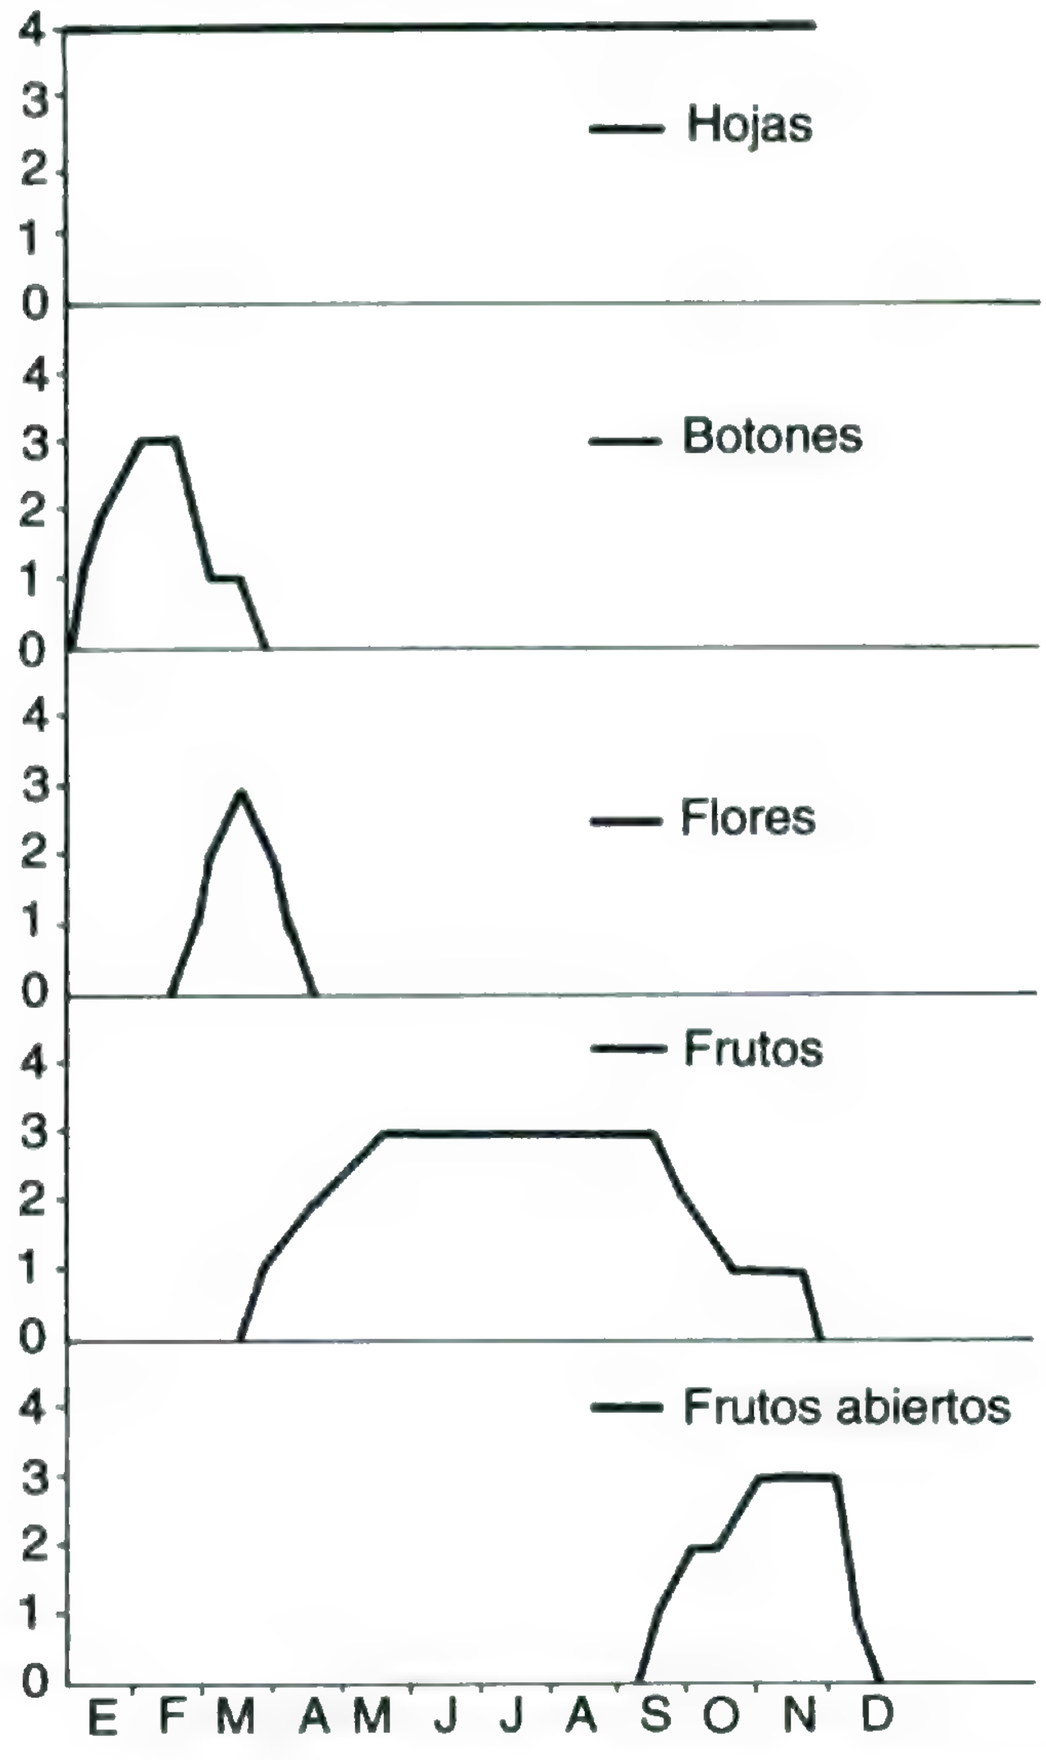

FIGURA 2. Promedios de cinco años de observaciones de las diferentes fenofases mediante el método de Fournier (1974).

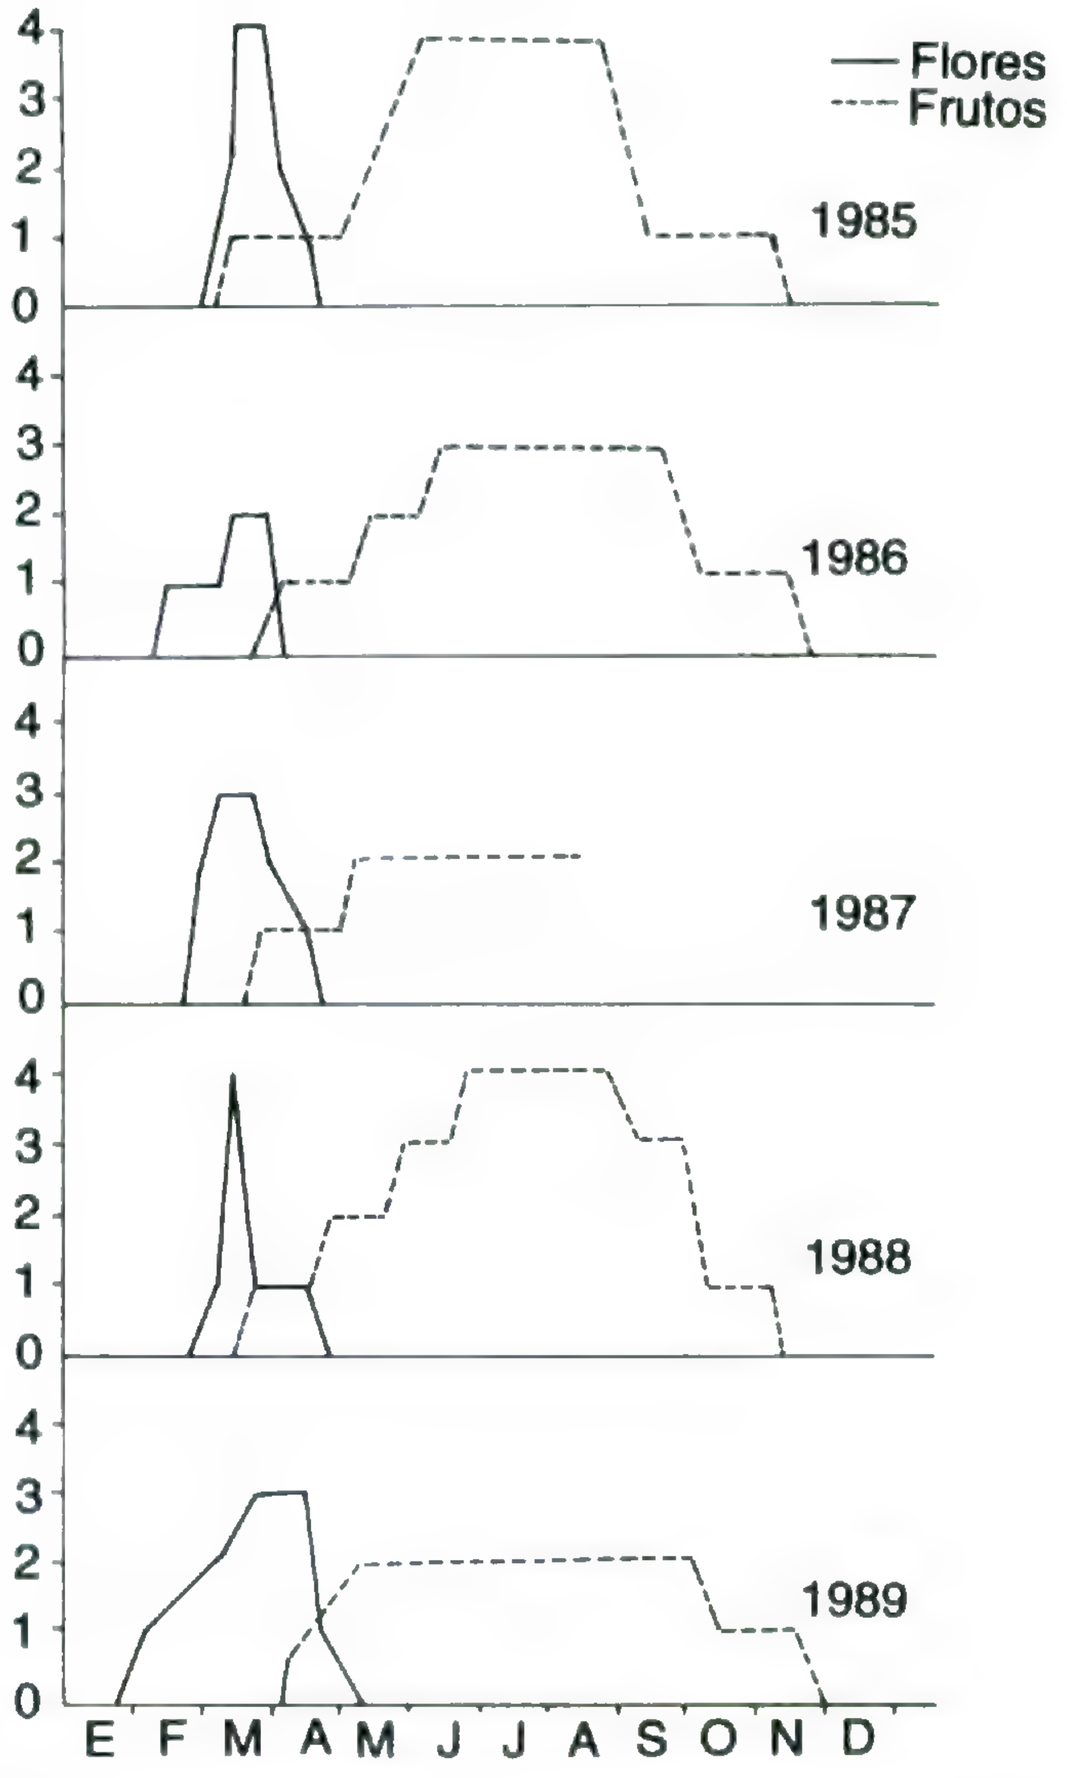

FIGURA 3. Promedios de producción anual de flores y frutos.

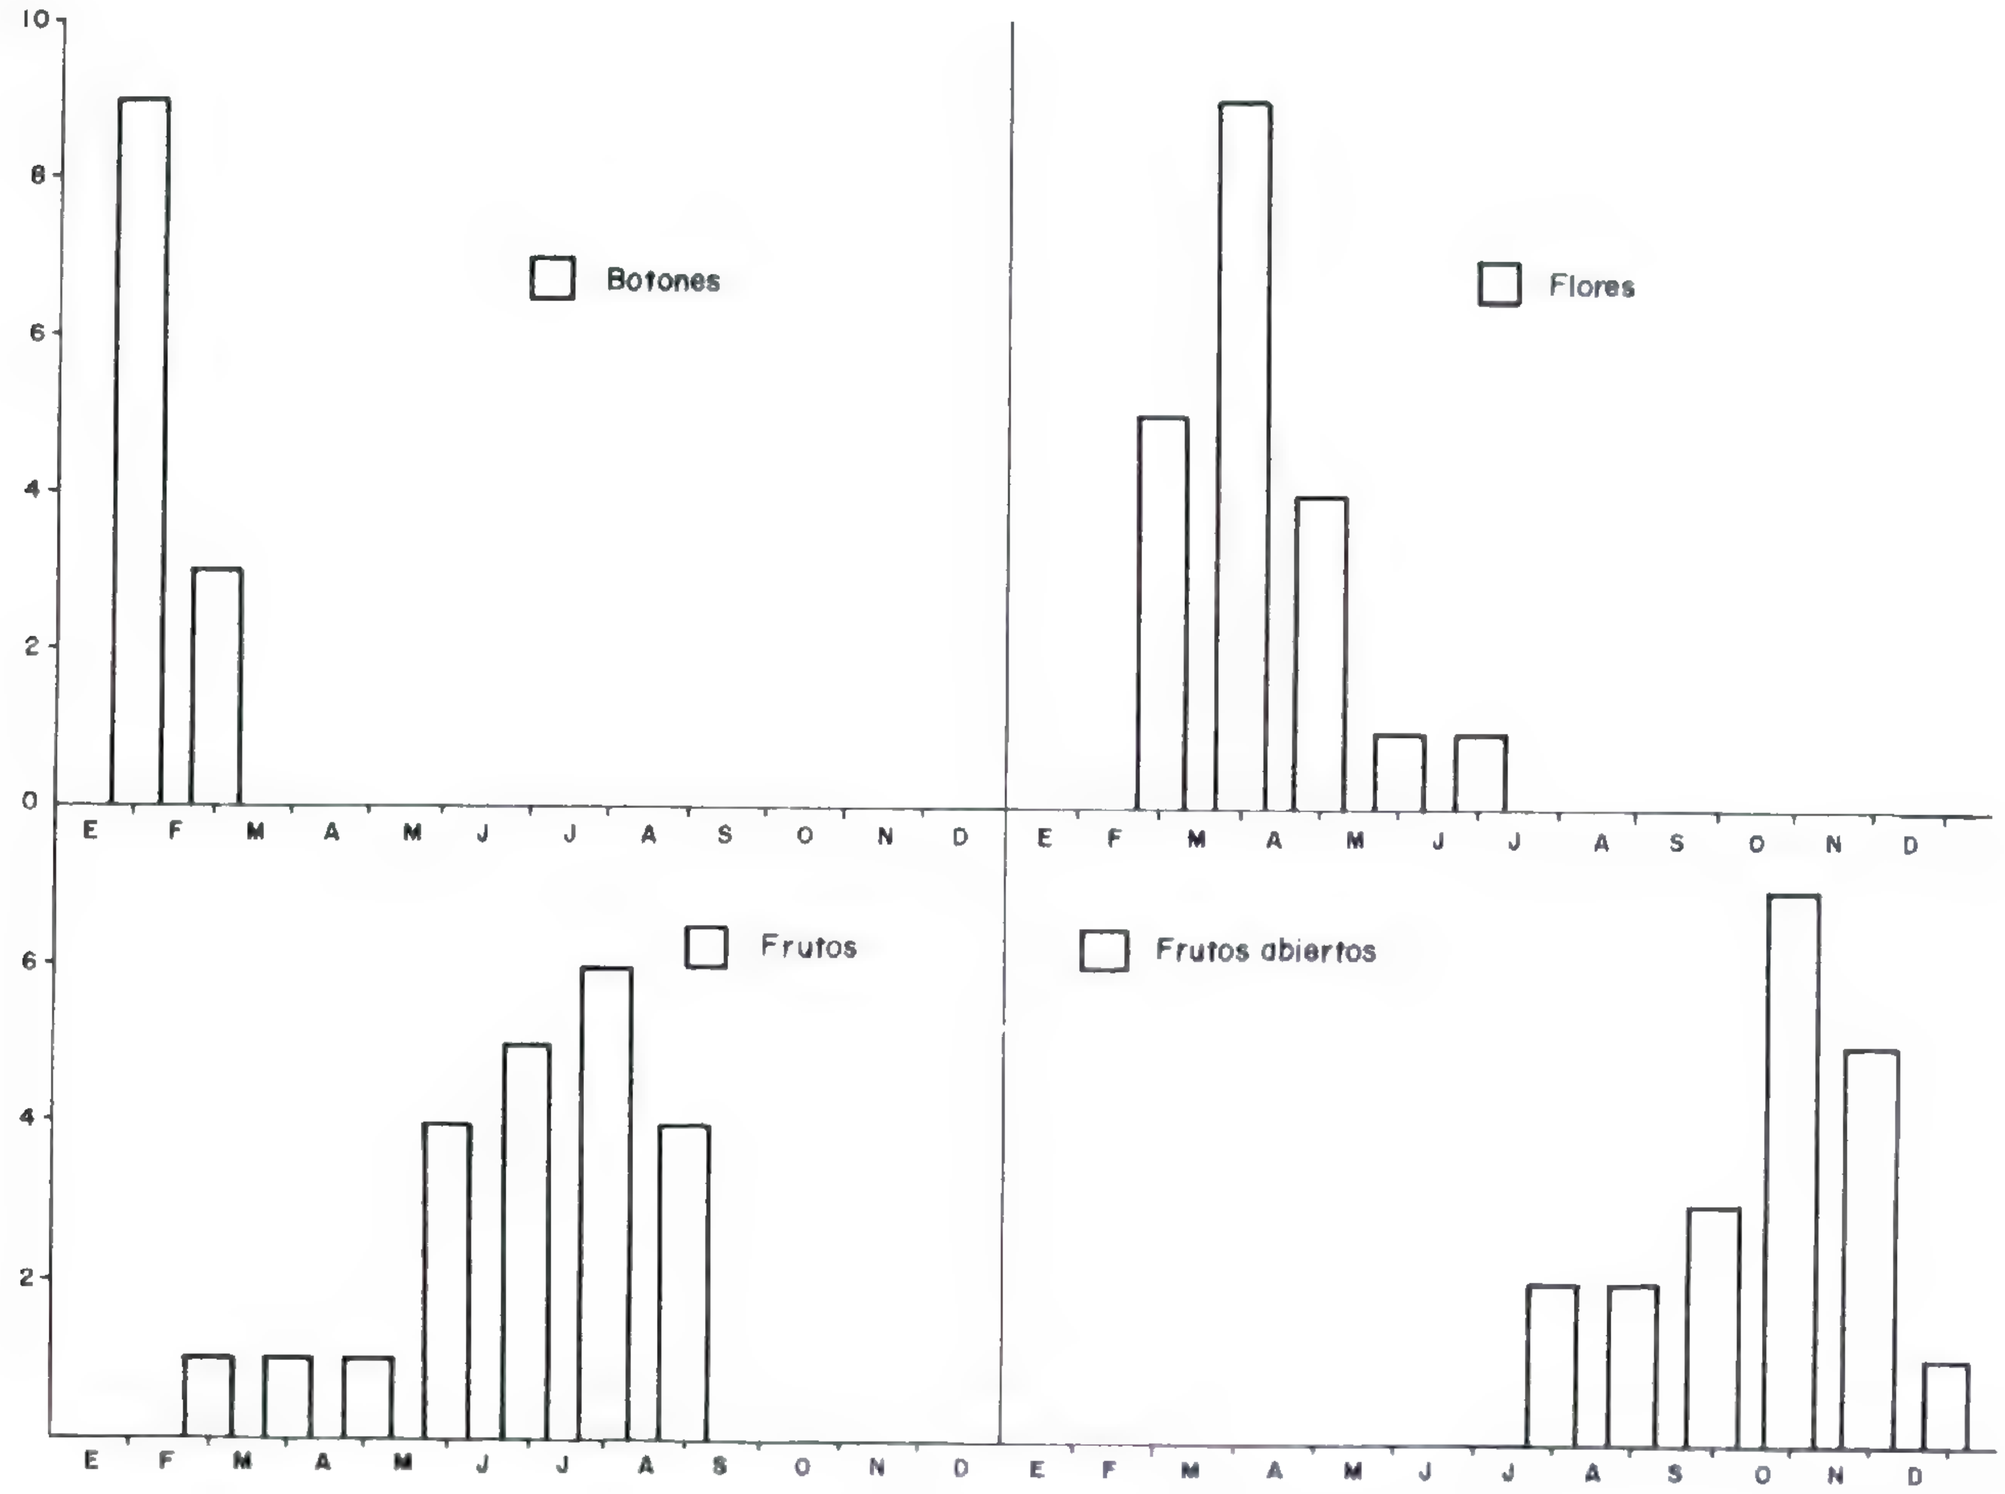

FIGURA 4. Histograma de frecuencias de los ejemplares de *Trichilia havanensis* depositados en los herbarios HAC y HAJB.

de producción anual de flores. Como podemos apreciar en los años 1985 y 1988 esta producción alcanza el rango 4 en la escala de Fournier lo que puede ser debido a un ligero aumento en las precipitaciones durante los años en cuestión ya que de acuerdo con Opler et al. (1976) y Mori & Prance (1987) la estacionalidad en los trópicos está fundamentalmente dada por este factor climático.

Los ejemplares florecidos procedentes de diferentes localidades del país ubicados en los herbarios anteriormente referidos (Fig. 4), los individuos situados en los alrededores del Instituto de Ecología y Sistemática, y las observaciones de campo realizadas en la provincia de Pinar del Río corroboran nuestros resultados, encontrándose los picos (máximos) de botones y flores en el mismo período que el encontrado como resultado de 5 años de observaciones fenológicas en el Parque Metropolitano de la Habana, lo que demuestra un gran sincronismo no solamente entre los árboles de una localidad, sino entre los individuos procedentes de las diferentes localidades del país.

Auspurger (1983) definió el sincronismo como un escape de las plantas a los depredadores de las flores y luego de las semillas, por lo que resulta una estrategia adaptativa para una exitosa polinización y dispersión de la semilla (Steven et al., 1987).

Con relación a los frutos, obtuvimos que durante los 5 años de observaciones, las plantas 3, 5 y 6 fructificaban y las restantes no, lo que concuerda con lo planteado con Pennington & Styles (1981) de que la especie *Trichilia havanensis* es dioica.

El período de fructificación de las plantas femeninas comienza generalmente desde mediados del mes de marzo hasta noviembre y abren sus cápsulas trimeras desde septiembre hasta finales de diciembre, etapa en la que si permanece algún fruto en la planta, este ya ha perdido las semillas, por lo que no se toman en consideración. De esta forma puede clasificarse como una especie de fructificación durante una temporada amplia según Castillo & Carabias (1982).

Como consecuencia de la abundante floración, la fructificación aparece con los mayores valores durante los años 1985 y 1988 (Fig. 3).

Los histogramas de frecuencias de "flores" y "frutos" confeccionados con los ejemplares depositados en los herbarios HAC y HAJB se encuentran ligeramente extendidos lo cual constituye una limitación de la fenología de herbario (Croat, 1969), pues los individuos pueden florecer en un año fuera de época, produciendo un alargamiento del período de la fenofase observada.

Las diferencias morfológicas entre las flores femeninas y masculinas se ponen de manifiesto en

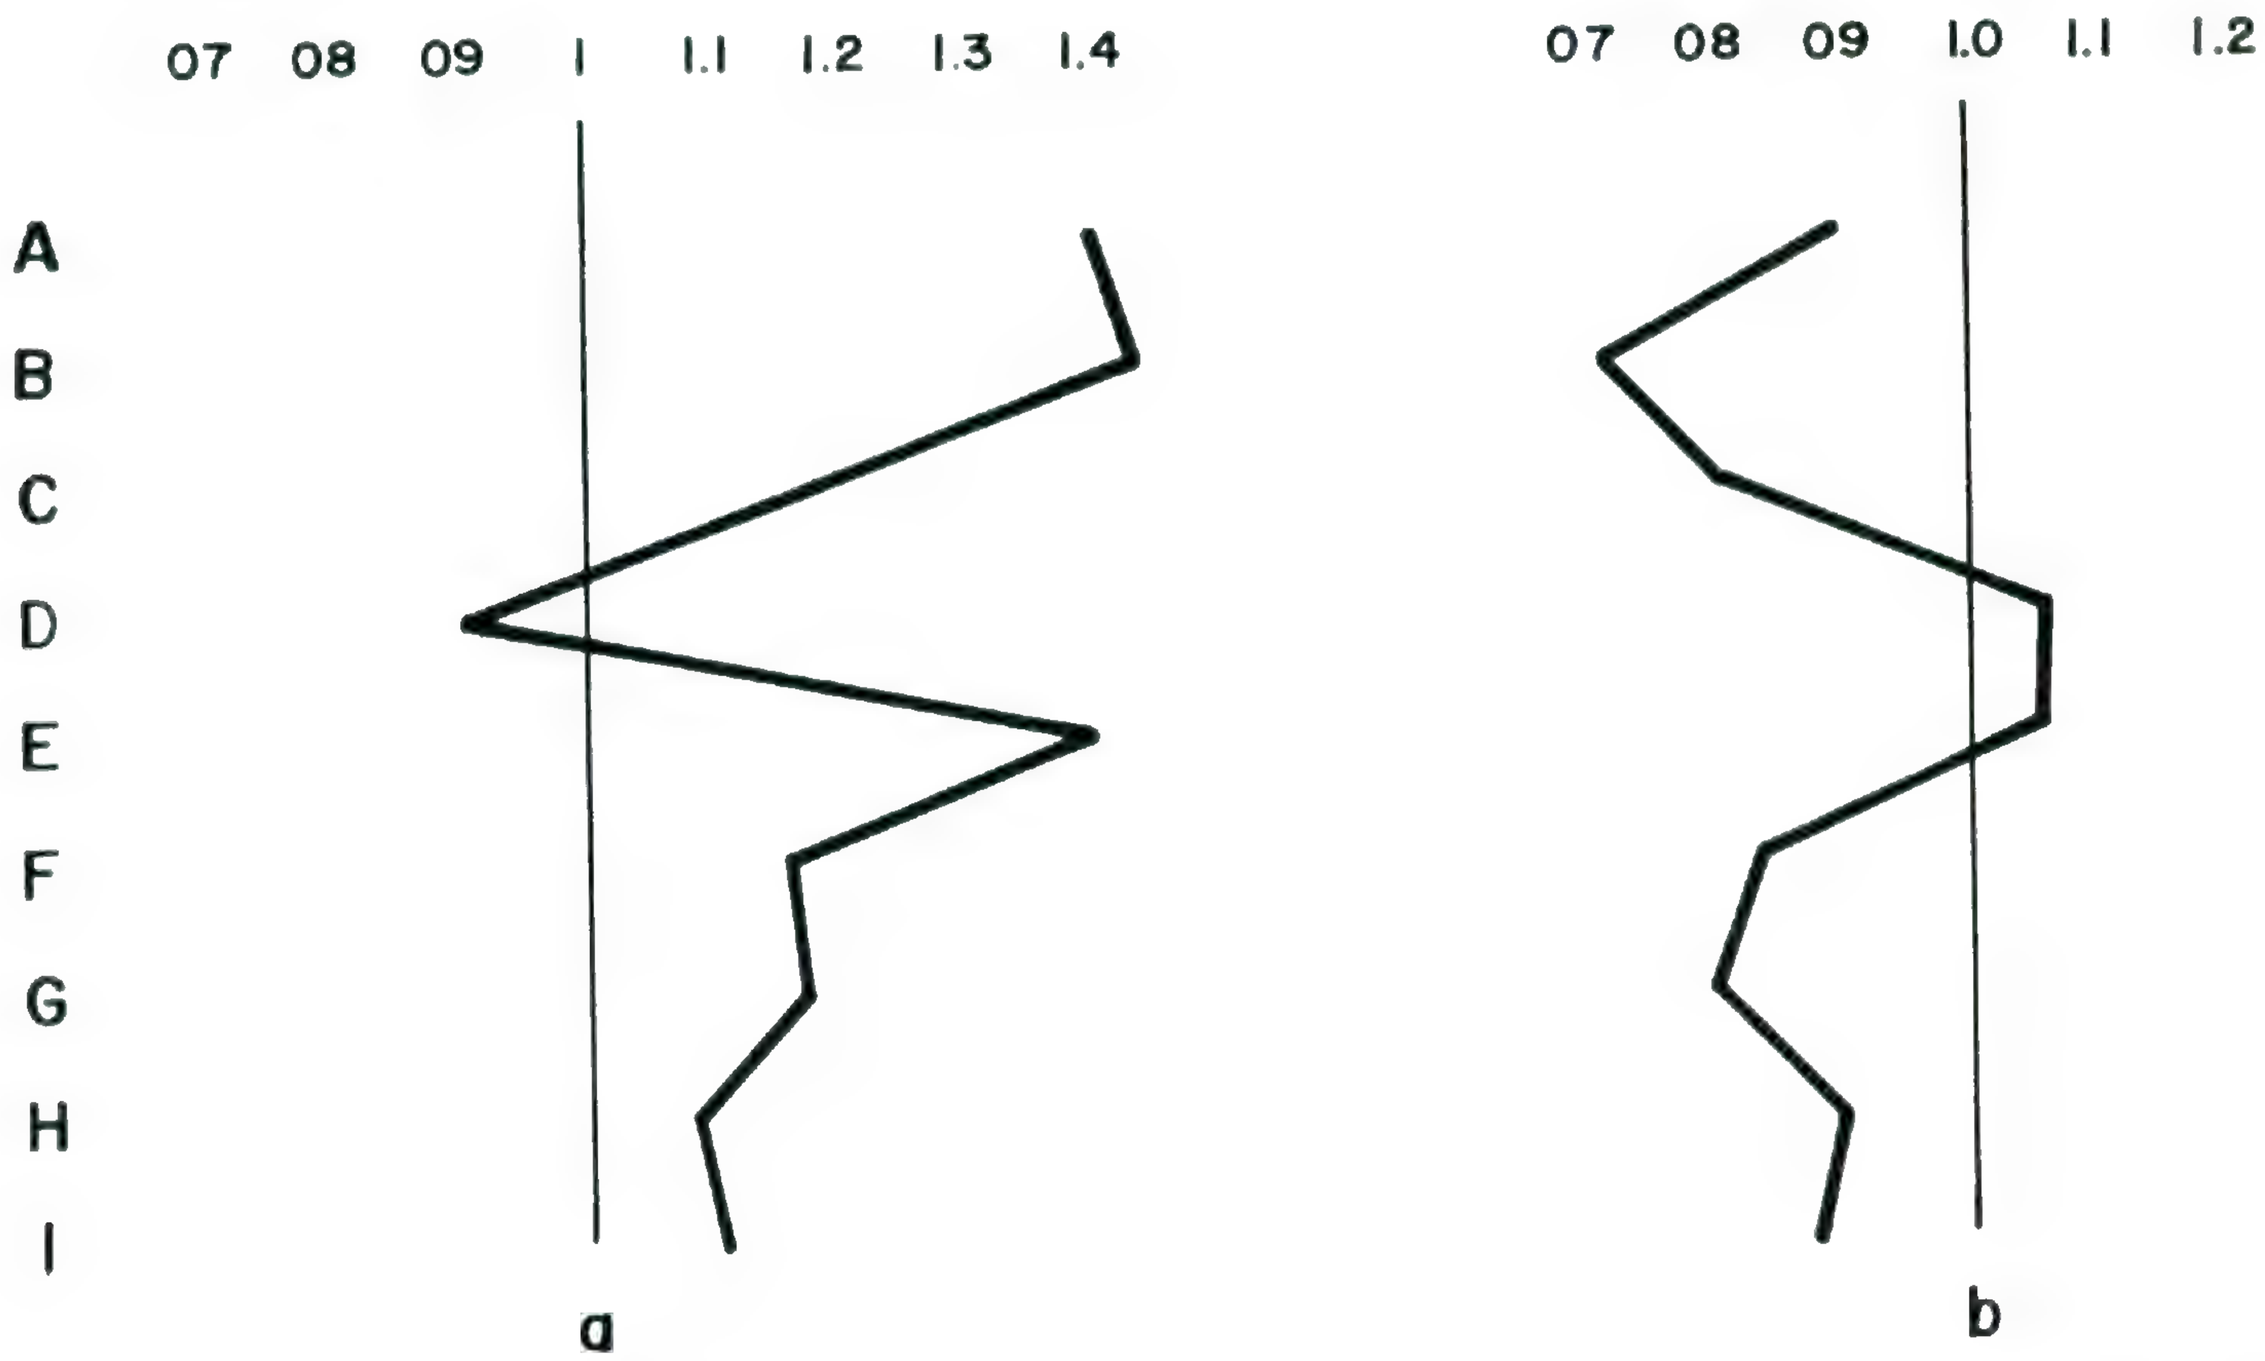

FIGURA 5. Gráficos de Jentys-Szaferowa medias calculadas en mm. —a. Ejemplares masculinos.—b. Ejemplares femeninos. Las letras corresponden con los caracteres y los números corresponden a las diferencias entre las medias particulares y la media general (ver materiales y métodos).

los gráficos de Jentys-Szaferowa (1959; ver Fig. 5, Tabla 1).

En las flores masculinas (Figs. 5a, 6A), todos los caracteres excepto el ancho del ovario (indice D) presentan mayores valores que en las femeninas (Figs. 5b, 6B).

Existen otras diferencias cualitativas entre las flores de ambos sexos como son las siguientes; la apertura floral en flores masculinas es completa, dejando descubierto totalmente al tubo estaminal y en las femeninas es parcial; y la coloración de las anteras en flores masculinas es amarilla mientras que en las femeninas es carmelita.

En período de floración encontramos una intensa actividad de la especie *Apis mellifera* L.

White en el prólogo de la monografía genérica de Meliaceae (Pennington & Styles, 1975), apuntó que un himenóptero insertaba su proboscis por una estrecha ranura formada entre las anteras y anteroides en *T. havanensis*, transfiriendo el polen de flores masculinas hacia la superficie estigmática de las flores femeninas.

Anteriormente Priestly y Scott, según de la Luz (1985), habían considerado que las flores de colores amarillo, blanco, y azul, con el color verde como follaje, eran visitadas con preferencia por los insectos, y atraen en especial a las abejas, las cuales a su vez prefieren las inflorescencias del tipo corimbo, capítulo y glomérulos, cuyas flores son reunidas y compactas, comportándose como superficies planas.

Este es el caso de las inflorescencias fasciculadas de *T. havanensis*, por lo que pensamos que la especie *Apis mellifera* L., abeja de miel, es probablemente la encargada de la polinización.

De acuerdo con lo señalado anteriormente, y si tomamos en cuenta que *Apis mellifera* es introducida en nuestro país, podemos corroborar lo planteado por Gentry (1986) de que la micrantia con flores agrupadas es poco específica para la polinización, motivo por el cual, muchas especies han podido establecerse en Cuba sin necesidad del agente polinizador.

Las hormigas son otros himenópteros que visitan las flores de *T. havanensis* pero estas no son consideradas como polinizadores, sino que se aprovechan y toman el néctar sin aportar beneficio a las plantas (Guerrant, 1981).

El que se hayan encontrado solamente tres plantas femeninas de las 10 estudiadas, está en correspondencia con lo que ocurre en la naturaleza de forma espontánea dentro de la familia Meliaceae, ya que el número de plantas masculinas es mucho mayor que el de femeninas (Styles, 1972).

Debemos señalar que la planta # 1, aunque se comportó durante tres años como masculina, en

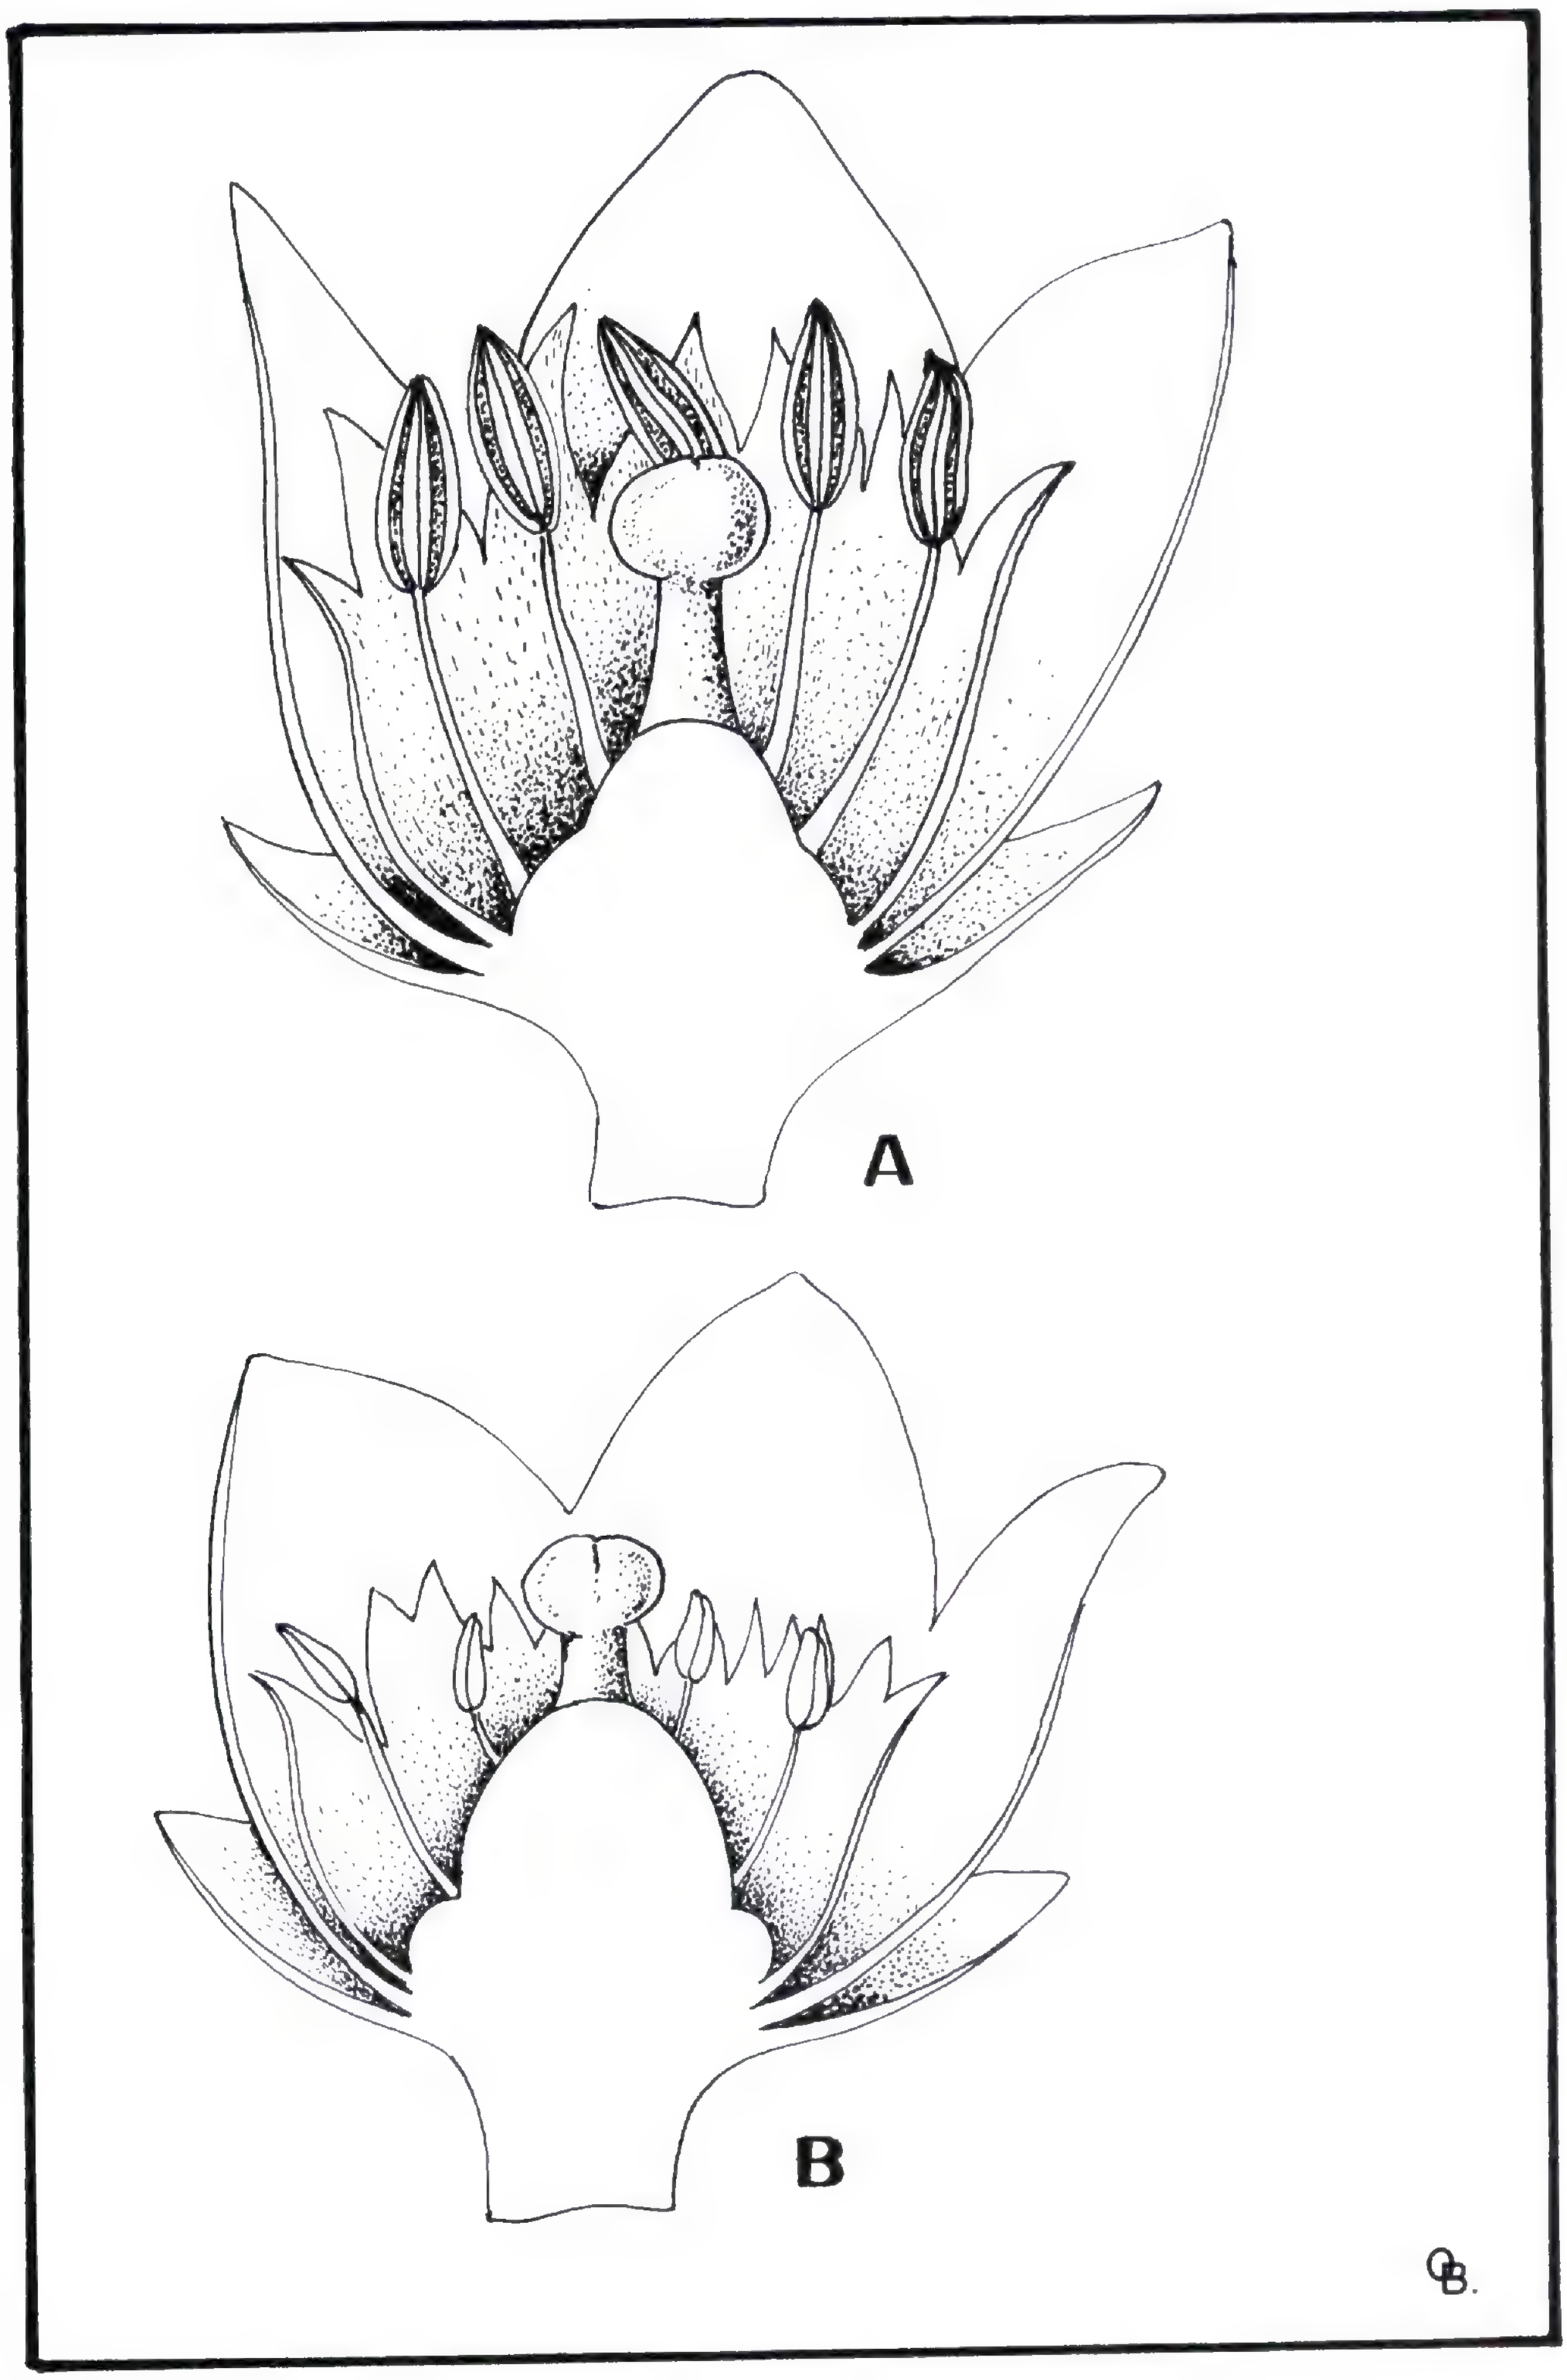

FIGURA 6. Flores de *Trichilia havanensis*—A. Flor masculina. B.—Flor femenina.

1988 comenzó a fructificar, desasrrollando frutos normales (hasta el rango 2 de la escala de Fournier).

A pesar de que fenómenos como el anteriormente expuesto han sido poco estudiados, existen algunos artículos referentes a la especie *Carica papaya* L. en los cuales se expone que aunque el tipo sexual básico está determinado genotípicamente, ciertos árboles machos y hermafroditas sufren reversiones sexuales de varios grados, atribuyéndole diferentes causas al mismo.

Por ejemplo, Muñoz Morales (1983), consideró que estas reversiones tienen dos origenes: ambiental y hereditario, y que los últimos producen cambios totales o parciales en las flores y órganos esenciales.

Este autor opina que las plantas femeninas no muestran variaciones por lo que son consideradas como el tipo floral de mayor estabilidad.

Ghosh & Sen (1975) señalaron la influencia del contenido de nitrógeno a favor de las plantas femeninas, así como el efecto de los reguladores del crecimiento, los cuales pueden alterar el proceso de floración provocando efectos de reversión sexual.

En nuestro caso, aunque no podemos descartar la influencia de los factores climáticos en este fenómeno, la situación en que se encuentran esas plantas es de "stress" ya que el bosque ha sido talado, ha aumentado el contenido de cal en el ambiente a causa de las construcciones que allí se producen, ha habido fuego (varias plantas del lugar han sido quemadas), o sea, que debido a la afectación antrópica observada en las áreas de estudio, los hábitos de vida de estos individuos han sido profundamente modificados.

De esta forma se demuestra que al igual que *Carica papaya* L., *Trichilia havanensis* es capaz de revertir sus hábitos reproductivos en condiciones extremas, lo cual probablemente es un mecanismo para la perpetuación de la especie.

## Conclusiones

Se pone de manifiesto la dioecia en la especie *T. havanensis* en Cuba, encontrándose un gran sincronismo en la floración de esta especie entre los meses de enero y abril. Se detecta mediante las observaciones fenológicas, que los principales agentes polinizantes parecen ser los himenópteros del grupo de los Apidos, colectándose especificamente la abeja de miel (*Apis mellifera*).

Las principales diferencias sexuales en las flores las encontramos en los caracteres del verticilo estaminal, mayor longitud del tubo, y anteras desarrolladas de color amarillo en las flores masculinas y tubo estaminal más pequeño y anteras carmelitas y arrugadas en las flores femeninas.

Existen otros caracteres que diferencian a las flores de ambos sexos como son: mayores dimensiones de los pétalos, disco nectarifero más desarrollado y apertura floral completa en flores masculinas, ocurriendo lo contrario en las femeninas.

Los fuertes cambios ecológicos observados en el hábitat de *Trichilia havanensis*, hacen que, al igual que ocurre con *Carica papaya* revierta sus hábitos reproductivos en condiciones extremas.

# THE GENUS *CLERODENDRUM* (VERBENACEAE) IN MESOAMERICA[1]

*Ricardo M. Rueda*[2]

## Abstract

*Clerodendrum* is the largest genus of Verbenaceae, with about 560 species and varieties. It is most abundant in Africa and Asia, with only 20 species native to the New World. In Mesoamerica, 15 species and one variety are known: five of these species are native, and the remainder are cultivated as ornamental plants; several are more or less naturalized. Three of the introduced species and one of the native ones are first records for the Mesoamerican region.

## Resumen

*Clerodendrum* es el género más grande de la familia Verbenaceae con cerca de 560 especies y variedades. La mayoría de estas especies ocurren en Africa y Asia; solamente 20 especies son nativas al Nuevo Mundo. En Mesoamérica se conocen 15 especies y una variedad: de éstas solamente 5 especies son nativas; el resto son cultivadas como ornamentales, y algunas son naturalizadas. Tres de las especies cultivadas y una de las nativas son nuevos reportes para Mesoamérica.

The genus *Clerodendrum*, comprised of small trees, shrubs, woody vines, and perennial herbs, is well known for its showy and attractive ornamental species. This genus, with about 560 taxa, is the largest in the Verbenaceae and is taxonomically complex. It is native to tropical and subtropical regions of both hemispheres, most abundant in the Old World, and poorly represented in the New World, where, however, it is frequently cultivated and often naturalized. The name *Clerodendrum* is formed from two Greek words, "kleros" (chance or destiny) and "dendron" (tree). The reason for the application of the name to the genus is obscure, but it may well come from the ancient belief that some species had healing properties, while others acted in exactly the opposite way.

Historically, the taxonomy of the genus *Clerodendrum* has been confused (see Munir, 1989). Much of this can be attributed to the wide use of ornamental species with different varieties. Many species seem to be closely related, with some hybridization reported. Some of the species are extremely variable, due to environmental factors and horticultural selection, which has led taxonomists to describe many taxa.

Because several species are found mostly in cultivation in Mesoamerica, they have been poorly collected. The large size of the leaves and inflorescences also led to a tendency to collect few leaves and partial inflorescences. Thus, few complete collections are available for study. In addition, Burman's (1737) spelling "*Clerodendron*" instead of the correct spelling "*Clerodendrum*" of Linnaeus (1753) is often found in the literature, thus causing confusion. This study is based on (1) an exhaustive examination of the types, (2) morphological characters, and (3) geographical information available.

[1] This study was completed as a partial fulfillment of the M.Sc. degree in biology at the University of Missouri, St. Louis. I am grateful to Alwyn Gentry and Victoria Sork for direction and critical revision of the manuscript. The collaboration of the staff of the Missouri Botanical Garden was particularly valuable. Financial support was provided by a Fulbright fellowship through the Latin American Scholarship Program of American Universities (LASPAU). The following institutions made their herbarium collections available: BR, CAS, CHAPA, CR, DUKE, E, ENCB, F, GH, IJ, K, L, MA, MEXU, MICH, MO, MSC, NY, P, TEFH, TEX, US. The illustrations were prepared by J. Myers.

## Morphological Characteristics

### HABIT

A liana habit is uncommon in Verbenaceae but is found in *Petrea* and *Holmskioldia*, the latter cultivated in the Mesoamerican region.

### WOOD

The genus does not have commercial value as a source of timber, probably because of its small stature. Record & Hess (1941) studied five species from Mesoamerica and the Caribbean region. They reported the wood of *Clerodendrum* to be yellow or whitish with a medium luster, moderately heavy with a fine texture, and easy to work with. Wood parenchyma is scanty, paratracheal. Wood fibers are in part septate, the pits numerous and medium-sized. Most of these anatomical characteristics are shared with such other genera of the family as *Aegiphila* and *Callicarpa* (both Verbenaceae). However, *Aegiphila* has wood parenchyma vasicentric to aliform and confluent, and *Callicarpa* has wood pores much larger than *Clerodendrum*.

### LEAVES

The leaves are simple decussate-opposite, ternate, or apically clustered and variable in size. *Clerodendrum aculeatum* has leaves ranging 0.9–4 cm long × 0.3–1.4 cm wide; *C. paniculatum* 6–35 cm long × 6–30 cm wide. Other American Verbenaceae genera with decussate-opposite leaves are *Verbena*, *Petrea*, and *Duranta*; however, none of them have the tremendous variability in size displayed in *Clerodendrum*. Like *Clerodendrum*, most Mesoamerican Verbenaceae have simple leaves, except *Vitex*, which has palmately compound leaves. Leaf shape is also variable; lanceolate in *Clerodendrum wallichii*; elliptic in *C. aculeatum*; and ovate in *C. japonicum*.

### VENATION PATTERNS

Venation patterns are variable, although most species are brochidodromous, sometimes only well above the base. Other less frequent types are craspidodromous as in *C. bungei*, and eucamptodromous as in *C. aculeatum* and *C. costaricense*. The angle of divergence of secondary veins from the midvein is variable but in most leaves is acute (45°–60°). In almost all of the species the secondary veins are broadly ascending and strongly arcuate. The number of secondary veins can vary from 5 to 9 on each side of the midvein.

### PETIOLES

Leaves are petiolate. The variability in petiole length is remarkable, 0.1–0.7 cm in *C. pittieri* and 1–40 cm in *C. paniculatum*. In a few species petioles are decurrent. Almost all of the species present elevated leaf scars, these becoming spinescent in such species as *C. aculeatum*.

### INDUMENTUM

The genus varies from glabrous or glandular-pubescent to pubescent with simple hairs. Calyx, petiole, pedicel, leaf, and twig pubescence are usually of different densities within a species. Most genera in Verbenaceae have annulate nodes, but some species of *Clerodendrum* have a band of tomentose hairs on the nodes. Disk-shaped glands on the calyx and scales on leaves are also present in some species.

### INFLORESCENCES

The inflorescences are both axillary and terminal, sometimes on the same plant. The inflorescences may range from 1 to 39 cm long and 1 to 25 cm wide. These inflorescences may be cymes, panicles, or solitary flowers, determinate or centrifugal, the flowers crowded or sparsely arranged. These types of inflorescences are also present in other genera such as *Aegiphila* and *Callicarpa*, but the flowers in these genera are regular and the stamens equal, unlike *Clerodendrum*, which has irregular flowers and didynamous stamens. Almost all the species of *Clerodendrum* have foliaceous bracts and linear-lanceolate bracteoles.

### CALYX

The calyx varies in size, ranging from 2 to 18 mm long. It is gamosepalous, commonly green, less often red or white, almost always campanulate, rarely elliptic, truncate, 5-lobed, glabrous or variously pubescent, sometimes glandular or lepidote, often accrescent in fruit. The accrescent calyx in fruits does not become thick and indurate as in *Aegiphila*, nor reflexed and patelliform as in *Callicarpa*.

### COROLLA

The size of the corolla ranges from 6 to 40 mm long to 3 to 20 mm wide, sometimes larger in the species of the Old World. It is gamopetalous, hypocrateriform, and may be white, red, pink, or purple. The limb is 5-parted, spreading at anthesis, mostly subactinomorphic. The corolla is glabrous,

pubescent, or glandular-puberulent. The corolla tube is not markedly curved and more or less 2-lipped, as in *Vitex*.

### STAMENS

The four stamens are didynamous, inserted on the corolla tube more or less at the same level. They are long-exserted, alternate with the corolla lobes; the anthers are glabrous, ovate or oblong, opening by longitudinal slits. This general pattern is shared by the majority of genera in Verbenaceae.

### POLLEN

The pollen is spheroidal, with echinate processes on the tectum. Rao & Tian (1974) described the pollen grains of *Clerodendrum inerme* Gaertner as spheroidal, 3-zonocolpate, the surface spiniliferous, and interspinular areas reticulate. Verbenaceae, including *Clerodendrum*, have pollen grains that are binucleate or seldom trinucleate, and most commonly triaperturate (Cronquist, 1981).

### PISTIL

The pistil protrudes more or less the same length as the stamens. It consists of a 2-carpelled ovary and a terminal style that is elongate and forked apically. The ovary is superior, imperfectly 4-loculate, glabrous, each locule 1-ovulate, the ovules pendulous, laterally attached, and hemianatropous.

### FRUITS

The fruit is drupaceous, mostly subglobose or obovoid, glabrous, usually separating at maturity into 4 pyrenes. The exocarp is more or less fleshy, often black or stramineous when mature, and the endocarp bony or crustaceous. Fruits range from 5 to 14 mm long and 5 to 8 mm wide. The fruits are not very useful in separating species because they are remarkably similar.

### SEEDS

The seeds may be 4, as in most Verbenaceae, or (by abortion) sometimes only 1–3. They are mostly oblong, with little or no endosperm. Most other American Verbenaceae uniformly have 4 seeds.

## Distribution and Ecology

*Clerodendrum* is most abundant in Africa and Asia, although a few native species occur in the New World, many more being cultivated and naturalized. In the New World the native species of *Clerodendrum* range from the northern part of Mexico (Tamaulipas and Oaxaca), and the West Indies, south to Peru (Ayacucho), and northern Argentina (Misiones). *Clerodendrum* occurs in the Old World from northern Africa (Senegal and Egypt) southward through the remainder of Africa and Madagascar. It also occurs eastward to China and Japan, and southward to Ceylon and northern New Zealand. Most of the species are in the Old World, especially in Zaire (67 species, 10 endemic), Tanzania (60 species, 13 endemic), Madagascar (67 species, 14 endemic), and the great Sunda Islands (66 species, 14 endemic) (Moldenke, 1980). The number of species in the New World is about 20, with most native species located in Colombia (6 species, 1 endemic), and Cuba (10 species, 7 endemic).

The species of *Clerodendrum* are reported growing in a wide variety of habitats. *Clerodendrum ligustrinum* (Fig. 1) is reported along the bank of a creek in Belize (*Lundell 6962*, F); *C. costaricense* (Fig. 2) was collected in cloud forest in Costa Rica; *C. pittieri* (Fig. 3) is reported growing in a mangrove area in Costa Rica on soil with up to 64‰ salinity (Jiménez & Soto, 1985); and *C. speciosissimum* (Campeche, Mexico; *Calzada et al. 6724*, MEXU) is found on limestone formations. Other habitats from which *Clerodendrum* has been reported include sand dunes (*C. ligustrinum*, Chiapas, Mexico; *Breedlove & Thorne 20913*, MO) and cloud forest (*C. philippinum*, Nicaragua; *Williams et al. 24693*, F).

*Clerodendrum* has been reported in association with many other plants. *Clerodendrum bungei* and *C. philippinum* are reported growing with *Quercus* in Chiapas, Mexico (*Breedlove 6837*, CAS, and *37852*, MEXU).

Altitudinally, species of *Clerodendrum* are more widely distributed in lowlands than in mountains. Most of the Mesoamerican species can grow very near sea level. Consequently, collections of *Clerodendrum* from higher elevations become progressively less frequent. Some of the species that may reach well into the mountains include *C. bungei* (2,100 m, Chiapas, Mexico; *Breedlove 6055*, F) and *C. philippinum* (1,400 m, Matagalpa, Nicaragua). The scarcity of high altitude records might be due partly to a decline in both individuals and species at higher altitudes.

## Animal Interactions

### POLLINATION AND DISPERSAL

Pollination in *Clerodendrum* is mostly carried out by butterflies, moths, and bees, which extract the nectar from the base of the corolla tube. In

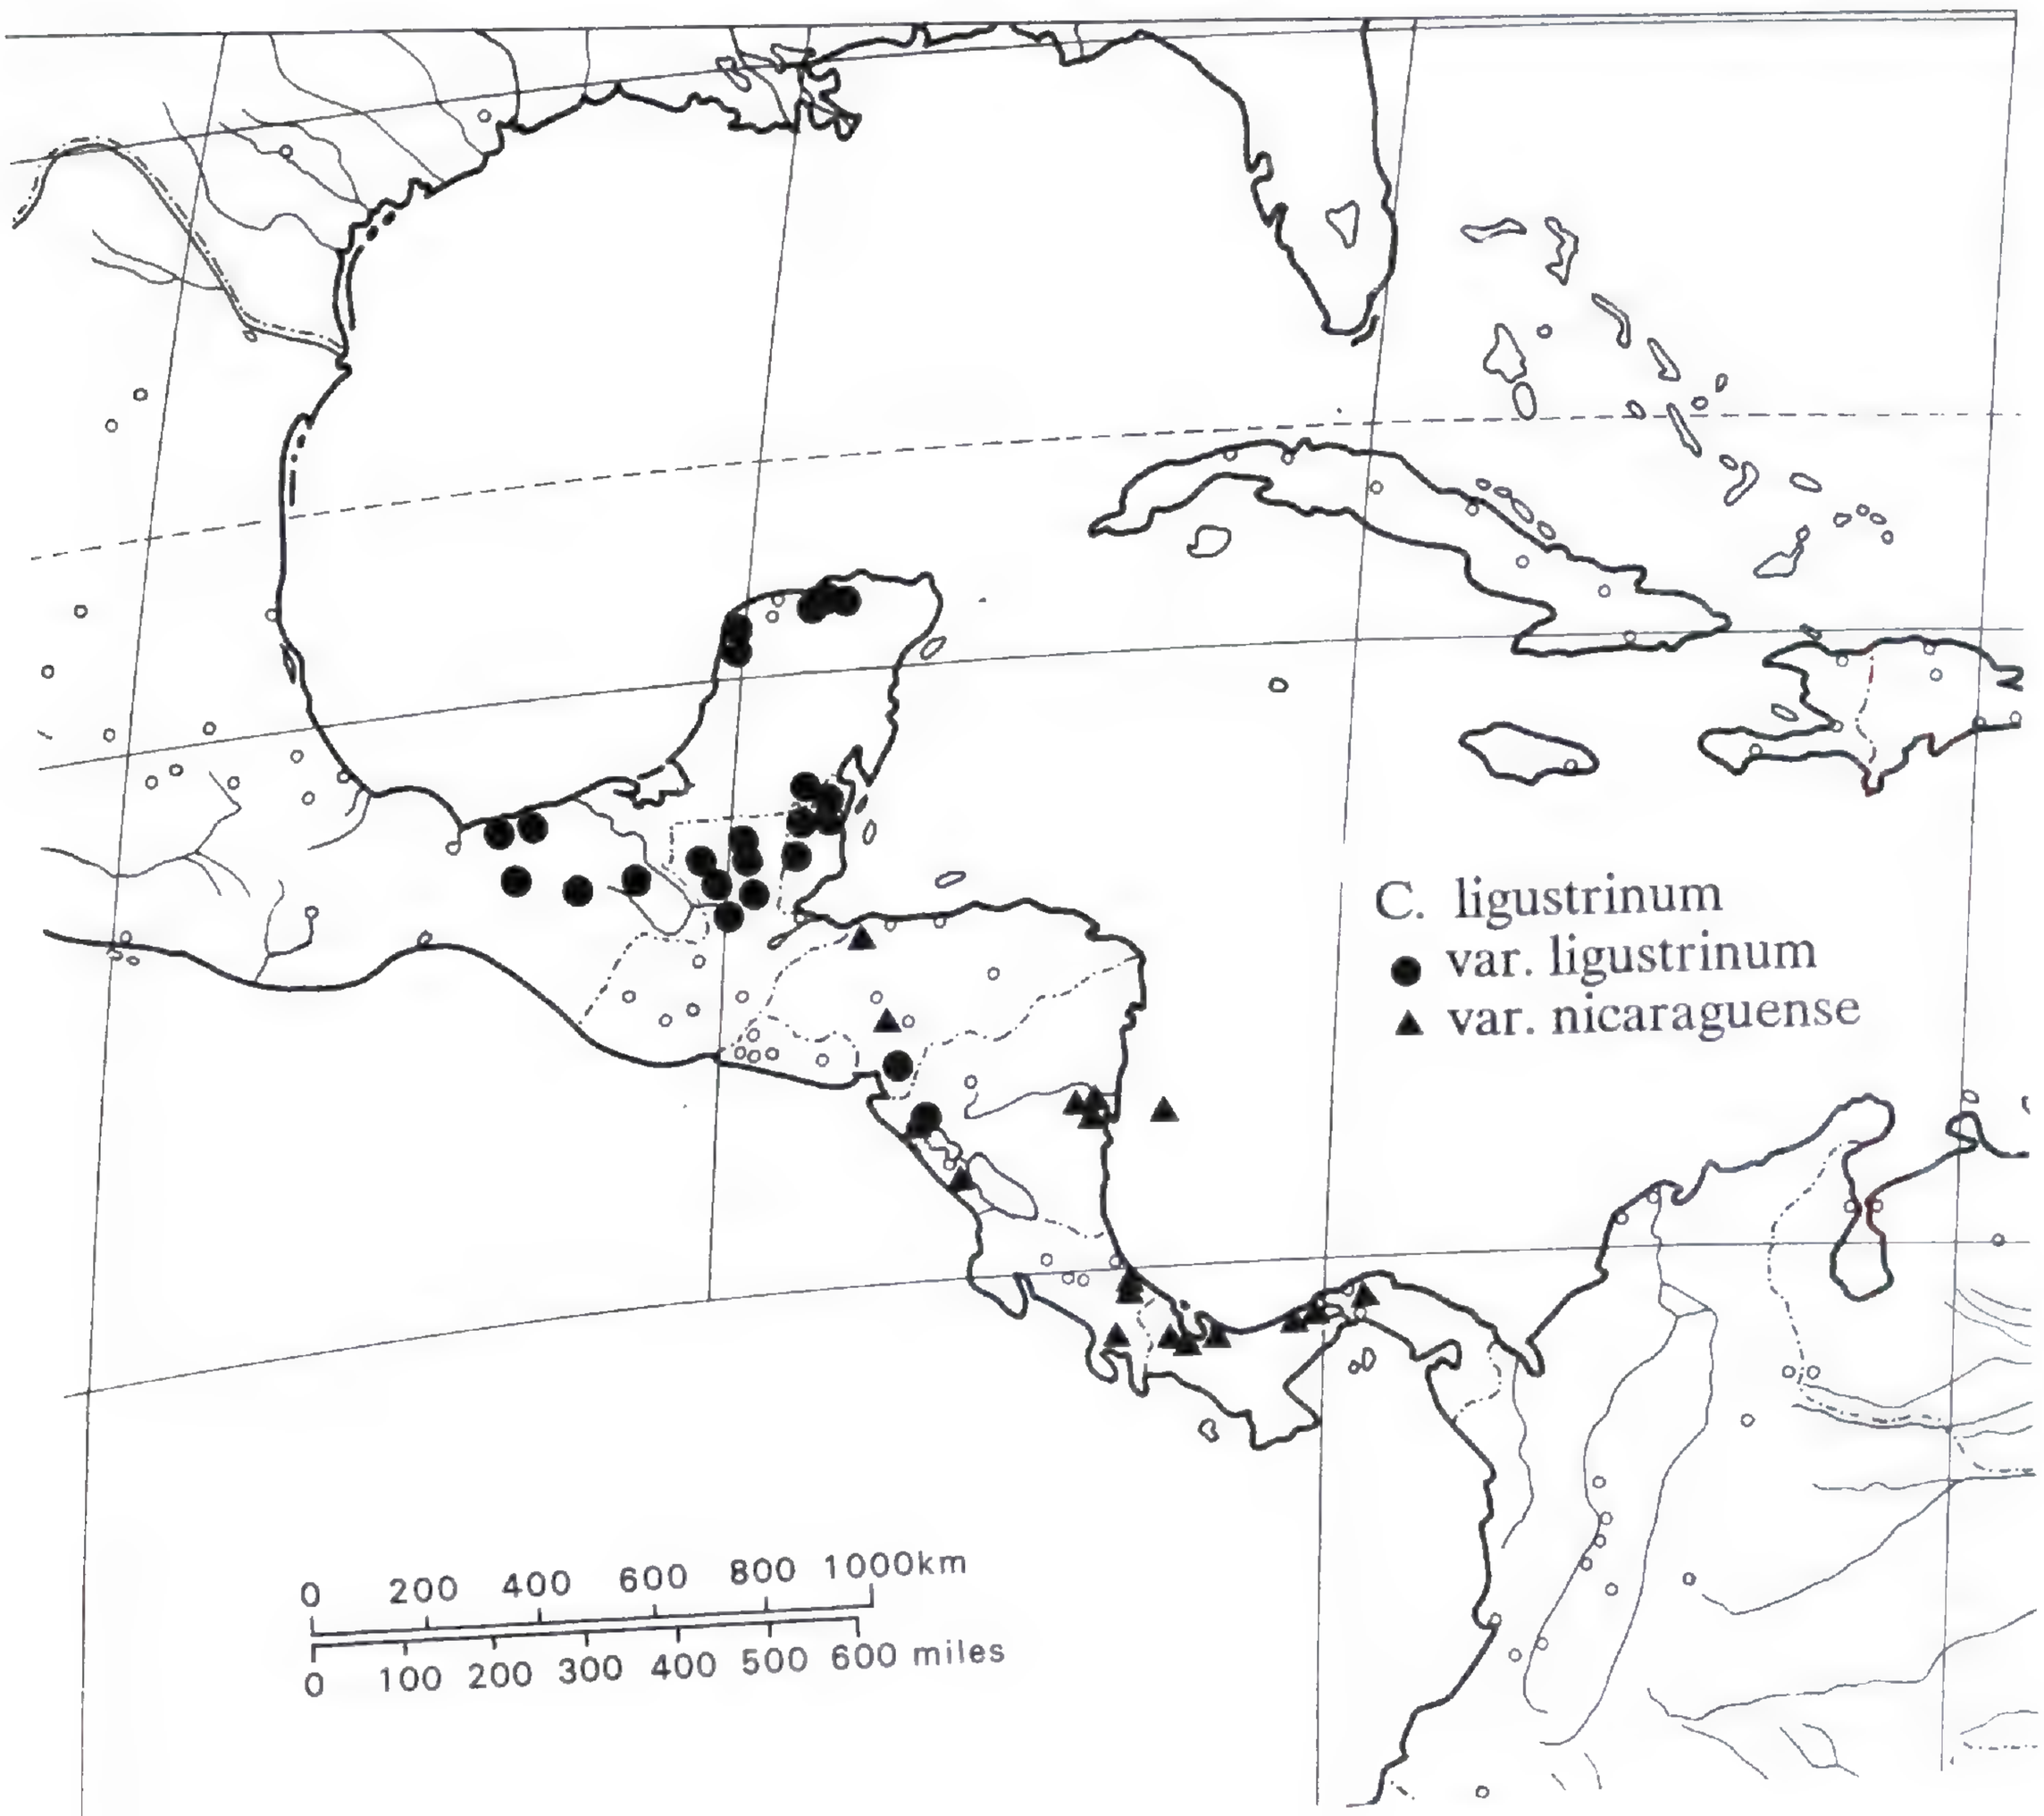

FIGURE 1. Distribution of *Clerodendrum ligustrinum* in Mesoamerica.

most species the stamens and style project from the lower side of the horizontally oriented flower; pollen is carried off on the underside of the insect. In such species as *C. aculeatum*, the flowers last more than one day, during which time the stamens first project and then curl back under the flower and leave the style exposed (Corner, 1952). In other species such as *C. serratum*, the stamens and style arch over the top of the flower and one of the petals is modified into a lower lip, which acts as a landing platform for visiting insects. In this last case the pollen is carried off on the upper side of the insect.

The fruits of *Clerodendrum* species are eaten by birds, which disperse the seeds (Moldenke, 1985). Ridley (1930) described the fruits of the genus as pulpy, often brightly colored, and distributed by birds. In many species the calyx provides a contrasting color, similar to those of red arils subtending black seeds. The pseudo-aril present in some species is actually a placental part of the pericarp that acts as an attractant to birds in the fruit dispersal process (van der Pijl, 1982).

ANTS

The relationship of some *Clerodendrum* species to ants was reported long ago. Beccari (1884) described *C. fistulosum* from Malaysia with internodes inhabited by *Camponotus* (*Colobopsis*) *clerodendri*. Mejía & Zanoni (*8508*, MO) reported many ants on plants of *C. speciosissimum* in the Dominican Republic. Dreisig (1988) reported the inflorescences of *C. speciosissimum* occupied by ants feeding on the nectar produced by the bracts. These ants belonged to three species, each having exclusive use of an inflorescence: *Wasmannia auropunctata* (Roger), *Camponotus abdominalis*

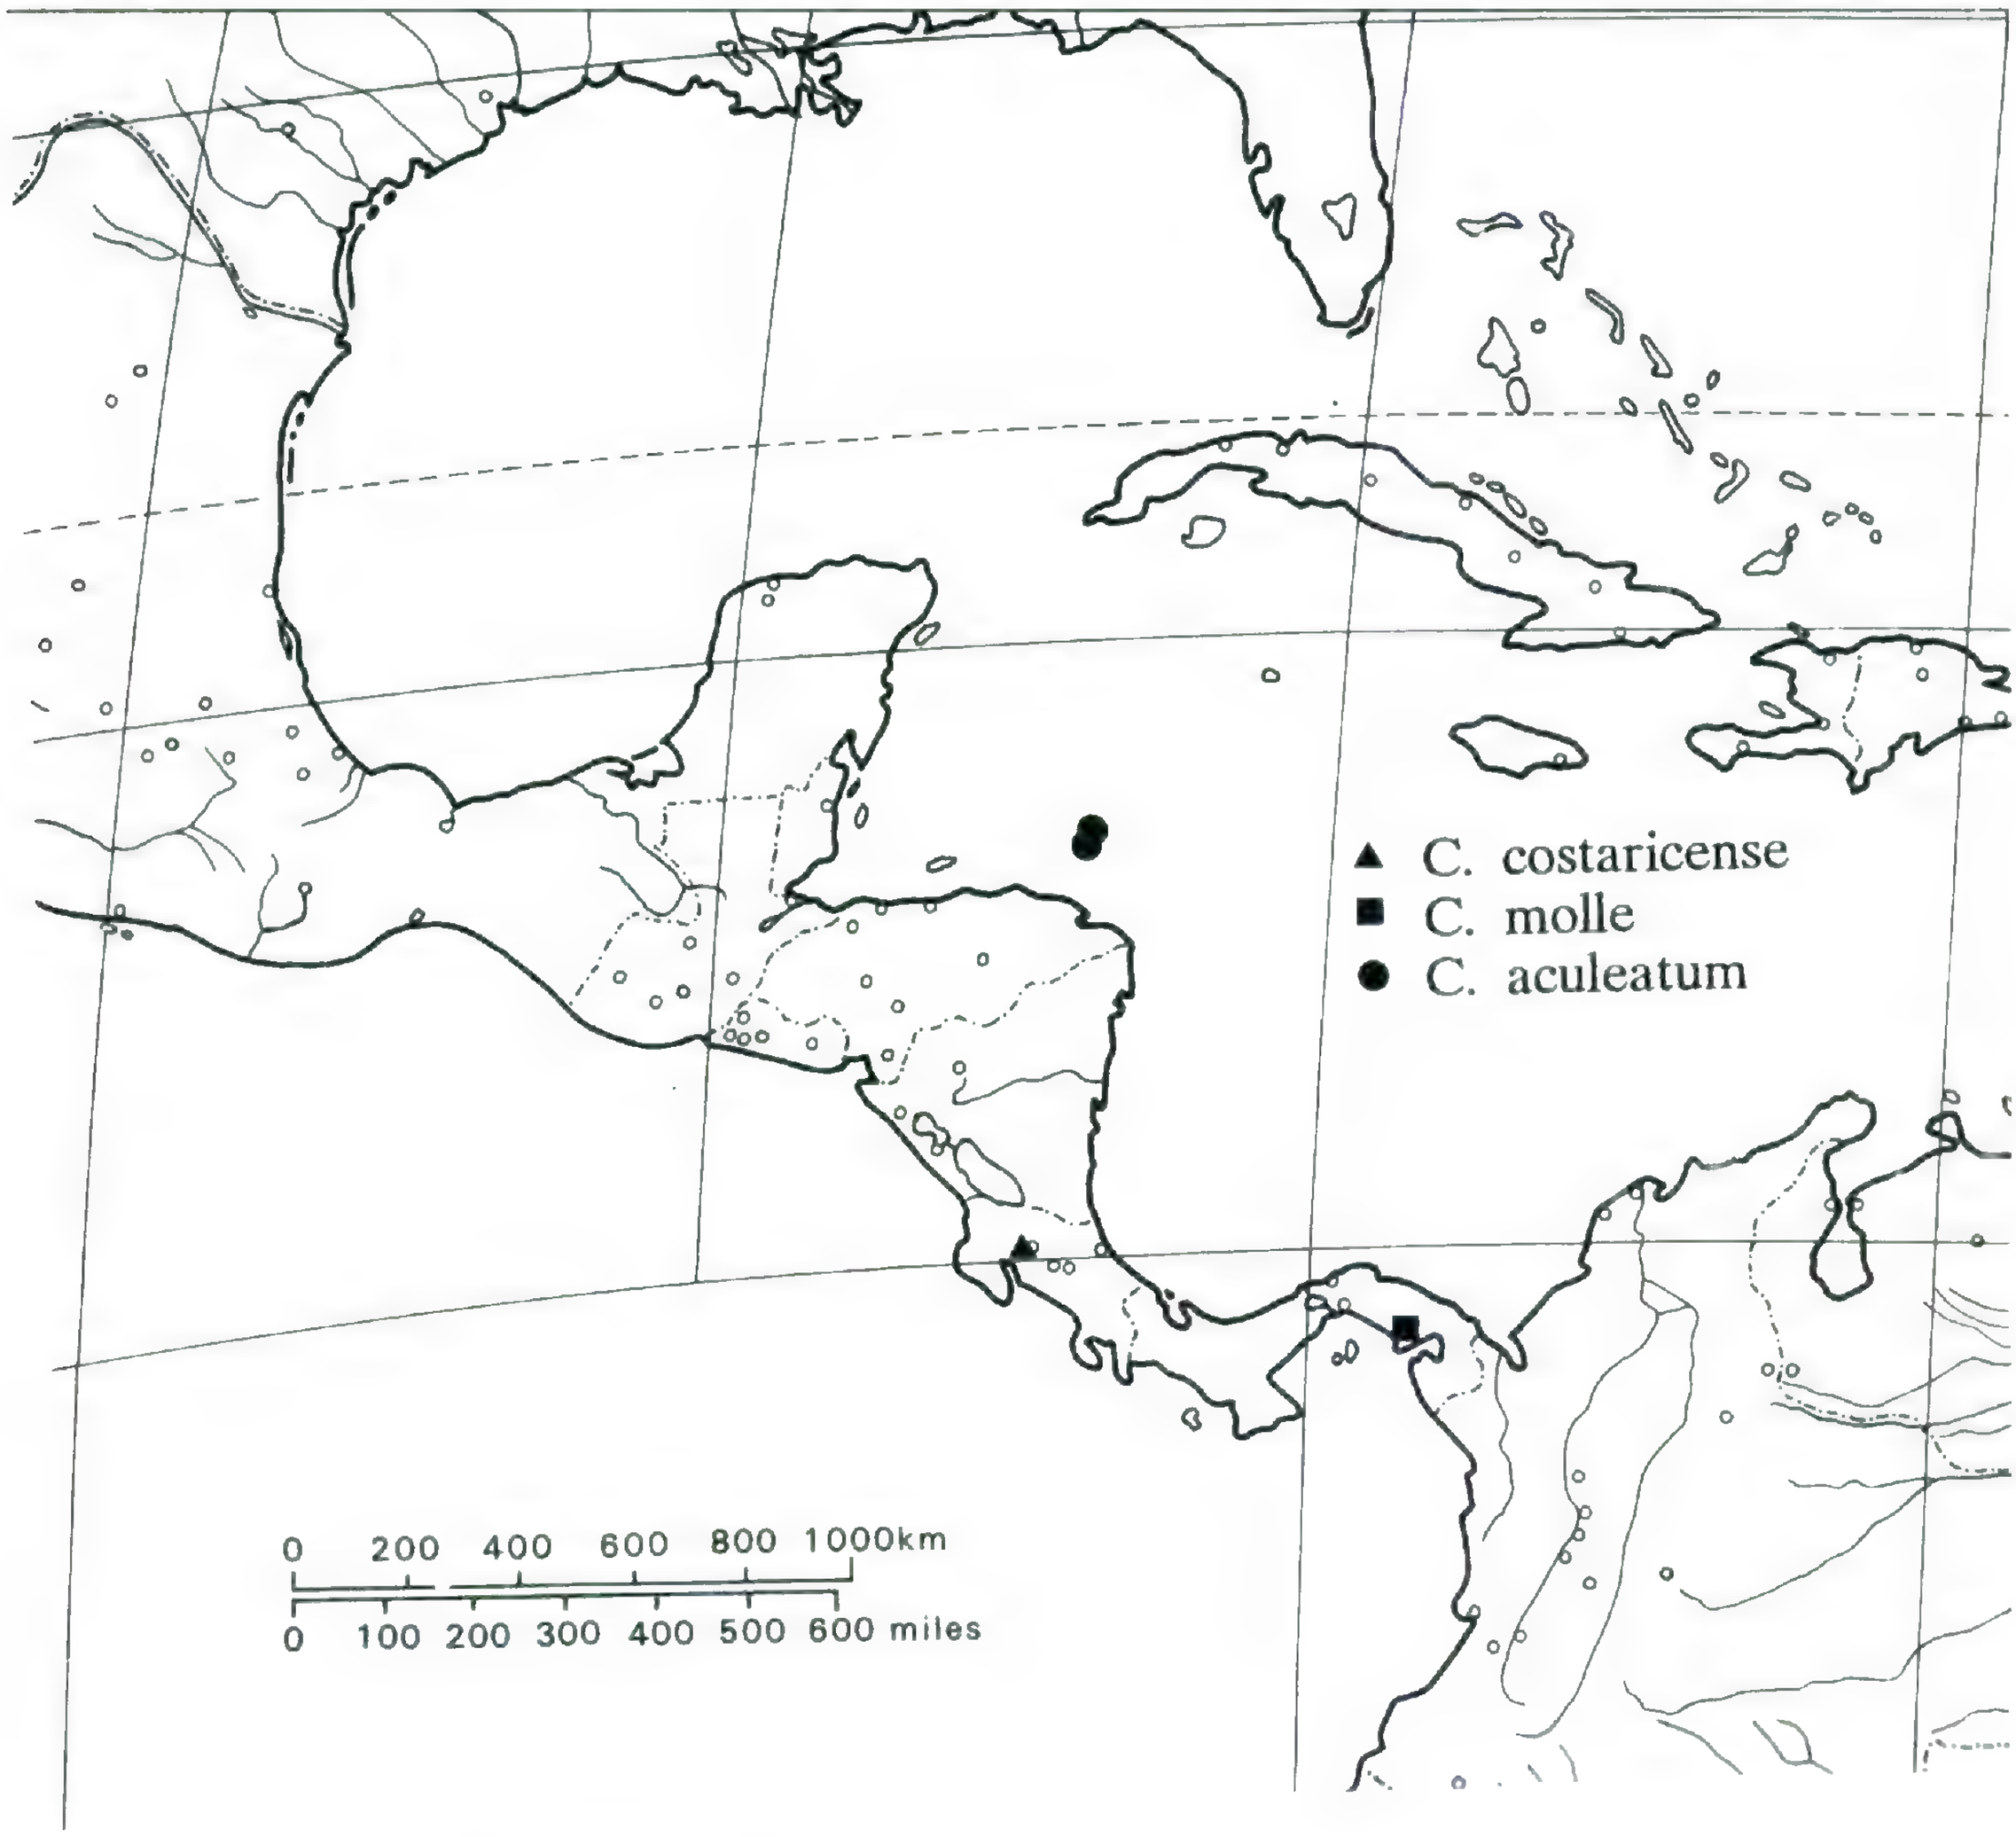

FIGURE 2. Distribution of *Clerodendrum costaricense*, *C. molle*, and *C. aculeatum* in Mesoamerica.

*floridanus* (Buckley), and *Conomyrma* sp. The foregoing observation, and especially the presence in some species of hollow stems and/or extrafloral nectaries (see Elias, 1983), clearly show that ants are intimately involved with some *Clerodendrum* species.

## CHROMOSOME NUMBERS

The chromosome numbers of the genus *Clerodendrum* are largely unknown. According to general chromosome indices (Cave, 1959, 1964; Bolkhovskikh et al., 1969; Moore, 1973; Kumar & Subramanian, 1987; Goldblatt, 1981, 1984, 1988), only 26 species and varieties have been studied to date, out of more than 560 species and varieties reported for the genus. Because *Clerodendrum* is mainly a paleotropical genus, most of the reports are from Old World taxa, among which are some of the species cultivated as ornamentals in Mesoamerica. Almost 50% of the species that are either cultivated or native in Mesoamerica have known chromosome numbers. Because of the poor cytological data on the genus there is not total agreement among researchers on the basic chromosome number. Thus, according to Moldenke (1985), the base chromosome number is $x = 12$ or 23; Raman & Kesavan (1963), $x = 15, 26$; and Mehra & Bawa (1969), $x = 12, 13$. It is at least clear that chromosome number in the genus is variable, ranging from $2n = 24$ in *C. aculeatum* to $2n = 184$ in *C. ugandense*.

## USES

The most popular use of *Clerodendrum* species worldwide is as ornamental plants. All of the Mesoamerican species except *C. costaricense* have

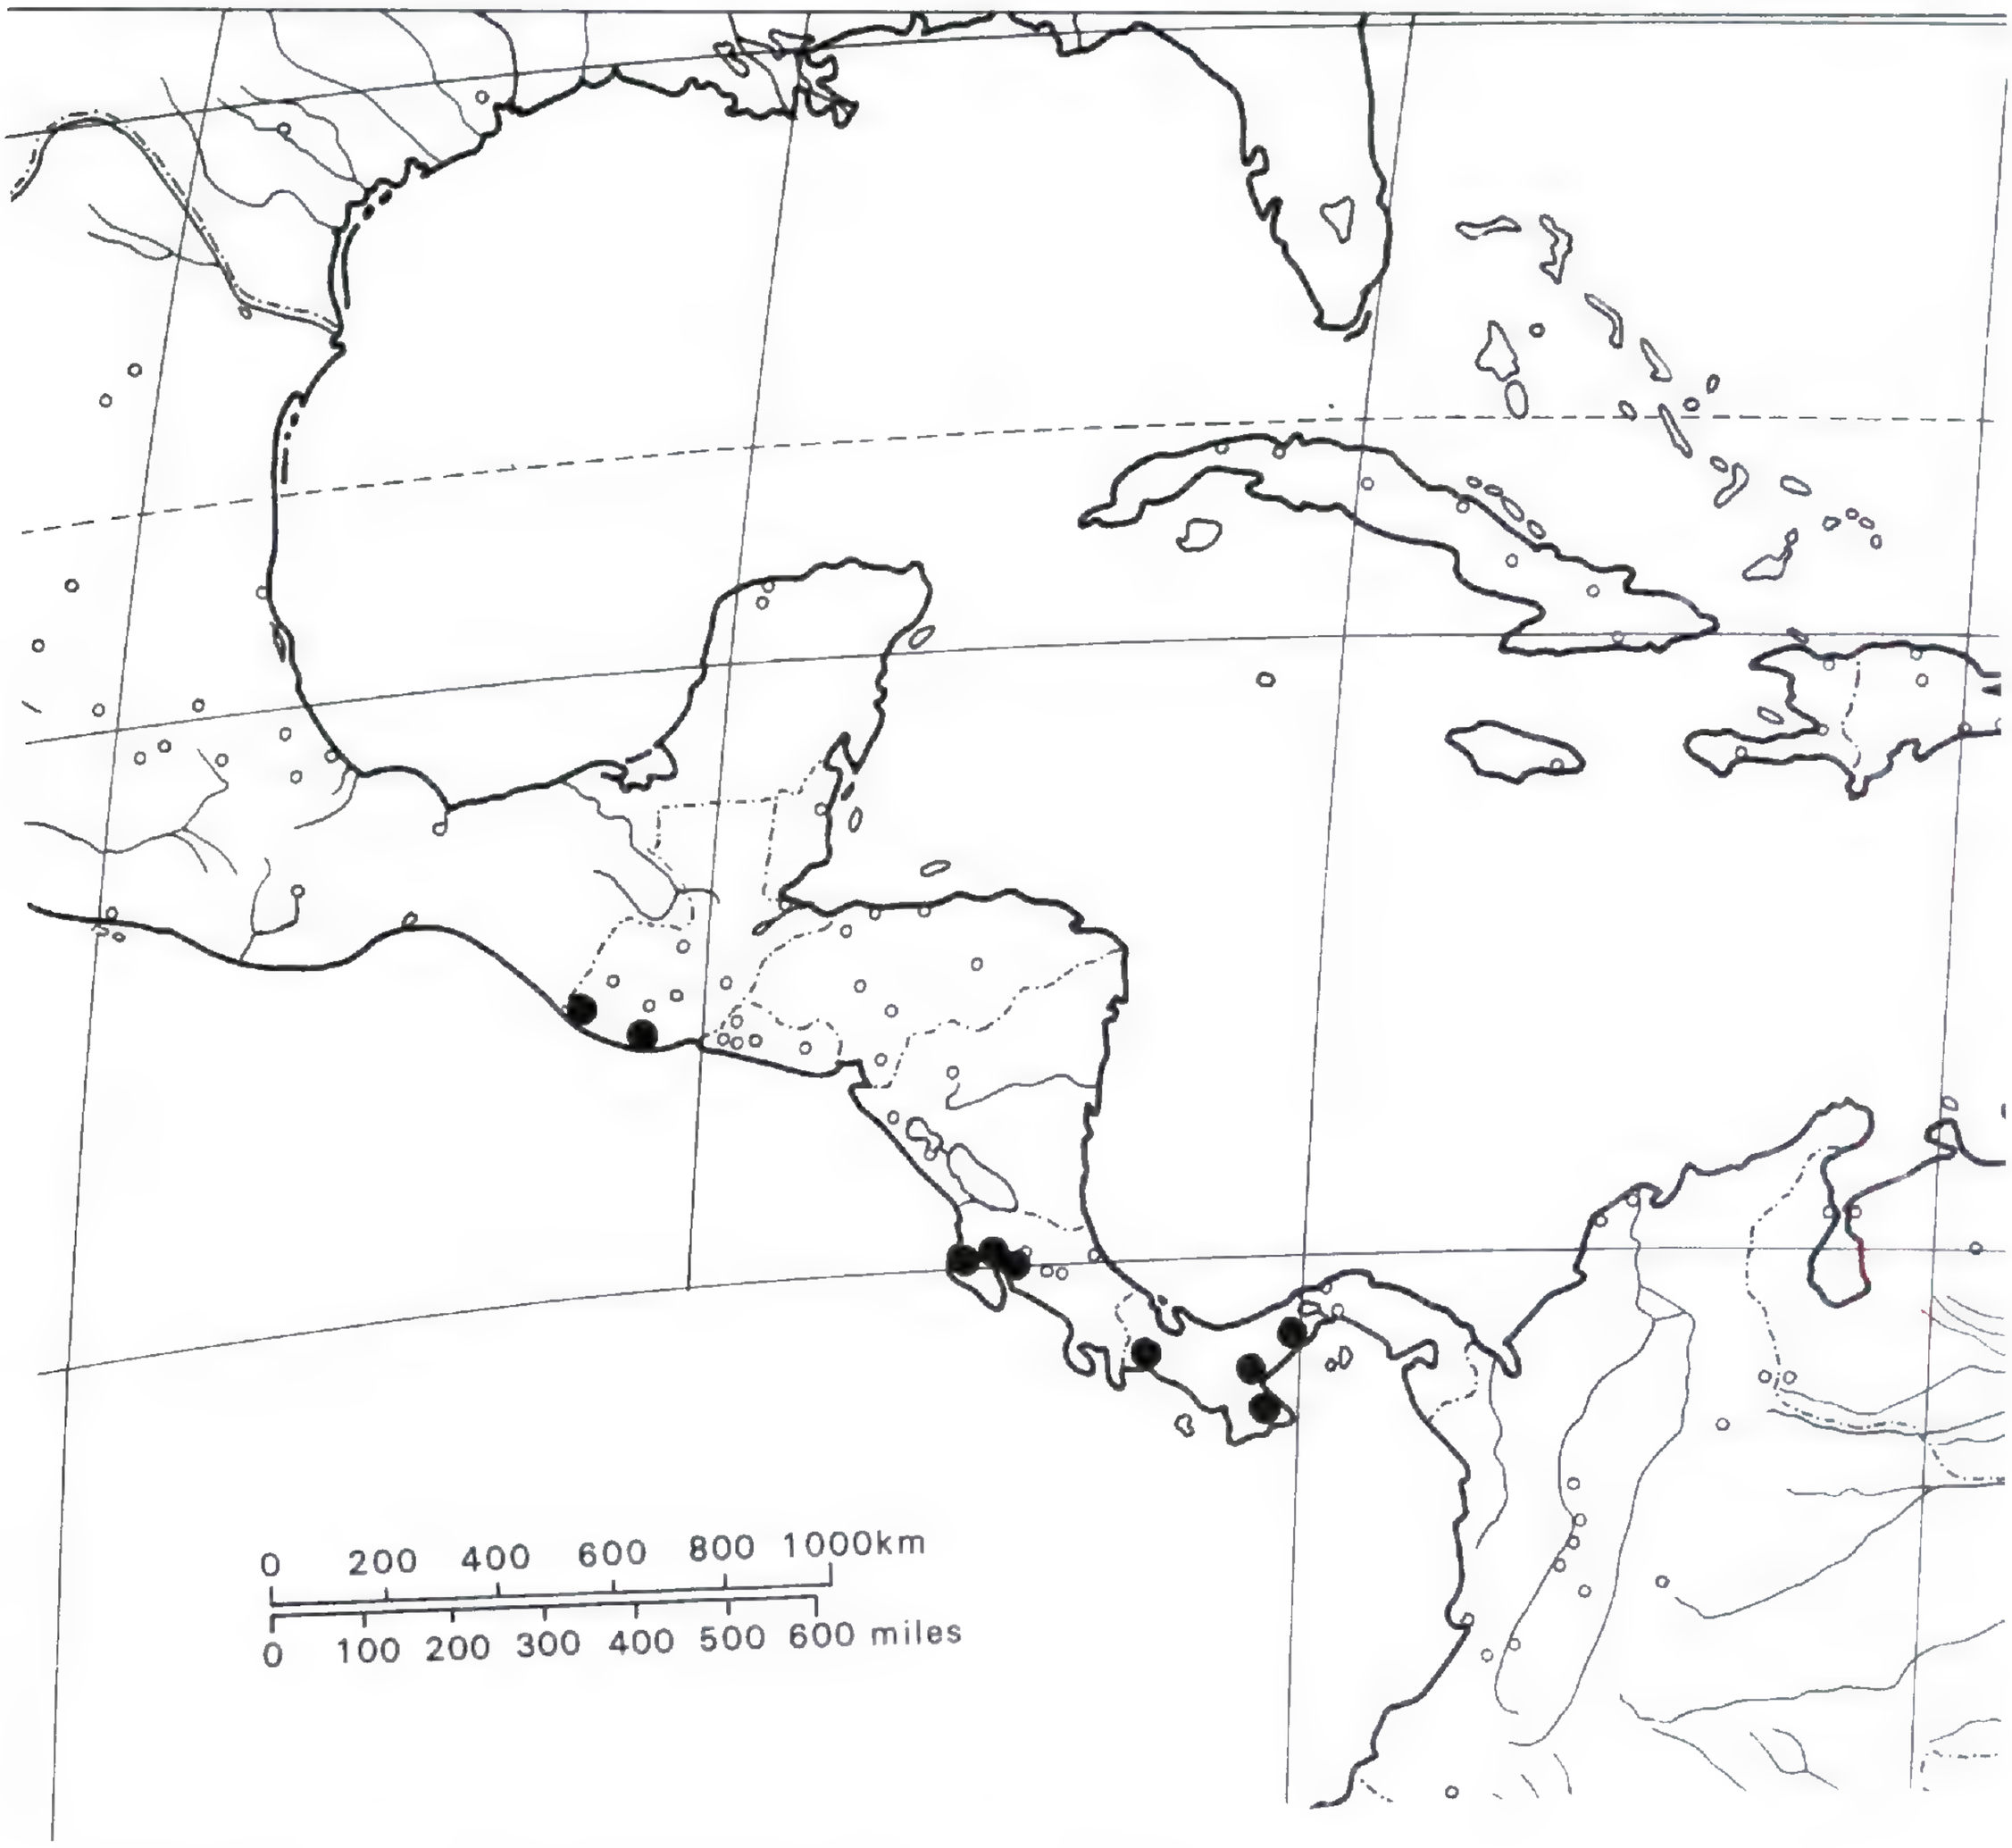

FIGURE 3. Distribution of *Clerodendrum pittieri* in Mesoamerica.

been planted ornamentally at one time or another. *Clerodendrum thomsonae* and *C. philippinum* are reported as ornamentals in Costa Rica (Pittier, 1978), and these two species plus *C. umbellatum* and *C. paniculatum* are cultivated as ornamentals in Nicaragua (pers. obs.). Molina (1975) listed seven species of ornamental *Clerodendrum* in Honduras; at least four species are cultivated as ornamentals in El Salvador (Standley & Calderón, 1941); and Gibson (1970) reported *C. philippinum* as one of the common ornamentals in Central America.

The folk use of the New World species of *Clerodendrum* is limited. In Yucatan, Mexico, the leaves of *C. ligustrinum* are used as a diuretic, even in the case of kidney stones (Mendieta & Del Amo, 1981). In Veracruz, Mexico, a leaf infusion is applied to snake-bites (Del Amo, 1979). In Petén, Guatemala, the leaves are also used in cooking to flavor fish (Gibson, 1970).

*Clerodendrum* is also important in having chemical compounds that may be used in medicine and industry. Gibbs (1974) reported that several species of *Clerodendrum* have D-manitol, saponins, tannins, cyanogenic (glycosides), quinones, and steroles.

## SYSTEMATIC TREATMENT

**Clerodendrum** L., Sp. Pl. ed. 1, 2: 637. 1753. TYPE; *Clerodendrum infortunatum* L. (Linn-810.1, microfiche, MO).

*Ovieda* L., Sp. Pl. ed. 1, 2: 637. 1753. TYPE: *Ovieda mitis* L. (Linn-807.1, microfiche, MO).

*Volkameria* L., Sp. Pl. ed. 1, 2: 637. 1753. TYPE: *Volkameria aculeata* L. (Linn-809.1, microfiche, MO).

*Volkmannia* Jacq., Pl. Hort. Schoenbr. 3: 48, pl. 338. 1798. TYPE: *Volkmannia japonica* Jacq. (type illustration ibid).

*Cornacchinia* Savi, Mem. Mat. Fis. Soc. Ital. Sci. Modena, Pt. Mem. Fis. 21: 184. pl. 7. 1837. TYPE: *Cornacchinia fragiformis* Savi (type illustration ibid).

Mostly shrubs, often scandent (arborescent in some species of the Old World), rarely herbaceous, unarmed, rarely the petiole base spinescent, glabrous or variously pubescent; branches usually tetragonal, sometimes medullose or hollow; nodes annulate sometimes with a band of hairs; leaf scars often prominent. Leaves simple, decussate-opposite or ternate, sometimes apically clustered, entire or variously dentate, sometimes lobed, mostly petiolate, glabrous or pubescent, often punctate beneath. Inflorescences cymose, cymes mostly loose-flowered (dense and capitate in some species of the Old World), pedunculate in the upper leaf axils, paniculate at the apex of the branches, often aggregate in terminal corymbs. Flowers actinomorphic or zygomorphic, often showy, perfect, hypogynous; calyx gamosepalous, green, sometimes the same color as the corolla, campanulate to tubular, sometimes inflated, the rim truncate to 5-toothed, often wide-spreading or accrescent with age; corolla gamopetalous, mostly hypocrateriform, usually purple, pink, red, or white, tube straight, sometimes incurved, limb 5-lobed, mostly subactinomorphic (plants bilabiate in some species of the Old World); stamens 4, didynamous, attached to the corolla tube, usually long-exserted; anthers glabrous, ovoid, 2-thecate, mostly basally attached, opening by longitudinal slits; pollen grains 3–6 colpate, tectum with echinate processes; ovary superior, 2-carpelled, imperfectly 4-locular, globose or oblong, glabrous, each locule 1-ovulate, ovules pendulous, laterally attached, hemianatropous; style terminal, filiform; stigma shortly bifurcate, sometimes globose. Fruit with calyx persistent, subtending or enclosing the fruit, sometimes colored; fruit drupaceous, often 4-sulcate, often brightly colored or black when mature, usually separating into 4 pyrenes or these sometimes united in pairs, by abortion sometimes 1–3 seeded; seeds oblong, endosperm absent; chromosome numbers: $x = 12$ or 23 (Darlington & Janaki, 1945; Darlington & Wylie, 1955; Hsu, 1968), $2n = 24–184$.

KEY TO SPECIES OF *CLERODENDRUM* IN MESOAMERICA

1a. Flowers pink, white, red, or purple, if white with the stigma globose; calyx always glabrous when flowers are pink; leaf scars never spinescent; plants cultivated, sometimes naturalized.
  2a. The largest leaves more than 15 cm long.
    3a. Inflorescences cymose, corymbose, 3–9 cm long.
      4a. Calyx 3 5 mm long; corolla tube 1.5–2.5 cm long (Fig. 4A) ..... 1. *C. bungei*
      4b. Calyx 1–1.5 cm long; corolla tube 1–1.5 cm long (Fig. 4B) ..... 2. *C. philippinum*
    3b. Inflorescences paniculate, 8–40 cm long.
      5a. Leaves not lobed.
        6a. Leaves glabrous.
          7a. Margins of leaves crenate, appressed teeth lacking; calyx 3–4 mm long ..... 3. *C. intermedium*
          7b. Leaves margin serrate with appressed teeth; calyx 8–16 mm long ..... 4. *C. japonicum*
        6b. Leaves pubescent ..... 5. *C. speciosissimum*
      5b. Leaves 3-lobed ..... 6. *C. paniculatum*
  2b. The largest leaves less than 15 cm long.
    8a. Corolla white to greenish white.
      9a. Corolla tube ca. 1.5 cm long; petioles 0.3–1 cm long ..... 7. *C. wallichii*
      9b. Corolla tube ca. 9 mm long; petioles 1–2.5 cm long ..... 8. *C. glabrum*
    8b. Corolla dark red to pink.
      10a. Calyx globose, 15 20 mm long, calyx lobes 1–1.8 cm long (Fig. 4C) ..... 9. *C. thomsonae*
      10b. Calyx campanulate, not globose, 7 13 mm long, calyx lobes 5–10 mm long (Fig. 4D) ..... 10. *C. umbellatum*

1b. Flowers pink, white, or yellowish, if white with the stigma bifid, not capitate; calyx pubescent, if glabrous with the leaf scars spinescent and flowers pink; plants native.
  11a. The largest leaves more than 4.5 cm long; leaf scars elevated but not spinescent.
    12a. Calyx glabrous; corolla tube ca. 1.2 cm long.
      13a. Leaves more than 10 cm long; calyx ellipsoid ..... 11. *C. costaricense*
      13b. Leaves less than 10 cm long; calyx campanulate.
        14a. Leaves decussate-opposite, glabrous beneath ..... 12. *C. ligustrinum*
        14b. Leaves ternate, pubescent beneath ..... 12a. *C. ligustrinum* var. *nicaraguense*
    12b. Calyx pubescent; corolla tube 1.8–2.5 cm long ..... 13. *C. molle*
  11b. The largest leaves less than 4.5 cm long; leaf scars spinescent.
    15a. Leaf scars spine-tipped; calyx lobed, pubescent; fruit subspheric ..... 14. *C. aculeatum*
    15b. Leaf scars not spine-tipped; calyx truncate, glabrous; fruit obovate ..... 15. *C. pittieri*

FIGURE 4. Inflorescence of:—A. *Clerodendrum bungei* Steudel (*Maxwell 94*);—B. *C. philippinum* Schauer (*Frye & Frye 2647*);—C. *C. thomsonae* Balf. f. (*Calderón 622*);—D. *C. umbellatum* Poiret (*Molina 10350*).

**1. Clerodendrum bungei** Steudel, Nomencl. Bot. ed. 2, 1: 382. 1840. *Clerodendrum foetidum* Bunge, Enum. Pl. China Bor. 52. 1833, non D. Don, 1825. TYPE: China, *Bunge 296* (holotype, LE not seen).

Shrub to 3 m tall; branchlets medullose, subterete or tetragonal, puberulent, lenticellate; leaf scars elevated. Leaves decussate-opposite, with an unpleasant odor when crushed; blade deltate-ovate or elliptic, 5–20 cm long, 3.5–15 cm wide, base truncate or acute, often decurrent, apex acute or acuminate, margin coarsely dentate, teeth often apiculate, puberulent, punctate beneath, often with glandular hairs on both surfaces, usually with discoid glands near the base beneath; midrib puberulent, secondaries 3–5 pairs; petioles 2–14.5 cm long, glabrous. Inflorescences cymose, terminal, rarely supra-axillary, subcapitate, corymbose 4–9 cm long, 3–12 cm wide, many-flowered, showy, puberulent; peduncles, 0–5 cm long; pedicels 1–6 mm long. Flowers usually fragrant; calyx tubular or campanulate, 3–5 mm long, outside glabrous and punctate, sometimes with a few disk-shaped glands, 5-lobed, lobes ovate, 1–3 mm long, acute or acuminate; corolla hypocrateriform or infundibular, usually red or rose to rose-purple, glabrous, 1.5–2.5 cm long, ca. 5 times as long as the calyx, limb 5-lobed, 1–1.5 cm wide, lobes oblong-ovate, 4–7 mm long; stamens 4, filaments long-exserted, to ca. 8 mm beyond the throat of the corolla tube, 1.2–1.4 cm long; ovary globose, style 2.8–3 cm long, exserted, shorter than or equal to the stamens. Fruit not seen; chromosome number: $2n = 108$ (Bolkhovskikh et al., 1969).

*Distribution and habitat.* This species occurs in Asia from China to northern India; it is cultivated worldwide and naturalized in tropical and subtropical regions. In Mesoamerica it has been collected in Mexico and El Salvador. *Clerodendrum bungei* is found on clay, limestone, or rocky soil, moist pastures, or frequently on oak-covered slopes, at altitudes up to 2,500 m.

*Vernacular names and uses.* "Bocamelia," "hortensia." The most important use is as an ornamental plant. The whole plant is decocted for lung weakness and cough (Duke & Ayensu, 1985).

*Note. Clerodendrum bungei* is frequently misidentified as *C. philippinum*. These two species can be separated using the length of the corolla in relation to the calyx. The corolla tube in *C. philippinum* only slightly exceeds the calyx in length, whereas the corolla tube in *C. bungei* is several times longer than the calyx. The holotype of *C. bungei* is probably deposited in LE. Although de Candolle (1880) and Sayre (1975) stated that the type may be in P, S. Barrier informed me that it is not in Paris.

*Selected specimens examined.* MEXICO. CHIAPAS: N end of San Cristóbal de las Casas, 2,100 m, 6 July 1964, *Breedlove 6055* (ENCB, F); W of Tenejapa center along the trail to Paraíso, 2,100 m, 4 Aug. 1964, *Breedlove 6837* (CAS, ENCB, MICH); along Mexican highway 190, 20 mi. NW of Comitán de Domínguez, 2,000 m, 23 June 1965, *Breedlove 10440* (CAS, ENCB, F, MICH, TEX, US); La Esperanza, Escuintla, 14 July 1947, *Matuda 16708* (F, MEXU). PUEBLA: ca. 2 mi. N of Teziutlan off road 125, 1,600 m, 27 June 1965. EL SALVADOR. SAN SALVADOR: cultivated in gardens, 1922, *Calderón 731* (US).

**2. Clerodendrum philippinum** Schauer in DC., Prodr. 11: 667 (as "*Clerodendron*"). 1847. TYPE: Philippine Islands, *Cuming 1096* (lectotype, designated by Howard & Powell (1968), GH).

*Volkmannia japonica* Jacq., Pl. Hort. Schoenbr. 3: 48, pl. 338. 1798. TYPE ILLUSTRATION: Japan, ibid, pl. 338.

*Clerodendrum fragrans* var. *multiplex* Sweet, Hort. Brit., ed. 1, 322. 1826. TYPE ILLUSTRATION: Curtis, Bot. Mag, 43: pl. 1834. 1816.

*Clerodendrum fragrans* var. *pleniflora* Schauer in DC., Prodr. 11: 666. 1847. TYPE: Martinique, *collector unknown s.n.* (holotype, G-DC 1908. 11: 666. 30, microfiche, MO).

*Clerodendrum philippinum* var. *subfertile* Mold., Phytologia 25: 368. 1973. TYPE: Sumatra, *Boeea 8394* (holotype, MICH not seen).

Shrub to 2 m tall; mostly reproducing vegetatively; branches medullose, angulated, puberulent, lenticellate; leaf scars often elevated. Leaves decussate-opposite or apically clustered; blade broadly ovate, 6–29 cm long, 5–28 cm wide, base cordate to subtruncate, often subcuneate, apex acute, margins coarsely serrate or sometimes the teeth apiculate, lightly strigillose-pubescent on both surfaces, usually more densely so on the venation beneath, sometimes with discoid glands near the base beneath; midrib glabrous, secondaries 3–5 pairs; petioles 2–20 cm long, puberulent. Inflorescences cymose, terminal, corymbose, 3–6 cm long, 4–9 cm wide, densely puberulent; peduncle 0–2 cm long; pedicels 1–5 mm long; bracts and bracteoles foliaceous 1–3 cm long. Flowers fragrant, often sterile; calyx campanulate, 1–1.5 cm long, sometimes with white blotches at or near the margins, sparsely strigillose-puberulent, outside with scattered disk-shaped glands, 5-lobed, lobes lanceolate, 4–10 mm long; corolla often "doubled," hypocrateriform, white to pink, glabrous, tube ampliate, 1–1.5 cm long, limb 5-lobed, 2 cm wide,

stamens and pistils often all modified into supernumerary petals; chromosome number: $2n = 46$ or 52 (Kumar & Subramanian, 1987).

*Distribution and habitat.* The original range of *Clerodendrum philippinum* is obscure, but it is likely native to Southern China to southern tropical Asia. It is cultivated and naturalized in tropical and subtropical regions worldwide. In Mesoamerica it has been collected from Mexico to Panama. This species is found in pastures, roadside embankments, riverbanks, open hillsides, slopes with *Quercus* and *Pinus*, and in disturbed high forest, at altitudes up to 2,100 m.

*Vernacular names and uses.* "Bocamelia," "flor de concha," "jasmín de noche," "mil flores," "misteriosa olorosa," "spanish jasmine," "verbena," and "viuda alegre." This species is one of the most common ornamentals of Mesoamerican gardens.

*Note.* The nomenclature of this species has been very confused. In 1804 Ventenat described *Volkameria fragrans* (*Clerodendrum philippinum*); he stated that this species was cultivated at the gardens in Paris and known as *Clerodendrum fragrans* and *Volkameria japonica*. But *Volkameria japonica* could not be used as a basionym in *Clerodendrum* for the plants now treated under *C. philippinum* because the epithet *japonica* was already occupied (Thunberg, 1780). *Clerodendrum fragrans* was published by Ventenat in synonymy, and therefore it is not a validly published name. *Clerodendrum fragrans* Willd., was illegitimate as published by Willdenow (1809) because he did not use Jacquin's type (Dan Nicolson, pers. comm.). To solve this problem, Howard & Powell (1968) designated the earliest valid name, *Clerodendrum philippinum* Schauer (1847).

*Selected specimens examined.* MEXICO. CHIAPAS: 8 km E of Las Margaritas, 1,700 m, 15 Sep. 1974, *Breedlove 37852* (MEXU). Hidalgo: Santa Ana, on Pan American Highway, 24 May 1939, *Frye & Frye 2647* (MO). BELIZE. EL CAYO: without precise locality, Mar.–June 1933, *Chanek 121* (F). GUATEMALA. BAJA VERAPAZ: El Niño Perdido, W of km 150/151, Aug. 1975, *Lundell & Contreras 19742* (F, MO). EL SALVADOR. SAN SALVADOR: vicinity of San Marcos, 5 Apr. 1922, *Standley 22796* (US). HONDURAS. CHOLUTECA: vicinity of San Marcos de Colon, 960–1,150 m, 12–22 Jan. 1949, *Standley 15796* (F). NICARAGUA. MATAGALPA: road to Senatorio de Aranjuéz, 1,000–1,400 m, 21 Feb. 1980, *Araquistain & Sandino 1401A* (MO). COSTA RICA. CARTAGO: Turrialba, 25 Aug. 1966, *Moldenke 1325* (TEX). PANAMA. BOCAS DEL TORO: vicinity of Almirante Bay, 19 Dec. 1938, *Von Wedel 15* (MO).

**3. Clerodendrum intermedium** Cham., Linnaea 7: "150" (i.e., 105). 1832. TYPE: Philippine Islands, *Cuming 481* (lectotype, here designated, L).

Shrub to 2 m tall; branches and branchlets tetragonal or subterete, medullose, puberulent, lenticellate; nodes annulate, the lower ones marked with a band of hairs; leaf scars slightly elevated. Leaves decussate-opposite; blades broadly ovate, 7–22 cm long, 6–20 cm wide, base deeply cordate, apex abruptly acute or acuminate, margin crenate, often abundantly light-dotted above and densely squamulose beneath; midrib puberulent, secondaries 5–7 pairs, the 2–4 lowest issuing palmately from the leaf base; petioles 2.5–23 cm long, lenticellate, strigillose. Inflorescence paniculate, terminal, 12–20 cm long, 8–18 cm wide, composed of 5–8 pairs of lax divaricate cymes, many-flowered; peduncles variable in length; pedicels 1–13 mm long, glabrous; bracts foliaceous, oblong-elliptic, the bracteoles and prophylls lanceolate to broadly linear, strigillose. Flowers with calyx campanulate, 3–4 mm long, granular lepidote, 5-lobed, lobes triangular-acuminate 2–3 mm long, equal to or longer than the tube; corolla hypocrateriform, bright red, outside puberulent and glandular, tube ca. 1.5 cm long, limb 5-lobed, ca. 1.3 cm wide, lobes oblong-ovate, 3–6 mm long, apically rounded-obtuse; stamens 4, long-exserted; filaments long-exserted ca. 2 cm beyond the throat of the corolla tube, 2.1–2.2 cm long; ovary oblong, style 2.3–2.5 cm long, exserted beyond the stamens. Fruit drupaceous, subtended by the calyx, 4–6 mm long, splitting into 2-bilobed, 2-seeded pyrenes at maturity; seed curved.

*Distribution and habitat.* *Clerodendrum intermedium* is native to the area between Taiwan and the Celebes and Sumatra islands. It is cultivated as an ornamental worldwide. In Mesoamerica it has only been collected in Honduras, which is the first report of this species in Mesoamerica.

*Vernacular names and uses.* In Honduras *Clerodendrum intermedium* is used as an ornamental plant. Gibbs (1974) reported the presence of cyanogens in the stem. Reis (1973) reported that the leaves of this species are made into a poultice and used for headaches.

*Note.* There are three species of *Clerodendrum* cultivated in Mesoamerica similar to *C. intermedium*. *Clerodendrum japonicum* has leaves similar to the leaves of *C. intermedium*, but the flowers are twice as big. *Clerodendrum intermedium* is also similar to *C. paniculatum* L. (not *C. paniculatum* Perrottet), but the latter has bigger inflorescences and lobulate leaves. The glabrate leaves of *C. intermedium* may be distinguished

easily from the pubescent leaves of the third species, *C. speciosissimum*. The type of this species is *Cuming 481*, as pointed out by Schauer (1847). He also commented that this material was deposited in B. This type seems to have been destroyed during the World War II, but there is one isotype in L, which is here designated as lectotype.

*Specimens examined.* HONDURAS. ATLANTIDA: Lancetilla valley, near Tela, 20–600 m, 6 Dec. 1927–20 Mar 1928, *Standley 56847* (F). MORAZAN: vicinity of El Zamorano, 800–850 m, 31 Aug. 1949, *Standley 23294* (F); El Zamorano, 800 m, 4 Oct. 1943, *Valerio 1092* (F).

**4. Clerodendrum japonicum** (Thunb.) Sweet, Hort. Brit., ed. 1, 322. 1826. *Volkameria japonica* Thunb., Nova Acta Regiae Soc. Sci. Upsal. 3: 208. 1780. TYPE: Japan, *Thunberg s.n.* (lectotype, here designated, UPS-14579, microfiche, MO).

*Clerodendrum coccineum* H. J. Lam, Verb. Malay. Archip. 296. 1919. TYPE: Java, *Buijsman 74* (holotype, BO not seen).

Shrub to 3 m tall; branches and branchlets tetragonal or subterete, medullose; puberulent, lenticellate; nodes annulate, the lower ones with a band of hairs. Leaves decussate-opposite; blades ovate, 10–30 cm long, 10–25 cm wide, base deeply cordate or auriculate, apex acute or acuminate, margin glandular serrate with appressed teeth, often light-dotted, puberulent on the venation and lipidote-squamulose beneath; midrib puberulent, secondaries 5–8 pairs, the 2–4 lower pairs issuing palmately from the leaf base, upper pairs ascending; petioles 2–15 cm long. Inflorescences paniculate, supra-axillary and terminal, 15–35 cm long, 13–30 cm wide; axillary peduncles 2–10 cm long; cymes 10–20 cm long, 4–10 cm wide, solitary in uppermost leaf axils; terminal panicles with 4–6 pairs of cymes; main peduncles 4–10 cm long, puberulent; pedicels 5–20 mm long; bracts foliaceous, a pair subtending each pair of cymes in the terminal panicles. Flowers with calyx campanulate, 8–16 mm long, puberulent, 5-lobed, lobes triangular-lanceolate, 10–14 mm long, apically acuminate; corolla hypocrateriform, deep red or scarlet, outside puberulent, tube curved, ca. 2 cm long, the limb 5-lobed, ca. 2.5 cm wide, lobes elliptic or oblong, 8–12 mm long; stamens 4, filaments long-exserted, ca. 3.5 cm beyond the throat of the corolla tube, 5–5.3 cm long; ovary oblong, style 6–7 cm long, exserted, shorter or equal to the stamens. Fruit not seen.

*Distribution and habitat.* *Clerodendrum japonicum* is native to Nepal, China, and upper Burma. It is also cultivated in tropical and subtropical regions and naturalized in Japan, Brazil, and Mexico. In Mexico this species is found in secondary deciduous forest, in secondary middle-elevation forest on rocky soil, and in coffee fields, at altitudes up to 1,300 m.

*Vernacular names and uses.* Floral bracts are chewed for hematuria and as a poultice for painful arthritis (Duke & Ayensu, 1985). In Mexico it is grown as an ornamental.

*Note.* There are three species of *Clerodendrum* cultivated in Mesoamerica that are similar to *C. japonicum* (see note under *C. intermedium*). The type material of *Clerodendrum japonicum* is deposited in UPS-Thunb. under the numbers 14579 and 14580. According to Roland Moberg, both numbers probably come from the same material divided into two sheets. However, neither of the two was designated as the holotype. The best specimen, 14579, should be regarded as the lectotype and 14580 as an isolectotype.

*Specimens examined.* MEXICO. OAXACA: Tuxtepec, 20 Apr. 1923, *Reko 4626* (US). VERACRUZ: 1 km E of Tenejapa, Hautusco–Cosmatepec road, 1,300 m, 2 Aug. 1979, *Avendaño & Calzada 445* (F); Tenochitlán, Colorado, Misantla–Tenochitlán road, 920 m, 27 Apr. 1976, *Hernández 175* (F, MO); Coetzala, by the road to Coetzapotitlán, 650 m, 25 Apr. 1976, *Vázquez 398* (F); Coetzala, by the road to Coetzapotitlán, 680 m, 25 Apr. 1976, *Velázquez 229* (F, MO).

**5. Clerodendrum speciosissimum** Morren, Hort. Belge 3: 322, pl. 68 (as "*Clerodendron*"). 1836. TYPE ILLUSTRATION: "Des Indes," cultivated by Baron Taffin at Van Geert Garden, Ghent, Belgium, pl. 68, ibid.

*Clerodendrum pulchrum* Fawcett in H. O. Forbes, Nat. Wand. East. Arch. 514. 1885. TYPE: Malaysia, *Forbes 3604* (holotype, BM not seen).

Shrub to 3 m tall; branches and branchlets tetragonal, usually medullose or hollow, puberulent, lenticellate; nodes annulate, sometimes with a band of hairs; leaf scars slightly prominent. Leaves decussate-opposite, blades broadly ovate, 8–25 cm long, 6–20 cm wide, base cordate, apex acute or short-acuminate, margin entire or irregularly crenate, above pubescent with whitish multicellular hairs, beneath with cinerous multicellular hairs, often with scattered disk-shaped glands along the midrib and secondaries beneath; midrib glabrous, secondaries 5–7 pairs, the two lower pairs issuing palmately from the leaf base, upper pairs arcuately

ascending; petioles 1.2–20 cm long, puberulent. Inflorescences terminal, panicle 8–35 cm long, 6–15 cm wide, composed of 5–13 pairs of cymes, puberulent; peduncles 3–6 cm long; pedicels 5–9 mm long, puberulent; bracts foliaceous, bracteoles and prophylls linear-setaceous, 1–5 mm long, puberulent. Flowers with calyx campanulate, 5–9 mm long, granular, puberulent, deeply 5-lobed, lobes ovate, 2–4 mm long; corolla hypocrateriform, red or scarlet, outside glandular-puberulent, tube 2–3 cm long, limb 5-lobed, 2–3 cm wide, 1.3–1.8 cm long; stamens 4, filaments long-exserted, ca. 2.5 cm beyond the throat of the corolla tube, 2.6–3 cm long; ovary oblongoid, style 4.5–5.5 cm long, exserted, shorter or equal to the stamens. Fruit drupaceous, subtended by the cupuliform calyx, globose, 5–8 mm long and wide, bilobed, separating into 4 pyrenes at maturity; chromosome number: $2n = 48$ (Bolkhovskikh et al., 1969).

*Distribution and habitat.* *Clerodendrum speciosissimum* occurs from Indonesia to the Caroline Islands and southeast to Tahiti and the Marquesas Islands. It is cultivated in most warm regions of the world. In Mesoamerica it has been collected from Mexico to Honduras.

*Vernacular names and uses.* The main use of this species is as an ornamental.

*Note.* There are three other species of *Clerodendrum* cultivated in Mesoamerica that greatly resemble *C. speciosissimum* (see note under *C. intermedium*). According to Moldenke & Moldenke (1983), the holotype of *C. speciosissimum* is a Morren collection taken from material given to him by Baron Taffin from the Van Geert Garden at Ghent, Belgium. In the original description, "August 1835" is reported as the date that the plant flowered for the first time, but a specimen either was not made or is missing. The type specimen should be in BR (fide Moldenke & Moldenke, 1983). However, according to Paul Bamps, curator of this herbarium, there are no Morren collections in BR (pers. comm.). Fortunately, the colored illustration (Morren, 1836: pl. 68) accompanying the original description is good enough to establish the identity of the species and may be considered as the type.

*Specimens examined.* MEXICO. CAMPECHE: Tixmucuy, road Holpechen–Tyxmucuy, 50 m, 11 Oct. 1980, *Calzada et al. 6724* (MEXU). YUCATAN: precise locality and date unknown, *Gaumer 909* (F, MO). GUATEMALA. ESCUINTLA: El Baúl Garden, 350 m, 3 Mar. 1921, *Tonduz 30* (F, US). EL SALVADOR. SAN SALVADOR: precise locality and date unknown, *Calderón 2533* (F); precise locality and date unknown, *Calderón 2544* (F, NY). HONDURAS. CORTES: San Pedro Sula, 80 m, 1951, *Pérez 12* (F).

**6. Clerodendrum paniculatum** L., Mant. Pl. 1: 90. 1767. TYPE: India, *collector unknown* (holotype, Linn 810.5, microfiche, MO).

*Clerodendrum splendidum* Wallich in Griffith, Not. Pl. Asiat. 4: 169. 1854. TYPE: India, *Wallich 1803* (holotype, K-Wall. 1803, microfiche, MO).

Shrub to 3 m tall; branches tetragonal, medullose or hollow, puberulent, lenticellate; nodes annulate, marked with a band of hairs; leaf scars slightly elevated. Leaves decussate-opposite; blades 3-lobed, ovate, 6–35 cm long, 6–30 cm wide, base deeply cordate and palmately veined, lobes apically acute to acuminate, central lobe larger and ovate, the others triangular, margin apiculate-denticulate to crenate-dentate or entire and with conspicuous glands mostly 3–10 mm apart, puberulent, often light-dotted above, densely squamose and punctate beneath; midrib puberulent, secondaries 5–7 pairs, the 2–4 lower pairs issuing palmately from the leaf base; petioles 1–40 cm long. Inflorescences terminal and sometimes axillary, terminal panicles 15–40 cm long and 13–35 cm wide; peduncles 2–10 cm long; pedicels 5–20 mm long. Flowers with calyx campanulate, 3–6 mm long, granular or puberulent, 5-lobed, lobes 2–4 mm long; corolla hypocrateriform, orange-red to scarlet, outside puberulent, tube 1–2 cm long, limb 5-lobed, ca. 1.2 cm wide, lobes oblong, 5–8 mm long; stamens 4, filaments long-exserted, ca. 2.2 cm beyond the throat of the corolla tube, 24–27 cm long; ovary oblong, style 3.5–4 cm long, exserted, shorter than the stamens. Fruit not seen.

*Distribution and habitat.* *Clerodendrum paniculatum* is native to the area from northern India eastward to Taiwan, south to Indonesia, and including the Andaman and Nicobar islands. It is cultivated in all warm regions of the world, where it is often naturalized. I have seen collections from Honduras, Nicaragua, Costa Rica, and Panama both from ornamentals and from plants naturalized into wet tropical forest, along streams, and in open grassy marshes at altitudes mostly below 500 m.

*Vernacular names and uses.* *Clerodendrum paniculatum* is used in Mesoamerica as an ornamental, especially cultivated along fencerows (Moldenke, 1973).

*Note.* There are three species of *Clerodendrum* cultivated in Mesoamerica that are similar to *C. paniculatum* (see note under *C. intermedium*). The holotype sheet (810.5) has the name Juan Bonge on it, but this may be a vernacular name. If this is the collector, it is an unknown one.

*Specimens examined.* HONDURAS. ATLANTIDA: Lancetilla Botanic Garden, 3 km SW from Tela, 10 m, 19 Apr. 1984, *Martínez 176* (TEFH). NICARAGUA. RIO SAN JUAN: San Juan del Norte, E side, 5 m, 2 Dec. 1982, *Araquistain 3371* (MO). COSTA RICA. HEREDIA: outskirts of Puerto Viejo or in the town itself, 13 July 1986, *Wilbur 39925* (DUKE). PANAMA. COLON: Barro Colorado Island, Canal Zone, in clearing at laboratory, 3 Dec. 1967, *Croat 4065* (MO).

**7. Clerodendrum wallichii** Merr., J. Arnold Arbor. 33: 220 (as "*Clerodendron*"). 1952. *Clerodendrum nutans* Wallich, Numer. List. 49, no. 1793. 1829. TYPE: Bangladesh, *Wallich 1793* (holotype, K; holotype and isotype on microfiche, MO), non W. Jack, 1820.

Shrub to 3 m tall; stems or branches usually simple and arching, medullose, tetragonal, puberulent; nodes annulate with a band of hairs; leaf scars slightly elevated. Leaves decussate-opposite or ternate; blades oblong-lanceolate, 4–13 cm long, 1–3 cm wide, basally acute or subcuneate, apex long-acuminate or caudate, margin entire or undulate, puberulent on both surfaces, punctate beneath; midrib glabrous, the secondaries 5–7 pairs; petioles 0.3–1 cm long, often slightly alate, puberulent. Inflorescences terminal, paniculate, puberulent, 9–30 cm long, 4–10 cm wide, with 6–10 pairs of divaricate cymes, each cyme 1–5-flowered; peduncles 1–4 cm long; pedicels 4–10 mm long; bracts foliaceous, subtending each pair of cymes. Flowers with calyx campanulate, slightly pentagonal, 0.5–1.2 cm long, puberulent, 5-lobed, lobes triangular-acuminate, 0.3–0.8 mm long; corolla hypocrateriform, white to greenish white, puberulent, tube ca. 1.5 cm long, limb 5-lobed, ca. 1.5 cm wide, lobes ovate, 0.9–1.3 cm long; stamens 4, filaments long-exserted, ca. 2.5 cm beyond the throat of the corolla tube, 2.3–2.8 cm long; ovary oblong, style 3–3.5 cm long, exserted, shorter than the stamens, stigma bifid, capitate. Fruit not seen.

*Distribution and habitat. Clerodendrum wallichii* is native to southern Asia, from the Himalayas to southern China, south to Indochina, the Nicobar Islands, and northeast to Pakistan. It is cultivated as an ornamental in all tropical and subtropical countries and in greenhouses elsewhere. In Mesoamerica it has been collected in Guatemala, El Salvador, and Costa Rica.

*Vernacular names and uses.* "Martinica" and "misteriosa." In Mesoamerica this species is only used as an ornamental.

*Note.* In Mesoamerica there are no other species similar to *Clerodendrum wallichii*. In addition, it is the only species of *Clerodendrum* known in Mesoamerica with a capitate-bifurcate stigma. The name *Clerodendrum nutans* was changed by Merrill in 1952 because this name had been used by Jack in 1820.

*Specimens examined.* GUATEMALA. ESCUINTLA: at S base of Volcán de Fuego, Finca Zapote, 780 m, 2 May 1939, *Standley 64521* (F). EL SALVADOR. SAN SALVADOR: vicinity of San Salvador, 650–850 m, 30 Mar.–24 Apr. 1922, *Standley 23645* (US). COSTA RICA. SAN JOSE: vicinity of San José, 1,130 m, 4 Dec.–10 Feb. 1926, *Standley 52498* (US).

**8. Clerodendrum glabrum** E. Meyer, Comm. Pl. Afr. Austr. 273 (as "*Clerodendron*"). 1838. TYPE: South Africa, *Drège s.n.* (holotype, G-DC 1906. 11: 661.2, microfiche, MO; isotype, MO).

*Ehretia triphylla* Hochst., Flora 27: 830. 1844. TYPE: South Africa, *Krauss 100* (isotype, MO).
*Clerodendrum ovale* Klotzsch in W. Peters, Naturw. Reise Mossambique 1: 257. 1861. TYPE: East Africa, *collector unknown s.n.* (holotype, B not seen).

Shrub to 3 m tall (sometimes a tree to 12 m tall in the Old World); branchlets solid, subterete or tetragonal, glabrous, lenticellate; leaf scars elevated. Leaves decussate-opposite or ternate with an unpleasant odor when crushed; blades elliptic-ovate to oblong, 3–8 cm long, 3–5 cm wide, base acute or short cuneate, apex acute or obtuse, margin entire, undulate, glabrous on both surfaces, densely punctate beneath; midrib puberulent, secondaries ca. 6 pairs, all ascending; petioles 1–2.5 cm long, lenticellate, glabrous. Inflorescences axillary in the uppermost axils and terminal, cymes opposite or whorled, many-flowered, puberulent, 7.5 cm long and 6 cm wide, several times bifurcate, terminal panicles corymbose; peduncles 1–3 cm long; pedicels 2–10 mm long, puberulent; bracts foliaceous, bracteoles and prophylls linear, 2–4 mm long. Flowers fragrant; calyx campanulate, 3–5 mm long, puberulent and glandular-lepidote, 5-lobed, lobes 1–3 mm long, shorter than the tube; corolla hypocrateriform, white, outside puberulent and glandular, tube ca. 9 mm long, limb 5-lobed, ca. 1 cm wide, lobes obovate, 3–4 mm long; stamens 4, filaments long-exserted, ca. 17 mm beyond the throat of the corolla tube, 2.5–2.7 cm long; ovary oblongoid, style 3–3.2 cm long, exserted, equal to or longer than the stamens. Fruit drupaceous, subtending calyx cupuliform, 5–9 mm long and wide, sulcate; seeds 1–2, oblong.

*Distribution and habitat. Clerodendrum glabrum* is native from Kenya to Angola and

throughout South Africa, and the Comoro and Seychelles islands. In Mesoamerica it has only been collected in Guatemala, which is the first report in Mesoamerica.

*Vernacular names and uses.* "Palo de perico." It is presumably an ornamental in Guatemala.

*Note.* The sole collection of *Clerodendrum glabrum* known from Mesoamerica seems to have been collected in an abandoned garden, since its accompanying label does not indicate that it was taken from a cultivated plant. The only similar species to *C. glabrum* in Mesoamerica is *C. ligustrinum*, from which it may be distinguished by the length of the calyx and corolla. The calyx and corolla of *C. ligustrinum* are twice as long as those of *C. glabrum*.

*Specimen examined.* GUATEMALA. GUATEMALA: San Juan Sacatepéquez, 1,480 m, *Morales 1874* (F, NY).

**9. Clerodendrum thomsonae** Balf. f., Edinburgh New Philos. J., ser. 2, 15: 233. pl. 2 (as "*Clerodendron*"). 1862. TYPE: from plant cultivated at the Edinburgh Botanical Garden sent by W. C. Thomson from Old Calabar, southern Nigeria, *collector unknown s.n.* (lectotype, here designated, E).

Shrub 2–2.5 m tall; branchlets tetragonal, medullose, puberulent, lenticellate; leaf scars often circular, corky, elevated. Leaves decussate-opposite; blades elliptic or elliptic-ovate, 4–13 cm long, 2–6 cm wide, base rounded or subacute, apex acuminate or short-acuminate, margin entire, ciliate, puberulent on both surfaces; midrib puberulent, secondaries 5–7 pairs, the lowest pair issuing palmately from the leaf base; petioles 0.5–3 cm long, puberulent. Inflorescences axillary, cymose, puberulent, 5–13 cm long, 5–15 cm wide, individual cymes 5–9 cm long, 4–8.5 cm wide, often trichotomous first and then dichotomous; peduncles 2–6 cm long, puberulent; bracteoles and prophylls linear, 2–11 mm long, puberulent. Flowers with calyx globose, coarse, ± pentagonal, 1.5–2 cm long, puberulent, 5-lobed, lobes ovate, 1–1.8 cm long, acuminate; corolla hypocrateriform, dark red to scarlet, externally glandular puberulent, internally puberulent, tube ca. 2.5 cm long, limb 5-lobed, ca. 1 cm wide, lobes oblong-elliptic, 5–9 mm long, obtuse or acute; stamens 4, filaments long-exserted, ca. 1.5 cm beyond the throat of the corolla tube, 2–2.2 cm long; ovary oblong, style filiform 2.9–3.2 cm long, exserted, shorter or equal to the stamens. Fruit drupaceous, covered by the calyx, 2.3 cm long, round or depressed-globose, 10–14 mm long and wide, glossy black, 2-bilobed; seeds oblong; chromosome number: $2n = 42$, 46, 48, or 50 (Bolkhovskikh et al., 1969).

*Distribution and habitat.* *Clerodendrum thomsonae* is a western African species that ranges from Senegal to Zaire. It has been collected throughout Mesoamerica.

*Vernacular names and uses.* "Arete de india," "arroz y frijoles," "bandera," "corazón sangrante," "fucsia," "lazo de amor," "matrimonios," "misteriosa," "moros y cristianos," "pasión de cristo," and "rice and beans." It is used in Mesoamerica exclusively as an ornamental.

*Note.* In Mesoamerica *Clerodendrum thomsonae* is not known to escape from cultivation. This species is very similar to *C. umbellatum*. However, the calyx in *C. thomsonae* is twice as large as in *C. umbellatum*. In addition, the calyx of *C. thomsonae* is coarser in texture than is that of *C. umbellatum*. The specimen in E, number 32/89 (1) was collected in January 1862, and the number 32/89 (2) was collected in July 1863. However, it is not known which is the holotype. Therefore, it is necessary to select a lectotype. The specimen 32/89 (1) should be regarded as a lectotype and 32/89 (2) as an isolectotype.

*Selected specimens examined.* MEXICO. CHIAPAS: Escuintla, 2 May 1948, *Matuda 17699* (F, MEXU). GUATEMALA. IZABAL: vicinity of Quirigua, 75–225 m, 15 31 May 1923, *Standley 24316* (GH, US). EL SALVADOR. SAN SALVADOR: vicinity of San Salvador, 650–850 m, 30 Mar. 24 Apr. 1922, *Standley 22377* (US); without specific locality, 1922, *Calderón 622* (MO). HONDURAS. COMAYAGUA: vicinity of Comayagua, 600 m, 12–23 Mar. 1947, *Standley & Chacón 5645* (F). NICARAGUA. ZELAYA: Bluefield, 29 Aug. 1948, *Long 208* (F). COSTA RICA. ALAJUELA: Ojo de Agua, 22 June 1946, *Echeverría 452* (CR). PANAMA. COLON: Canal Zone, 20–80 m, 13 Feb. 1911, *Pittier 2739* (US).

**10. Clerodendrum umbellatum** Poiret in Lam., Encycl. 5: 166. 1804. TYPE: West Africa, *Smeathman s.n.* (holotype, P-LA 6207. 510: I. 6, microfiche, MO; isotype, K).

*Clerodendrum hirsutum* G. Don, Edinburgh New Philos. J. 11:349. 1824. TYPE: West Africa, *Don s.n.* (holotype, BM not seen).

Shrub 0.2–3 m tall; branches and branchlets tetragonal, medullose or hollow, puberulent, sometimes lenticellate; leaf scars often elevated. Leaves decussate-opposite; blades ovate, elliptic or oblong, 4–13 cm long, 2–9 cm wide, base obtuse or subcordate, apex short-acuminate or acute, margin entire, impressed punctate beneath; midrib puberulent, secondaries 5–7 pairs, lower 1–2 pairs issuing palmately from the base; petioles 1–3 cm

long, puberulent. Inflorescences axillary, cymose, in a terminal panicle, 10–25 cm long, 12–24 cm wide, individual cymes several times branched, flowers 5–11 cm long, 3–12 cm wide, terminal panicles subumbellate; peduncles 2.5–6 cm long, puberulent; pedicels 5–15 mm long; bracts narrowly elliptic. Flowers fragrant; calyx campanulate, 0.7–1.3 cm long, puberulent, 5-lobed, lobes ovate or lanceolate, 0.5–1 cm long; corolla hypocrateriform, dark red to pink, with a pinkish or reddish throat, outside puberulent, tube ca. 2.2 cm long and ca. 1 cm wide, lobes obovate, 7–9 mm long; stamens 4, filaments long-exserted, ca. 2 cm beyond the throat of the corolla tube, 2.3–3 cm long; ovary oblong, style 3.8–4.2 cm long, exserted, equal to the stamens; chromosome number: $2n = 24$ or 48 (Goldblatt, 1981).

*Distribution and habitat.* *Clerodendrum umbellatum* is an African species that occurs from Senegal and Mali southeast to Kenya and Tanzania. In Mesoamerica this species has been collected in Mexico, Honduras, Nicaragua, and Panama; it may also be naturalized in the area. This is the first report of *C. umbellatum* in Mesoamerica.

*Vernacular names and uses.* *Clerodendrum umbellatum* is used as an ornamental, especially in fencerows.

*Note.* The label data indicate that this species sometimes escapes in Mesoamerica. An example is *Ramos 2* found growing in pine plantations in La Paz, Honduras.

*Selected specimens examined.* MEXICO. CHIAPAS: Huixtla, along the street of Huixtla, 30 m, 16 Jan. 1972, *Breedlove 23780* (CAS). TABASCO: Comalcalco, km 28 of the road Cardenas to Comalcalco, 25 Jan. 1979, *Cowan 1943* (TEX). HONDURAS. ATLANTIDA: La Lancetilla experimental station, 20 m, 17 Mar. 1962, *Molina 10350* (F, US). ISLAS DE LA BAHÍA: Isla de Guanaja, at sea level, 28 July 1984, *Nelson & Cruz 9032* (TEFH). LA PAZ: Sigamane, 5 km E of Marcala, 1,460 m, 26 June 1985, *Ramos* 2 (TEFH). NICARAGUA. MANAGUA: Península de Chiltepe, Comarca Alfonso González, 80–100 m, 3 July 1980, *Guzmán et al. 252* (MO). RIVAS: Isla de Ometepe, Balgue, 40–100 m, 18 Jan. 1987, *Moreno 19659* (MO). PANAMA. LOS SANTOS: Las Tablas, La Baja, 20 June 1971, *Carrasquilla 154* (F).

**11. Clerodendrum costaricense** Standley, Field Mus. Publ. Bot. 18: 1002 (as "*Clerodendron*"). 1938. TYPE: Costa Rica, *Smith H588* (holotype, F; isotype, MO; fragment and photo, NY).

Shrub to 5 m tall; branchlets and twigs medullose, subterete, lenticellate; leaf scars elevated. Leaves decussate-opposite; blades oblong-elliptic, 11–14 cm long, 6–9 cm wide, base obtuse, apex short-acuminate, margin entire, undulate and thickened, punctate beneath; midrib prominent, secondaries ca. 6 pairs; petioles 1–2 cm long, sparsely lenticellate. Inflorescences axillary, 3-flowered, glabrous; peduncles 3–6 cm long; pedicels 0.5–1 cm long, glabrate, bracts foliaceous, oblong-lanceolate, bracteoles linear-setaceous, 2–3 mm long, puberulent. Flowers with calyx ellipsoid, 10–12 mm long, glabrous, shortly lobed, lobes ovate, apically caudate-apiculate; corolla hypocrateriform, pale greenish yellow at anthesis, fading to brown, glabrous, the tube cylindric, ca. 1.2 cm long, the limb ca. 2 cm wide, the lobes spreading, oblong, as long as the tube, apically obtuse. Other floral parts not examined. Fruit unknown.

*Distribution and habitat.* *Clerodendrum costaricense* has only been collected in Alajuela, Costa Rica (Fig. 2). It was found in the Caribbean cloud forest climbing over vegetation at the edges of woodland, at 1,650 m.

*Vernacular names and uses.* None reported.

*Note.* The available material of this species is very poor, especially in reproductive structure. The specimens have only buds or incomplete flowers, and the description is accordingly incomplete.

*Specimen examined.* COSTA RICA. ALAJUELA: La Peña del Zarcero, 1,650 m, 4 Apr. 1938, *Smith H588* (F, MO, NY).

**12. Clerodendrum ligustrinum** (Jacq.) R. Br., in W. T. Aiton, Hortus Kew. ed. 2, 4: 64. 1812. *Volkameria ligustrina* Jacq., Coll. Suppl. 118, pl. 5, fig. 1. 1797. TYPE: material cultivated in Vienna, Austria, from "Mauritius island," plate 5, fig. 1, ibid.

*Clerodendrum culinare* Sessé & Mociño, Fl. Mexic., ed. 2, 2: 151. 1894. TYPE: Mexico, *collector unknown s.n.* (holotype, MA not seen).

*Clerodendrum fortunatum* Sessé & Mociño, Fl. Mexic., ed. 2, 2: 151. 1894. TYPE: Mexico, *collector unknown s.n.* (holotype, MA not seen).

*Clerodendrum inermis* Sessé & Mociño, Fl. Mexic. ed. 2, 2: 152. 1894. TYPE: Mexico, *collector unknown s.n.* (holotype, MA not seen).

*Clerodendrum mexicanum* Brandegee, Univ. Calif. Publ. Bot. 3: 39. 1909. TYPE: Mexico, *Purpus 3336* (isotypes, F, MO, NY, US).

Shrub to 5 m tall; branchlets subterete or tetragonal, medullose, puberulent, lenticellate; nodes annulate, often with band of hairs; leaf scars elevated. Leaves decussate-opposite, blades elliptic to lanceolate, 1.5–9 cm long, 0.6–5 cm wide, base acute or cuneate, apex subacuminate, margin entire, glabrous and densely punctate beneath; midrib prominent beneath, secondaries 5–7 pairs; petioles

FIGURE 5. *Clerodendrum ligustrinum* (Jacq.) R. Br. (*Palmer 407*).—A. Habit.—B. Flower.—C. Stamens.—D. Pistil.—E. Fruit.

5–10 mm long, puberulent. Inflorescences supraaxillary or rarely terminal, cymose, the cymes solitary, opposite, 3–7.5 cm long, 2–7 cm wide, usually only 3- or 4-flowered, often twice dichotomous and then 7-flowered, the terminal ones, when present, similar but usually smaller; peduncles 1.5–4 cm long; pedicels 3–10 mm long, puberulent; bracts foliaceous, caducous, bracteoles and prophylls linear, 1–6 mm. Flowers with calyx campanulate, 5–8 mm long, outside puberulent, 5-lobed, lobes lan-

ceolate or deltoid, 3–4 mm long; corolla hypocrateriform, white, outside resinous-punctate, internally slightly pubescent, tube slender, 1–2 cm long, limb 5-lobed, 1–1.3 cm wide, lobes oblong, 3–5 mm long; stamens 4, filaments long-exserted, ca. 2 cm beyond the throat of the corolla tube, 21–23 cm long; ovary oblong, style 2.8–3.1 cm long, equal to the stamens. Fruit drupaceous, subtending calyx cupuliform, subspheric, 8–12 mm long and wide, bilobed, splitting into two-seeded pyrenes at maturity; seeds obovate (Fig. 5).

*Distribution and habitat.* *Clerodendrum ligustrinum* occurs from northern Mexico to Nicaragua (Fig. 1). It is also cultivated as an ornamental in Mesoamerica and other parts of the New World, as well as in the Old World. This species has been reported from roadsides, creek and river banks, marshes and swamps, beach ridge forest, sandy bushy areas, secondary forests, and evergreen or subevergreen forests. It occurs from near sea level to 500 m.

*Vernacular names and uses.* "Arbol sagrado," "itsimte," "moste," "palo blanco cimarrón," and "snake-tree." It is used as an ornamental in Honduras; Sessé & Mociño (1894) and Gibson (1970) reported that the leaves of this species are used in Mexico and Guatemala in native cooking to flavor fish; Del Amo (1979) reported that a leaf infusion is applied to snake-bites; Mendieta & Del Amo (1981) reported this plant as a diuretic, even in the case of kidney stones.

*Note.* There are three species of *Clerodendrum* in Mesoamerica similar to *C. ligustrinum*: *Clerodendrum aculeatum*, *C. molle*, and *C. pittieri*. However, the calyx of *C. ligustrinum* is not pubescent as is the calyx of *C. molle*, nor is it truncate as is the calyx of *C. pittieri*. In addition, the leaf scars in *C. ligustrinum* are not as prominent as in *C. pittieri* and *C. molle*, nor spine-tipped as in *C. aculeatum*. This species was originally described (Jacquin, 1796), in error, as from Mauritius, based on material cultivated in Vienna. The plant may already have been cultivated on Mauritius and erroneously considered to be native by Jacquin. Another possibility is that the material originally came from Mesoamerica, and Jacquin mistakenly believed that it was from Mauritius. According to Harald Riedl, there is not herbarium voucher in W; Jacquin usually did not make herbarium vouchers of cultivated plants. Therefore, the name must be typified by reference to Jacquin's plate 5, figure 1. Fortunately, this illustration in Jacquin (1796) is adequate to establish the identity of this species.

*Selected specimens examined* MEXICO. CAMPECHE: 20 km E of Champotón, 27 Mar. 1982, *Cabrera 2286* (CAS). VERACRUZ: vicinity of Pueblo Viejo, 2 km S of Tampico, 23–31 May 1910 (*Palmer 407*). BELIZE. 5 mi. from Belize city, past international airport, 22 Mar. 1973, *Dwyer 10351* (MO). GUATEMALA. EL PETEN: La Libertad and vicinity, 19 Mar. 1934, *Aguilar 353* (F, MICH). HONDURAS. CHOLUTECA: vicinity of Choluteca, 20 m, 31 Oct.–9 Nov. 1949, *Standley 24599* (F, US). NICARAGUA. LEON: La Paz Centro, Km 59, new highway to León, 50 m, 13 June 1984, *Moreno 24218* (MO).

**12a. Clerodendrum ligustrinum** var. **nicaraguense** Mold., Phytologia 1: 416. 1940. TYPE: Nicaragua, *Chávez 227* (holotype, US).

This variety differs from the typical form of the species by having leaves and axillary cymes usually ternate and the leaf blades puberulent or pubescent beneath.

*Distribution and habitat.* It occurs from Honduras to Panama in dense wet forest, weedy fields, and bordering mangrove swamps, mostly below 900 m.

*Vernacular names and uses.* "Jasmín," and "si me miras te enamora." It is cultivated as an ornamental in Mesoamerica.

*Note.* A specimen from Chiapas, Mexico (*Breedlove 20913*: *C. ligustrinum*), was referred to this variety by Moldenke (1987) but is incorrectly attributed to this taxon.

*Selected specimens examined.* HONDURAS. CORTES: vicinity of La Lima, 30 m, 11–20 Apr. 1947, *Standley & Chacón 7249* (F). NICARAGUA. CHINANDEGA: vicinity of Chichigalpa, 90 m, 12–18 July 1947, *Standley 11488* (F, NY). ZELAYA: region of Braggman's Bluff, without date, *Englesing 120* (NY). COSTA RICA. LIMON: near Lamm Hotel, near sea level, 19 Oct. 1980, *Gómez 6048* (CR). PANAMA. BOCAS DEL TORO: Almirante out along the road to the Bomba, 15 Oct. 1965, *Blum 1350* (DUKE, MO). COLON: along ocean trail between Río Indio and Miguel de La Borda, at sea level, 7 July 1976, *Croat 36888* (MO).

**13. Clerodendrum molle** Kunth, Nov. Gen. Sp. 2: 244. 1817. TYPE: Ecuador, *Bonpland 3837* (holotype and isotype P-HB. 6209. 46: III. 1, microfiche, MO).

Shrub or small tree to 5 m tall; branchlets subterete or tetragonal, medullose, densely short pubescent, lenticellate; leaf scars prominent. Leaves decussate-opposite or ternate, blades elliptic, 1.5–5.5 cm long, 1–2.5 cm wide, base acute, apex acute, puberulent above, short-tomentose beneath, punctate beneath; midrib usually more densely puberulent than the blade above, secondaries 3–6 pairs; petioles 3–8 mm long, pubescent, the lowest

1–2 mm long, persisting as a corky protuberance after the blade has fallen. Inflorescences axillary or terminal, cymes ternate, solitary in each axil, 3–7 cm long, 1–4 cm wide, 3–9-flowered, pubescent; peduncles 1–3.7 cm long, pubescent; pedicels 1–7 mm long, densely pubescent; bracteoles and prophylls linear, ca. 1 mm long, densely pubescent. Flowers with calyx campanulate, 4–7 mm long, pubescent, 5-lobed, lobes ovate, 2–3 mm long; corolla hypocrateriform, white or pinkish, outside pubescent and resinous-punctate, internally slightly pubescent, tube 1.8–2.5 cm long, limb 5-lobed, 1–1.3 cm wide, lobes oblong, 2–3 mm long; stamens 4, filaments long-exserted, ca. 1.5 mm beyond the throat of the corolla tube, 15–20 mm long, anthers oblong; ovary oblongoid; style 3–3.3 cm long, equal to or longer than the stamens. Fruit not seen.

*Distribution.* *Clerodendrum molle* is native from Panama to Colombia, coastal Ecuador, and the Galápagos Islands. In Mesoamerica it is only known from Panama (Fig. 2). It is found mostly on the seashore and at lower elevations, especially on rocky coastline precipices, lava flows, and in open woodland on hillsides, from sea level to less than 500 m.

*Vernacular names and uses.* None reported in Mesoamerica.

*Note.* The Mesoamerican specimen was collected in the late 1700s or earliest 1800s. The specimen label indicates that the specimen was collected in Panama, and that is possible since the species occurs in coastal Ecuador; however, it is also possible that a label mixup occurred and it was actually collected in Ecuador, and not in Panama. There are three Mesoamerican species of *Clerodendrum* that resemble *C. molle* in habit and habitat (see note under *C. ligustrinum*).

*Specimen examined.* PANAMA. PANAMA: *Nee s.n.* (MA).

**14. Clerodendrum aculeatum** (L.) Schldl., Linnaea 6: 750. 1831. *Volkameria aculeata* L., Sp. Pl. ed. 1, 1: 637. 1753. TYPE: Jamaica, *Browne s.n.* (holotype, Linn-809.1, microfiche, MO).

*Clerodendrum aculeatum* var. *grandifolium* Kuntze, Revis. Gen. Pl. 2: 505. 1891. TYPE: St. Thomas, *collector unknown s.n.* (holotype, NY not seen).

Shrub to 2.5 m tall; branches, branchlets, and twigs subterete or tetragonal, medullose, appressed-pubescent, lenticellate, spinose; spines 2–7 mm long, ternate or opposite, borne on and subtending the nodes. Leaves decussate-opposite, ternate, or apically clustered, on the upper side of a spine; blade elliptic or lanceolate, 1–4 cm long, 0.3–1 cm wide (sometimes larger and wider in the West Indies), base acute or cuneate, usually mucronulate, glabrous on both surfaces, punctate beneath due to deeply sunken resinous peltate glands; midrib prominulous beneath, secondaries 3–7 pairs; petioles of the primary leaves with a very stout, ligneous spinescent base, 3–11 mm long, eventually breaking off obliquely ⅓ to ½ the distance from apex to base, the base persisting as a sharp, subulate-tipped spine, petioles of the small axillary leaves obsolete or very short and not spinescent. Inflorescences axillary, pedunculate, crowded at the apex or upper nodes of the branchlets and twigs, cymes solitary, 2–6 cm long, 1.5–3.5 cm wide, 3–7-flowered; peduncles 1–3.5 cm long, puberulent; pedicels 2–10 mm long, puberulent; bracts linear. Flowers cymose, slightly zygomorphic; calyx tubular or campanulate, 3–7 mm long, outside, usually pubescent, 5-lobed, lobes ovate, 2–3 mm long; corolla hypocrateriform or infundibular, white, outside resinous-punctate, inside slightly pubescent, tube slender, 1.3–2.3 cm long, limb 5-lobed, 1–1.5 cm wide, lobes oblong, 5–8 mm long, shorter than the tube; stamens 4, filaments much exserted, 2–3 cm long; ovary minute, style 3–3.2 cm long, much exserted and equal to the stamens. Fruit drupaceous, subtending calyx cupuliform, 5–10 mm long and wide, in age 4-lobed, splitting in 2-seeded pyrenes; seeds oblong; chromosome number: $n = 12$ (Cave, 1959, 1964).

*Distribution and habitat.* *Clerodendrum aculeatum* occurs in the West Indies from the Bahamas south to Barbados. It is planted and sometimes naturalized from Veracruz (Mexico) south to northern South America, and in the Old World (Moldenke, 1980). In Mesoamerica, it is known only from the Swan Islands, off Honduras, which is the first report for the species in Mesoamerica. It is often locally abundant and occurs in open grassland, dry scrub, limestone, swamplands, and beachside areas, mostly from sea level to 500 m.

*Vernacular names and uses.* None are reported in Mesoamerica. *Clerodendrum aculeatum* is used in living fencerows and medicinally in cases of gonorrhea; a decoction of the leaves is used as a cough remedy (Reis & Lipp, 1982).

*Note.* This species closely resembles *C. inerme* of Asia, *C. ligustrinum* and *C. pittieri* from Mesoamerica, and *C. molle* and *C. ternifolium* of South America in habit and habitat. However, *C. aculeatum* differs from these species in the very

sharp-tipped spine at the nodes. According to Fred Barrie, the Linnaeus specimen number 809.1 is the same specimen named by Browne (1756) "*Clerodendrum fruticosum, spinosum; foliis inferioribus confertis, superioribus oppositis; pedunculis tripartitis, trifloris, alaribus.*" Apparently, Linnaeus never saw actual material of this species until after he had published his binomial based on Browne's material mentioned above. Therefore, specimen 809.1, although not sent by Browne to Linnaeus until 1756, is presumably the basis for Browne's polynomial and for Linnaeus's epithet. Specimen 809.2, also identified as *Volkameria aculeata*, lacks spines and is probably *C. inerme* rather than *C. aculeatum*.

*Specimens examined.* HONDURAS. SWAN ISLANDS: Great Swan Island, surroundings of the military base, 17 May 1980, *Cruz & Espinal 263* (TEFH); without precise locality, 15–24 Aug. 1971, *Proctor 32509* (IJ, TEX); tropical wet forest, at sea level, 10 June 1986, *Nelson et al. 9770* (TEFH).

**15. Clerodendrum pittieri** Mold., Phytologia 1: 416. 1940. TYPE: Panama, *Pittier 4965* (holotype, US; isotype, F, MO).

Shrub to 3 m tall; branches and branchlets tetragonal, slightly flat at the nodes, medullose, with appressed hairs, lenticellate; leaf scars spinescent but not sharp-tipped. Leaves decussate-opposite, ternate, or sometimes clustered on reduced axillary twigs; blade lanceolate to elliptic, 0.7–4 cm long, 0.3–2.5 cm wide, base acute or cuneate, apex acute or obtuse, densely punctate beneath; midrib prominent beneath, secondaries 3–7 pairs; petioles with a ligneous subspinescent base, 1–8 mm long, eventually breaking off obliquely 1–2 mm from the base, the petioles of the axillary clustered leaves obsolete or very short and not spinescent. Inflorescences axillary, at the upper nodes of branchlets and twigs, cymes solitary at the axils of the spines, 3–5 cm long, 1.5–3.5 cm wide, 1–3-flowered; peduncles 0.7–2 cm long, with appressed hairs; pedicels 0.5–1.2 cm long, subglabrate; prophylls linear-subulate, 1–2 mm long. Flowers with calyx campanulate, 2–4 mm long, puberulent, truncate, 5-dentate; corolla hypocrateriform, white or tinged pink-purple, puberulent, internally slightly pubescent, tube 1.5–2.2 cm long, limb 5-lobed, lobes oblong or elliptic, 4–8 mm long; stamens 4, filaments much exserted, 2.3–2.5 cm long; ovary oblong, style 3.3–3.6 cm long, much exserted, equal to or shorter than the stamens. Fruit drupaceous, subtending calyx cupuliform, obovate, 5–13 mm long and wide, bilobed, splitting into two 2-seeded pyrenes at maturity; seeds oblong.

*Distribution and habitat.* *Clerodendrum pittieri* occurs from Guatemala to Ecuador and Venezuela. All the Mesoamerican collections are from the Pacific Coast (Fig. 3). The occurrence of *C. pittieri* on the Atlantic Coast is restricted to Colombia and Venezuela. This species is usually found in mangrove areas, dry forested hills above mangroves, salt flats, around tidal pools, and on riverbanks near saltwater. It is common in Nicaragua, in the mangrove forest of Poneloya (León) and Puerto Morazán (Chinandega) (pers. obs.).

*Vernacular names and uses.* "Espino." No uses reported.

*Note.* *Clerodendrum pittieri* closely resembles three other Mesoamerican species of *Clerodendrum* (see note under *C. ligustrinum*). The name was used for the first time by Standley in 1938, but was validly published by Moldenke in 1940.

*Selected specimens examined.* GUATEMALA. ESCUINTLA: near San José, at sea level, 30–31 Jan. 1939, *Standley 63974* (F). SAN MARCOS: Ocós, 1–2 m, 15 Mar. 1940, *Steyermark 37854* (F). COSTA RICA. GUANACASTE: Puerto Jesús on the Gulf of Nicoya ca. 13 km E of La Mansión, 20 July 1981, *Wilbur 31775* (DUKE). PUNTARENAS: Pacific Coast, banks between Los Loros and Tivines, 17–26 Feb. 1938, *Brenes 22671* (F, NY). PANAMA. CHIRIQUÍ: vicinity of David, 30 80 m, 30 Mar. 1911, *Pittier 3374* (F, US). COCLE: Aguadulce, near sea level, 3–6 Dec. 1911, *Pittier 4965* (F, MO, US).

## EXCLUDED TAXA

# POLLEN DEVELOPMENT AND FERTILIZATION IN *LACANDONIA SCHISMATICA* (LACANDONIACEAE)[1]

*J. Márquez-Guzmán,[2] S. Vázquez-Santana,[2] E. M. Engleman,[3] A. Martínez-Mena,[2] and E. Martínez[2]*

## Abstract

The flower of *Lacandonia schismatica* is bisexual. Three or sometimes four bilocular or trilocular anthers occupy the center of the flower inside the zone of carpels. The anther wall comprises four layers: epidermis; endothecium whose cells develop helical wall thickenings; one middle layer, which disappears early; a tapetum of the secretory type. The tapetal cells apparently form cytoplasmic bridges among themselves. The microspore tetrads are in an isobilateral arrangement, surrounded by a thick wall. The mature anther wall has only two cell layers: epidermis and endothecium. The pollen grain is three-celled by the time germination occurs. Anther dehiscence has not been observed and probably does not occur.

Pollination of *Lacandonia schismatica* occurs in the unopened flower bud. The pollen grains germinate within the anthers, which do not dehisce, and the pollen tubes grow within the receptacle until they reach the ovules. The pollen tube enters the embryo sac through the micropyle and one synergid, and fertilization is completed by anthesis. This reproductive pattern conforms to Lord's definition of preanthesis cleistogamy.

*Lacandonia schismatica* E. Martínez and C. H. Ramos is endemic to shady sites in a rainforest of southeastern Mexico. It is a saprophyte, and flowers all year if moisture is adequate. Flowering is especially abundant in November and December, after the rainy season (Martínez & Ramos, 1989).

*Lacandonia schismatica* has been proposed as a new monotypic family, the Lacandoniaceae (order Triuridales) (Martínez & Ramos, 1989). It is closely allied to the Triuridaceae (see the description in Maas & Rübsamen, 1986); in fact, it has been proposed that the genus be included in the Triuridaceae (Rübsamen-Weustenfeld, 1991).

The position of the androecium inside the zone of carpels makes the flower unique in angiosperms and gives room for more speculation about the origin of the flower and of the Triuridales. Otherwise, the reproductive structures of *L. schismatica* (Márquez-Guzmán et al., 1989; Martínez & Ramos, 1989) are comparable to those mentioned for the Triuridaceae to which *Lacandonia schismatica* is most closely related (Tomlinson, 1982; Maas & Rübsamen, 1986; Rübsamen-Weustenfeld, 1991).

On the other hand, its uniqueness makes one wonder if the structure is homologous to flowers in other angiosperms (Stevens, 1991). This paper is a report of continuing studies on the reproductive anatomy of *L. schismatica* (see Márquez-Guzmán et al., 1989). We analyze here the development of the anther, the formation of the pollen grains, some aspects of their germination and observations on the fertilization, an aspect of special interest in this monotypic family, unique in the flowering plants. Supplementing data on microsporogenesis is provided by Davidse & Martínez (1990).

## Materials and Methods

Flowers in anthesis, older flowers, and flower buds of different ages were fixed at the site of collection in the Lacandona forest, Chiapas, Mexico. They were collected in January and August 1990. Three fixatives were employed: (a) FAA (5% formalin + 5% acetic acid + 63% ethanol + 27% water); (b) glutaraldehyde (5% glutaraldehyde + 0.25 M sucrose + 0.1 M phosphate buffer, pH 6.8); (c) glutaraldehyde paraformaldehyde (5% glutaraldehyde + 4% paraformaldehyde + 0.1 M s-collidine, pH 7.2). The material fixed in FAA was embedded in paraffin. The sections (8–10 μm) were mounted in 0.005% aniline blue for fluorescence micros-

copy. The material fixed in glutaraldehyde was dehydrated in acetone and embedded in JB-4 plastic mixture. Sections were cut at 1–2 μm. They were stained with toluidine blue. The third fixative was followed by postfixation in osmium tetroxide. After alcohol dehydration, the tissues were embedded in Epon 812. They were cut at 1–2 μm and stained with toluidine blue. Additionally, fine sections were examined by transmission electron microscopy.

## Results

*Lacandonia schismatica* is a specialized saprophyte. Perfect flowers are produced on its aerial shoots. The gynoecium consists of 60–80 papillose carpels. Each carpel surrounds a basal sessile ovule that is anatropous and bitegmic. The inner integument forms the micropyle. The androecium consists of three or sometimes four bilocular anthers with introrse stomia. The mature pollen grains contain three cells (Márquez-Guzmán et al., 1989; Martínez & Ramos, 1989).

When the tepals have finished development, the floral meristem begins to form lobes (Fig. 1). As the lobes grow, the central ones become recognizable as primordia of the sessile anthers in the center of the flower. They also are larger than the surrounding lobes that will form the carpels (Fig. 2).

In the anthers some of the subprotodermal cells elongate perpendicularly to the surface. These become the archesporial cells. Two cells result from a periclinal division of an archesporial cell (Fig. 3). The internal one (the sporogenous cell) divides repeatedly and forms the sporogenous tissue. The outer one (the parietal cell) divides twice to form the endothecium, a single intermediate layer, and the tapetum (Fig. 4). Sterile cells in the sporogenous zone divide the anther into two or rarely three pollen sacs (Fig. 5).

After the anther wall cells have completed division, the microspore mother cells begin meiosis (Fig. 6). At this time the anticlinal and internal walls of the tapetum disappear. The tapetal cells are at their maximum size and protoplasmic content; the nuclei are large. The tapetal cells apparently form cytoplasmic bridges among themselves (Fig. 7). After meiosis, the microspore tetrads are in an isobilateral arrangement as a result of successive cytokinesis, and they are surrounded by callose walls (Fig. 8).

At the time of separation of the microspores, they are still surrounded by a thick wall. The tapetum seems to be functional and some of its cells are binuclear (Fig. 9). During development of the pollen grains, the intermediate layer and the tapetum disappear (Fig. 10).

By the time pollen grains are mature, the endothecium has helical wall thickenings. These thickenings taper off to nothing as they approach the external wall (Fig. 11). The bands of thickening are sometimes connected at the edges of the internal wall. Thus, the internal wall is traversed by the bands, but not by a plate of secondary wall. The epidermis persists to maturity.

We have observed an apparently new phenomenon in at least eight flowers in anthesis: the anthers did not dehisce and the pollen grains germinated within the pollen sac.

The development of the anther is precocious with respect to the carpels (Fig. 12). The male gametophytes mature before the female ones. By the time pollen grains in unopened buds are at the three celled stage (Fig. 13), the carpels are usually in early stages of development. However, the ovules and embryo sacs continue to develop until, before the flower opens, the megagametophyte has seven cells and the egg apparatus is located at the micropylar end, next to the receptacle (Fig. 14).

At this stage, the first signs of germination were observed in the pollen grains inside the unopened anthers (Fig. 15). The resultant pollen tubes grow toward the base of the anther, which is united to the receptacle (Fig. 16). The pollen tubes grow through the receptacle (Fig. 17) to reach the carpels (Fig. 18). They enter the ovule via the micropyle and then penetrate the embryo sac through one synergid (Fig. 19). When the flowers open, fertilization already has occurred, and only the pollen walls (Fig. 20) remain in the unopened anthers.

Dehiscence of the anthers does not occur, nor have we seen pollen tubes growing through the anther walls. Pollen grains have not been detected outside the anthers, neither in sections of flower buds nor in images of scanning electron microscopy of open flowers.

## Discussion

*Lacandonia schismatica* shares many characters with the Triuridaceae (Maas & Rübsamen,

ES, embryo sac; II, inner integument; MY, micropyle; OI, outer integument; PT, pollen tube; R, receptacle cells; S, synergids; W, pollen wall.

1986; Martínez & Ramos, 1989; Márquez-Guzmán et al., 1989; Davidse & Martínez, 1990; Rübsamen-Weustenfeld, 1991): anthers bilocular or rarely trilocular or tetralocular, persistent anther epidermis, successive microsporogenesis, tetrads isobilateral, mature pollen grains with three cells.

Maas & Rübsamen (1986) found that the tapetum in Triuridaceae is intermediate between periplasmodial and secretory and tends to protrude into the pollen chamber. The cell walls degenerated at an earlier stage in *Sciaphila* than in *Triuris*. We did not detect a plasmodial stage in the tapetum

of *Lacandonia*, but we did find apparent cytoplasmic bridges among the cells.

There are no data on pollination in Triuridaceae. It is to be expected that several kinds of insects are attracted to the flowers, although this is not directly recorded (Maas & Rübsamen, 1986).

Germination of pollen grains inside the anther sac in *Lacandonia* appears to be unique in Triuridales and a consequence of its cleistogamic reproduction.

Double fertilization in Triuridaceae has not been observed; however, most likely it takes place in several species (Maas & Rübsamen, 1986). Tomlinson (1982) suggested that there is evidence for a possible apomictic process. Dahlgren et al. (1985) mentioned that the egg cell of Triuridales may develop parthenogenetically. Rübsamen-Weustenfeld (1991) observed double fertilization in one embryo sac of *Soridium spruceanum* Miers.

Anderson (1980) described similar pollination and fertilization phenomena to those of *L. schismatica* in four genera of Malpighiaceae. However, these four genera also produce chasmogamous flowers on the same plants. Apparently, in *L. schismatica* all flowers are cleistogamous. In these genera of Malpighiaceae, the cleistogamous flowers generally lack styles, but in *L. schismatica* all the flowers have them.

Philbrick (1984) has found that ovules of two species of *Callitriche* are fertilized by pollen tubes that grow through various tissues between the anther of a male flower and the ovary of an adjacent female flower.

Lord (1981) reported that cleistogamy occurs in 56 families and covers a wide range of dimorphic forms. Under her classification, *L. schismatica* belongs to the category of preanthesis cleistogamy, in which both pollination and fertilization occur in a flower bud which later opens.

Autogamy generally is expected to lead to homozygosity in the population. This has been demonstrated in *L. schismatica* by Coello et al. (1993).

# LACK OF GENETIC VARIATION IN *LACANDONIA SCHISMATICA* (*LACANDONIACEAE: TRIURIDALES*) IN ITS ONLY KNOWN LOCALITY[1]

*Gerardo Coello,[2] Ana Escalante,[2] and Jorge Soberón[2]*

## ABSTRACT

*Lacandonia schismatica* has only one known population in a small patch of tropical rain forest. Using electrophoretic techniques, we assessed its genetic variation in eight loci; no variation was found. We discuss this result and its implications for the conservation prospects of this threatened species.

*Lacandonia schismatica* (Martínez & Ramos, 1989; Márquez-Guzmán et al., 1989), the only species of Lacandoniaceae, is unique in having a central androecium surrounded by an apocarpous gynoecium. A series of studies of the plant is underway to determine its relationships and taxonomic status, which is still under debate (Stevens, 1991).

The unusual morphology and restricted distribution of *Lacandonia schismatica* suggest that it is an interesting model to study macroevolutionary mechanisms. In this paper we report results on the genetic variation of *L. schismatica* as estimated by enzyme electrophoresis.

## METHODS

The only known locality for *L. schismatica* is the type locality (Fig. 1), which is a ca. 15-ha tropical rainforest patch a few miles north of the Montes Azules Biosphere Reserve in Mexico. The climatological station at Bonampak, close by and at a similar altitude, has a mean annual temperature of 24.6°C and precipitation of 2,609 mm per year (Meave, 1990). The type locality is almost completely surrounded by secondary growth vegetation and cattle pastures. The plants are found within the forest, but only 10–100 m from the edge with a natural savanna. This edge has wet soil, almost a marsh, with an underground water level at about 60 cm below the surface during the dry season. During the dry season, the plants are inconspicuous and can only be found under the litter. During the rains, however, rotting logs are often covered with carpets of *L. schismatica* (E. Martínez, pers. comm.).

Individuals of *L. schismatica* were collected in a 0.5-ha plot (Fig. 1) on three dates, all during the dry season: (A), 10 individuals, April 1988; (B), 72, April 1989; and (C), 27, July 1989. The sample size changed between sites depending on the abundance of the plant. Plants from sample A were collected along a 100-m transect. Plants from samples B and C come from 10–20-$m^2$ high-density patches not more than 50 m away from each other. Live specimens were transported to Mexico City and maintained in growth chambers at 25°C and 80% humidity until prepared for electrophoresis.

Starch gel (12%) enzyme electrophoresis (Vallejos, 1983) was carried out on fresh stem tissue homogenized with gel buffer and absorbed in filter paper wicks (Whatman 17). Eighteen enzymes were assayed, but only eight resolved well in two buffer systems. The enzymes analyzed and the stain references are shown in Table 1.

System I consisted of tris-citrate pH 7 electrode buffer and L-histidine pH 7 gel buffer and system

[1] We thank Esteban Martínez for taking us to the *Lacandonia* site and helping with the fieldwork, and for many discussions about the plant. His assistant Gabriel Aguilar was very helpful as well. Daniel Piñero and Luis Eguiarte made several useful comments on the manuscript. An anonymous referee significantly corrected our English. Gabriela Jiménez drew the location sketch.

II of lithium-borate pH 8 electrode buffer and tris-borate pH 8.6 gel buffer (Soltis et al., 1983). Electrophoresis was conducted at 55 mA for system I and 45 mA for system II until the front migrated 10 cm.

## RESULTS

No electrophoretic variation was detected among any of the plants or sites in the 14 loci examined. Stems of 109 individuals were assayed and the

same alleles were expressed in all of them. Table 2 shows the number of loci that resolved for each enzyme analyzed, and the zymogram of Figure 2 shows the activity zone of each loci.

Assuming that the specimens represent a random sample of 218 alleles at each locus, we would have detected any variant allele that existed at an overall frequency of 1.4% or greater with a probability of 95% ($P = 0.986^{218} = 0.05$). Thus, genetic variation is not apparent in our sample.

Lack of genetic variation has also been reported for other endemic species (Hamrick et al., 1979; Waller et al., 1987) and has implications for a conservation program (Holsinger & Gottlieb, 1989).

## DISCUSSION

Lack of genetic variation can be explained by a number of mechanisms, including random drift, genetic bottlenecks (Waller, et al., 1987), and apomixis (Marshall & Brown, 1981). In the case of *Lacandonia schismatica*, the lack of genetic variation can be explained by the autogamic fertilization system reported by Márquez-Guzmán et al. (1993, this issue).

Since *Lacandonia schismatica* is apparently restricted to a small area, the existence of several subpopulations cannot be rejected at this time. The small size of the plant, its location under the litter, and its cleistogamous pollination system (Márquez-Guzmán et al., 1993, this issue) suggest very low levels of gene flow, which may lead to several subpopulations within a small area. The samples used in this study were collected in roughly the same site, and it may be that other subpopulations could have the same low genetic variation but for different sets of alleles. This still has to be tested.

The low genetic variation has contradictory im-

plications for the conservation of the plant. On one hand, obtaining representative variation for preservation in the greenhouse may be feasible using only a small number of specimens. Unfortunately, to date all attempts to preserve living specimens in growth chambers for more than two or three months have failed. Failure may be due to death of the associated root fungi. On the other hand, the forest patch in which the only known population of *L. schismatica* is located will soon be completely surrounded by secondary vegetation and natural and artificial grasslands. It is likely that microenvironmental conditions in its habitat will change, and it may be the case that *L. schismatica* lacks the genetic variability to adapt to the new situation. Although it now appears that the locality of *L. schismatica* will not be cleared and will be kept as a sanctuary by the owners, the Chole Indian community of Corozal, it is important to begin intensive ecological and genetic studies of the species in order to insure its conservation. It is unlikely that the area in which the plant is located will be able to support a viable population without some degree of management. Given the situation of the habitat, and what is known about the plant's genetics and biology, it is clear that an immediate effort is required to preserve the plant in laboratory conditions and to understand its ecological requirements and genetic structure in order to propose sound management strategies.

# PATTERNS OF SPECIES DISTRIBUTIONS IN THE DRY SEASONAL FORESTS OF SOUTH AMERICA[1]

*Darién E. Prado[2] and Peter E. Gibbs[3]*

ABSTRACT

Studies of the distributions of species of seasonal woodland habitats in South America by means of dot-mapping and phytosociological analyses indicate the presence of three nodal areas: the Caatingas nucleus of arid northeastern Brazil; the Misiones nucleus, comprising a roughly right-angled triangular area enclosed by lines connecting Corumbá–Puerto Suarez (Brazil/Bolivia) southward to Resistencia–Corrientes in northern Argentina, and eastward to the upper Uruguay River valley system in Argentinian Misiones and Brazilian Santa Catarina, and thus including most of eastern Paraguay and the west bank of the Paraguay River; and the Piedmont nucleus, which extends from Santa Cruz de la Sierra in Boliva to Tucumán and the sierras of east Catamarca in northwestern Argentina. Distribution maps are presented for over 70 taxa that show this kind of distribution pattern or its modifications. Most of the seasonal woodland species of this affinity are notable by their absence from the cerrado vegetation of central Brazil, although some occur on calcareous outcrops in the general cerrados area, and they also avoid the Chaco of northern Argentina. It is proposed that these fragmentary and mostly disjunct distributional patterns are vestiges of a once extensive and largely contiguous seasonal woodland formation, which may have reached its maximum extension during a dry-cool climatic period ca. 18,000–12,000 BP, coinciding with the contraction of the humid forest.

Various authors have drawn attention to the "savanna corridor" (Schmidt & Inger, 1951) or "diagonal of open formations" (Vanzolini, 1963, 1974), which extends across South America from Maranhão–Ceará in north-northeastern Brazil, to the Chaco region of northern Argentina (Fig. 1), and numerous commentaries on possible floristic and faunistic links have been made (e.g., Andrade-Lima, 1954, 1982; Vanzolini, 1974; Prance & Schaller, 1982; Bucher, 1982; Haffer, 1985; Ratter et al., 1988), particularly for the Caatinga–Chaco poles of this diagonal. In the course of a recent critical reevaluation of the alleged floristic links between the caatingas of northeastern Brazil and the Gran Chaco vegetation of northern Argentina–Paraguay–Bolivia (Prado, 1991), a series of dot-map distributions were plotted for woody species of the deciduous and semideciduous forests of South America. The Caatinga–Chaco links proved to be negligible, but a different and rather more interesting distribution pattern emerged.

The distributions hint at a once extensive arc of seasonal woodland, which ranged from northeastern Brazil (with some Amazonian and Caribbean links) through southeastern Brazil to the confluence of the Paraguay and Paraná rivers, into southwestern Bolivia and northwestern Argentina, and extending sporadically northward in dry Andean valleys of Peru. In most cases, these species skirt the impoverished soils of the central Brazilian cerrado vegetation (Eiten, 1972), but some taxa "island-hop" across this area by way of the restricted outcrops of calcareous-rich soils within the cerrados.

## CLIMATIC CHANGES IN SOUTH AMERICA DURING THE LAST GLACIAL MAXIMUM

Many authors (e.g., Damuth & Fairbridge, 1970; Ab'Sáber, 1977, 1982) have postulated a major dry-cool climatic period in South America at the time of the Northern Hemisphere Wisconsin–Würm

[1] We thank the directors of the Royal Botanic Gardens at Edinburgh and Kew for provision of herbarium and library facilities during repeated visits, and also to the following herbaria for the loan of specimens: Arnold Arboretum of Harvard University, Conservatoire et Jardin botaniques de la Ville de Genève, Gray Herbarium of Harvard University, Empresa Pernambucana de Pesquisa Agropecuária, Recife, and Herbário, Botánica y Ecología Vegetal, Universidad de Rosario. D. Prado is grateful to Maria Angêlica Figueiredo, Maria das Graças, M. Pires, and Arnildo and Vali Pott for kind assistance with field excursions in Brazil, and acknowledges financial assistance from CONICET Argentina, the University of St. Andrews, and the Committee of Vice-Chancellors and Principals of the Universities of the U.K. for an Overseas Research Student's award.

[3] Plant Science Laboratories, Sir Harold Mitchell Building, The University, St. Andrews KY16 9AL, Scotland, U.K.

glaciation, about 18,000–12,000 BP. There has been considerable discussion devoted to the consequences of such a dry period with regard to the contraction of the humid forest to isolated "islands" and the "refuge theory" as a possible stimulus for speciation events that are reflected in present-day Amazonian forest diversity patterns (Brown & Ab'Sáber, 1979; Prance, 1973, 1982, and various contributions in Prance, 1982). Other authors, however, have urged caution in interpreting present-day species distributional patterns in terms of supposed Pleistocene forest refuges (e.g., Benson, 1982; Nelson et al., 1990).

Unfortunately, paleo-palynological studies for South America, which could provide valuable evidence for dry periods and consequent vegetational changes, are sparse and mostly apply to Andean areas (e.g., Van der Hammen, 1974, 1982), and the few studies in the Amazonian regions are for more recent Holocene strata (Absy, 1982). However, on the basis of local palynological investigations some authors have attempted to circumscribe in more detail the possible regional shifts in climate and vegetation in the Paleocene (Markgraf, 1989), while others have reported evidence that conflicts with areas of alleged humid forest refuges (Kam-biu & Colinvaux, 1985; Colinvaux, 1989).

Most discussion concerning the postulated Pleistocene dry periods in South America has focused on the consequences of contraction of the humid forest, and less attention has been given to the influence of such climatic changes on the expansion of semideciduous and deciduous vegetation of the region. Here we present a series of distribution maps for a number of species of seasonal woodland formations, which reveal floristic links between the flora of the caatingas vegetation of semiarid northeastern Brazil (sensu Andrade-Lima, 1981) and two other areas. In our opinion, these distributions are remnants of once continuous forests, and they provide some evidence for the previous extensive occurrence of seasonal forests in South America. While we are fully conscious of the dangers of facile interpretations from dot-maps, and particularly the possible influence of localized collecting, we consider that the repetitive distributions that emerge from these maps do reflect past floristic links. We offer these distribution maps as a contribution to the ongoing debate concerning the historical biogeography of the seasonal formations in South America.

FIGURE 1. The "dry diagonal" of seasonal woodlands in South America with Caatingas, Cerrado, and Chaco areas delimited.

## METHODS

This series of species distribution maps began as an attempt to plot accurately the full distributions of the woody taxa of the caatinga vegetation (Andrade-Lima, 1981; Prado, 1991) of northeastern Brazil. It soon became evident that many of the nonendemic caatinga species showed a common overall distribution pattern that mostly avoided the cerrado region but extended to southeastern and southern Brazil and, in many cases, into well-defined areas in Paraguay, Argentina, and Bolivia. The maps involved an exhaustive check of the taxonomic literature and verification of the identity of species cited in diverse floristic lists, made possible by repeated visits to The Royal Botanic Gardens at Edinburgh and Kew, and herbarium material obtained on loan from various institutions. The species dot-maps are based on verified specimens or citations in modern taxonomic revisions (solid symbols) together with citations in reliable vegetation surveys in the areas concerned (open symbols).

In addition to mapping species distributions, a suite of floristic lists from 18 seasonal woodland communities across South America were compared by means of a classic phytosociological analysis of the Zurich-Montpellier school, in the version modified by Mueller-Dombois & Ellenberg (1974), and also by means of a complete linkage algorithm from Wishart's (1987) package employing Sørensen's (1948) similarity index, and a Principal Compo-

nents Analysis from the JMP IN statistical software (Prado, 1991). Details of these latter analyses are not given here, but both approaches strongly supported the close floristic links between the caatinga vegetation and woodlands in south-southeastern Brazil and Paraguay, and the piedmont forests of northwestern Argentina–southern Bolivia.

### Residual Pleistocenic Seasonal Formations Arc

Ab'Sáber (1977) has postulated that during a major dry episode in South America, equivalent to the Wisconsin–Würm glacial period, there was an expansion of semiarid vegetation in the continent. According to this view, caatinga-like vegetation, which usually occurs on mineral-rich soils, may well have surrounded a core area of cerrado vegetation in central Brazil, and both seasonal formations very probably extended into the Amazon region, whereas tropical rainforests underwent contraction. It is likely that the slow return of a more humid climate during the past 12,000 years, in addition to favoring a re-expansion of the evergreen forest, was also accompanied by leaching and acidification of soils in various areas, perhaps increasing the cerrado region, and fragmenting the originally much more widespread semiarid vegetation of base-rich soils (Ratter et al., 1988).

A number of the woody species that are likely to have been involved in the cyclic expansion-retreat migrations of the Pleistocene are today members of diverse tropical and subtropical deciduous forest communities in South America, such as the caatingas of northeastern Brazil and some semideciduous (i.e., non-Mata Atlântica) forests in São Paulo and Paraná states, the forests of the upper Uruguay River valley and most of those surrounding the Paraguay–Paraná rivers system, the serranías of Santiago and Chiquitos in southeastern Bolivia, the piedmont forests in the so-called Transitional areas in northwestern Argentina and southwestern Bolivia (running parallel to the sub-Andean mountains from Tucumán in Argentina to Santa Cruz de la Sierra in Bolivia), and more scattered outposts in semiarid and arid Andean valleys in northern Bolivia, throughout Peru and sometimes even reaching southwestern Ecuador. Some of these species are not only important members of these communities but are also dominant in several instances.

One such case, and here taken as paradigm, is that of the mimosoid *Anadenanthera colubrina* (Vell.) Brenan var. *cebil* (Griseb.) Altschul ("angico," "cebil"). For the distribution of this species (Fig. 2A) three nuclei can be identified. The first and major nucleus consists of the caatingas of northeastern Brazil, where the "angico" is a very important and frequent tree, and it is present in most of Andrade-Lima's (1981) vegetation units. Outside the caatingas, it has been reported in the "brejos" from Pernambuco (Andrade-Lima, 1964), particularly in the dry forests of the slopes of the "serras," and in the so-called "caatingas" in Maranhão state (Galvão, 1955). Bigarella et al. (1975) claimed that disjunctions of caatingas occur on the road Coroatá–Vargem Grande (Maranhão), and the exsiccatum marked on our map corresponds to Presidente Dutra, which is just to the south of these localities. This northeastern Brazilian nucleus for the angico type of distribution (which we can call the Caatingas nucleus) is intermittently linked to the second nucleus, which occurs along the Paraguay–Paraná rivers system, by the way of mesotrophic cerradão woodlands in Goiás and Mato Grosso (Ratter et al., 1978), and in Mato Grosso do Sul (Ratter et al., 1988; Prado et al., 1992).

The second nucleus has a somewhat triangular shape with its northernmost apex on the axis Puerto Suárez–Corumbá (Bolivian–Brazilian border), a straight meridian side reaching south on the axis Resistencia–Corrientes in Argentina and thus paralleling the Paraguay River up to its confluence with the Paraná River, a latitudinal side eastward from that confluence to the upper Uruguay River valley in Misiones (Argentina) and Santa Catarina (Brazil), and from here a diagonal side returning in northwest direction to Pto. Suárez–Corumbá. Thus, this nucleus (which we can refer to as the Misiones nucleus, employing this term in its older, more general geographical concept rather than the current restricted Argentinian or Paraguayan usage) includes nearly all of eastern Paraguay and a good deal of the western bank of the River Paraguay, that is, a north–south strip parallel to the river and several kilometers inland in the geographical Gran Chaco region. Within this triangle, *Anadenanthera colubrina* var. *cebil* is common but rarely dominant. It has been reported by Fiebrig (1933) along the western bank of the River Paraguay, by Tortorelli (1967) and Esser (1982) for several areas of eastern Paraguay, by Morello & Adámoli (1967) for eastern Formosa, and by Eskuche (1986) for northeastern Argentina in the Paranense phytogeographical province (Cabrera & Willink, 1980).

This second nucleus connects with the third one, located in southwestern Bolivia and northwestern Argentina, via the Santiago and Chiquitos hill ranges, forming a curved line uniting Corumbá to Santa

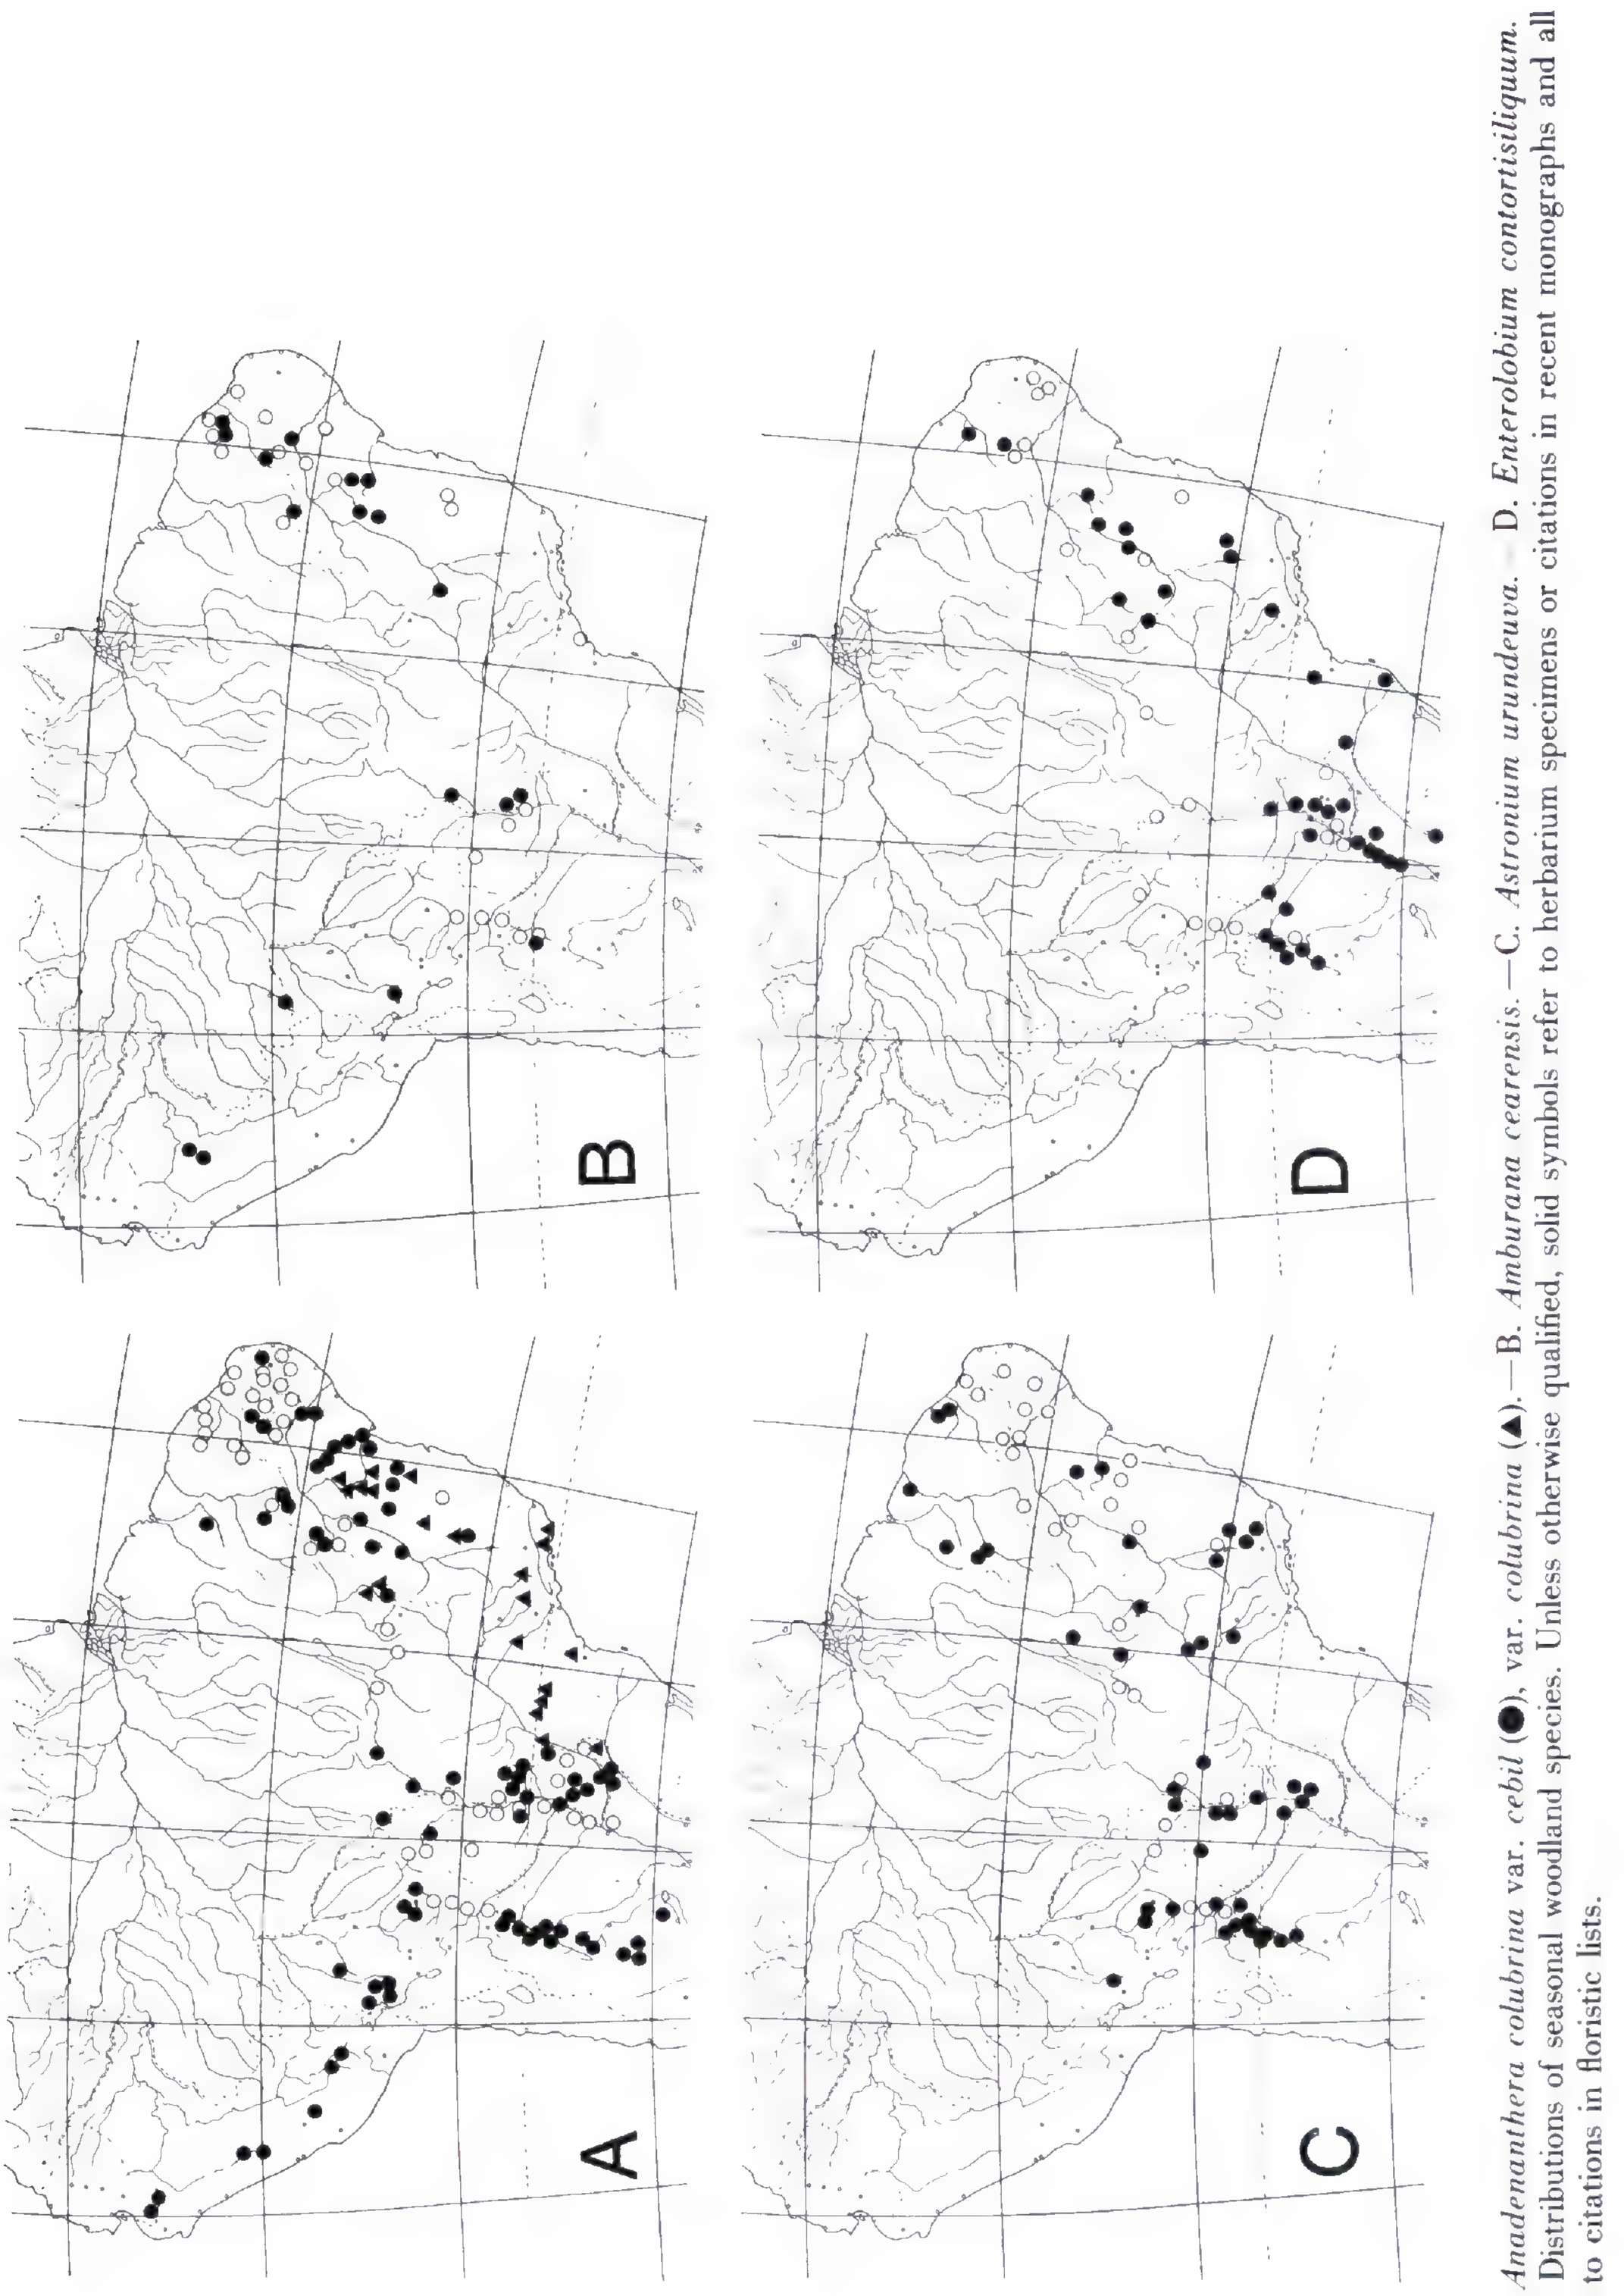

FIGURE 2[4].—A. *Anadenanthera colubrina* var. *cebil* (●), var. *colubrina* (▲).—B. *Amburana cearensis*.—C. *Astronium urundeuva*.—D. *Enterolobium contortisiliquum*. [4] FIGURES 2–15. Distributions of seasonal woodland species. Unless otherwise qualified, solid symbols refer to herbarium specimens or citations in recent monographs and all open symbols refer to citations in floristic lists.

Cruz de la Sierra. The flora of this region has scarcely been studied and even less collected, but Herzog (1910, 1912) gave a fairly accurate impression of what the vegetation was like in the area. In the sector enclosed by this previous line and hills, by the western limit of the second nucleus, and by the north–south narrow strip of the third nucleus, the true chaco vegetation is encased. There are very few outposts of *Anadenanthera colubrina* var. *cebil* within the Chaco area (as is the case with most of the species with this pattern of distribution). The Cerro León records of this tree are not an exception to its absence from the plains of the Chaco sens. str., because the vegetation on the slopes of this tectonic horst (which comprises Silurian and Devonian rocks as opposed to the æolian sediments surrounding the hill) shows strong links with the sub-Andean Piedmont forests in northwestern Argentina (Ramella & Spichiger, 1989, *sub* Transitional Forests).

The third nucleus extends from Santa Cruz de la Sierra south to Tucumán and the sierras of eastern Catamarca in Argentina. This follows the piedmont area of the sub-Andean Mountains, which is the area of the so-called transitional forests, so-named because their floristic composition has been considered to be intermediate between that of the chaco thorn forests and the upland subtropical rainforests (the "Yungas" sens. str.). We can refer to this nucleus, therefore, as the Sub-Andean Piedmont nucleus. *Anadenanthera colubrina* var. *cebil* was so important in the southern half of this nucleus in Argentina that Lillo (1919, as cited in Hauman, 1931, and Digilio & Legname, 1966) called it "zona del cebil," but today there is little left of the original vegetation in this area, which is known locally as "tipa-pacará" forest (from the species *Tipuana tipu* (Benth.) O.Kuntze and *Enterolobium contortisiliquum* (Vell.) Morong). The northern remainder of the nucleus where the angico occurs comprises the "palo blanco" forest, dominated by *Calycophyllum multiflorum* Griseb. and *Phyllostylon rhamnoides* (Poisson) Taubert, and which extends from mid-eastern Jujuy in Argentina to, presumably, Santa Cruz de la Sierra. *Anadenanthera colubrina* var. *cebil* is one of the five commonest members of both these forests (Cabrera, 1976: 7).

From this third nucleus this species, and the pattern of distribution dealt with here, becomes scattered along the northeast-facing slope of the Andes in Bolivia and southern Peru, i.e., from Santa Cruz to Cuzco, to even more scattered localities in dry inter-Andean valleys such as those of the Apurímac, Huállaga, and Marañón rivers (Weberbauer, 1936), finally reaching southern Ecuador in what corresponds to the "Savannah and Dry Scrub vegetational types" (see map in Harling, 1979). The distribution of the typical variety, *Anadenanthera colubrina* var. *colubrina*, further extends the range of the species (Fig. 2A), since although it occurs sympatrically with variety *cebil* in the southern area of the caatingas in Bahia, and also in Misiones in Argentina, it is distributed allopatrically in Rio de Janeiro state and the planalto forests of São Paulo and Paraná states. Altschul (1964) has argued cogently that the typical variety evolved from variety *cebil*, in which case variety *colubrina* has developed in wetter areas than those of its parental stock.

A number of woody caatinga species have a similar, sometimes virtually identical, distribution pattern to that of *Anadenanthera colubrina*. For example, *Amburana cearensis* (Allemão) A. C. Smith (Leguminosae) is a frequent, albeit not abundant, characteristic tree of the caatingas even in the more shrubby types of communities, and it occupies a similar niche in the palo blanco forest (Piedmont nucleus), while it is rather rare in the Misiones nucleus except for some dense populations on calcareous substrate on the Apa River region in Paraguay (Fiebrig, 1933; Tortorelli, 1967). It has also been reported for the Cerro León (Ramella & Spichiger, 1989), and it appears very occasionally in the Andean sector of this pattern of distribution; a collection from Acre state in Brazil should be noted (Fig. 2B). The tree *Astronium urundeuva* (Allemão) Engl. (Anacardiaceae) is an important member of the arboreal caatinga, in which it is characteristic and dominant (Andrade-Lima, 1981), but it also extends into the shrubby caatinga as an isolated low tree (as does *Amburana cearensis*, according to Egler, 1951). *Astronium urundeuva* is considered an indicator species of mesotrophic facies cerradão (cerradão is a well-developed woodland type, which is usually characteristic of richer soils) within the cerrado area in central Brazil (Ratter et al., 1978). It has also been collected in the Cerro León, and it is very frequent in the sub-Andean Piedmont nucleus, but there are no records from the Andean dry valleys (Fig. 2C).

The mimosoid tree *Enterolobium contortisiliquum* (Vell.) Morong is usually conspicuous, not for its frequency but rather for its size. Somewhat scarce in the caatingas (Fig. 2D), it has been reported for the agreste (Andrade-Lima, 1954) and arboreal caatinga (Andrade-Lima, 1975). In the forests of southeastern Brazil its presence is recorded by collections and phytosociological works (Martins, 1979), and it is an important component

of the vegetation on the banks of the Paraguay–Paraná system (Reboratti & Neiff, 1986; Prado et al., 1989), and also of the sub-Andean piedmont forests (particularly in the tipa-pacará variant), but again is absent from the Andean area. *Enterolobium contortisiliquum* has also been collected in the gallery forests that border the Chaco vegetation (see Fig. 2D and Morello & Adámoli, 1974), where it occurs with other nonchaquenian subtropical species, on the alluvial levees beside the main rivers (Adámoli et al., 1972). *Pterogyne nitens* Tulasne (Leguminosae) has a very similar distribution (Fig. 3A) and is also reported for gallery forest and humidity-dependent communities within the Chaco (Morello, 1967; Morello & Adámoli, 1974), but as a rather rare element of the latter. The species *Ruprechtia laxiflora* Meisn. (Polygonaceae) was originally described by Meisner (1855) from Blanchet exsiccata collected in the caatingas (Cocucci, 1961), but it was not recorded subsequently in this area until recent collections by Harley et al. from around Camaleão in Bahia. It was, however, abundantly collected in Paraguay and Argentina in both the Misiones and Piedmont nuclei, where it is a very important element (Fig. 3B). The scandent shrub or treelet *Celtis pubescens* (Kunth) Sprengel (Ulmaceae) follows much more closely the *Anadenanthera colubrina* var. *cebil* pattern (although it is far less frequent in the caatingas), and it reaches central Ecuador (Fig. 3C) and is also recorded from Acre state in Brazil.

One of the most important and characteristic trees in the caatingas is *Schinopsis brasiliensis* Engler (Anacardiaceae). Engler (1876) recognized two varieties, variety *glabra* Engler and the typical variety of this species. Meyer & Barkley (1973) subsequently considered the former variety to merit specific status, based on its lack of indumentum and larger leaflets when compared to variety *brasiliensis*. However, from the numerous exsiccata we have examined it would seem that although presence–absence of indumentum is a fairly consistent character, leaflet size is unreliable. A traditional view has been taken of *S. brasiliensis*, therefore, to include the two sympatric varieties, *brasiliensis* and *glabra*, and they have been mapped together (Fig. 3D). This tree is not only present and abundant in the caatingas, from where it extends into isolated localities in the Federal District of Brazil and in Minas Gerais (where it has been reported to form a dense community in a flood-prone area by Pinto, 1985), but it is also the dominant species in forests in Mato Grosso do Sul (Prado et al., 1992). *Schinopsis brasiliensis* also extends from Corumbá to the west along the Santiago and Chiquitos ranges (Herzog, 1910), and there are many exsiccata from the humid slopes of the Andes in northwestern Bolivia, but it has not been recorded for Peru, where, however, it seems to be replaced by a similar and little known species, *S. peruviana* Engler, which has been collected only twice (Fig. 3D).

The species *Piptadenia viridiflora* (Kunth) Benth. (Leguminosae) poses an interesting case since it is an important element of the caatingas, frequently reported in the literature, whereas it is a relatively rare species in northwestern Argentina in the piedmont deciduous forests (Fig. 4A). Burkart (1952) cited this tree for Colombia and Venezuela (presumably for the dry Caribbean area), but no exsiccata or references have been encountered to confirm this assertion. Both the species and the genus seem to be missing from the Misiones nucleus of this pattern of distribution, that is, the Paraguay–Paraná system, but this may simply be due to a problem of taxonomic interpretation, since all previously considered *Piptadenia* species for this area have been transferred to other genera (*Anadenanthera* Speg., *Goldmania* Rose ex Micheli, *Parapiptadenia* Brenan). It is noteworthy that the species *Goldmania paraguensis* (Benth.) Brenan, endemic to this sector, is very close to section *Pityrocarpa*, to which Burkart (1952) referred *Piptadenia paraguensis* (Benth.) Lindm. (= *Goldmania paraguensis*), while Brenan (1955) transferred *Piptadenia viridiflora* to his genus *Pityrocarpa*.

There is only one collection of *Carica quercifolia* (A. St.-Hil.) Hieron. (Cariacaceae) known from the caatingas, from Irecê in Bahia (Badillo, 1971), and this would represent a very wide disjunct occurrence from the main, "amphi-Chaco," area of distribution of this species (Fig. 4B) if it were not for three additional isolated collections in Goiás, Minas Gerais, and São Paulo states, which tenuously link the Bahian record to the second nucleus of the Pleistocenic Arc. The rest of the distribution is divided into two more or less continuous zones separated by the Chaco plains. One corresponds to the Misiones nucleus, extending eastward along the upper Uruguay basin to include the planalto forests, but also with an extension westward into the eastern Chaco. The second corresponds to the piedmont deciduous forests on the sub-Andean slopes. *Carica quercifolia* is also common in dry valleys between Andean ranges in northwestern Bolivia and southern Peru.

The shrub *Combretum leprosum* Mart. (Combretaceae) is another typical caatinga species that follows relatively well the Pleistocenic Arc (Fig.

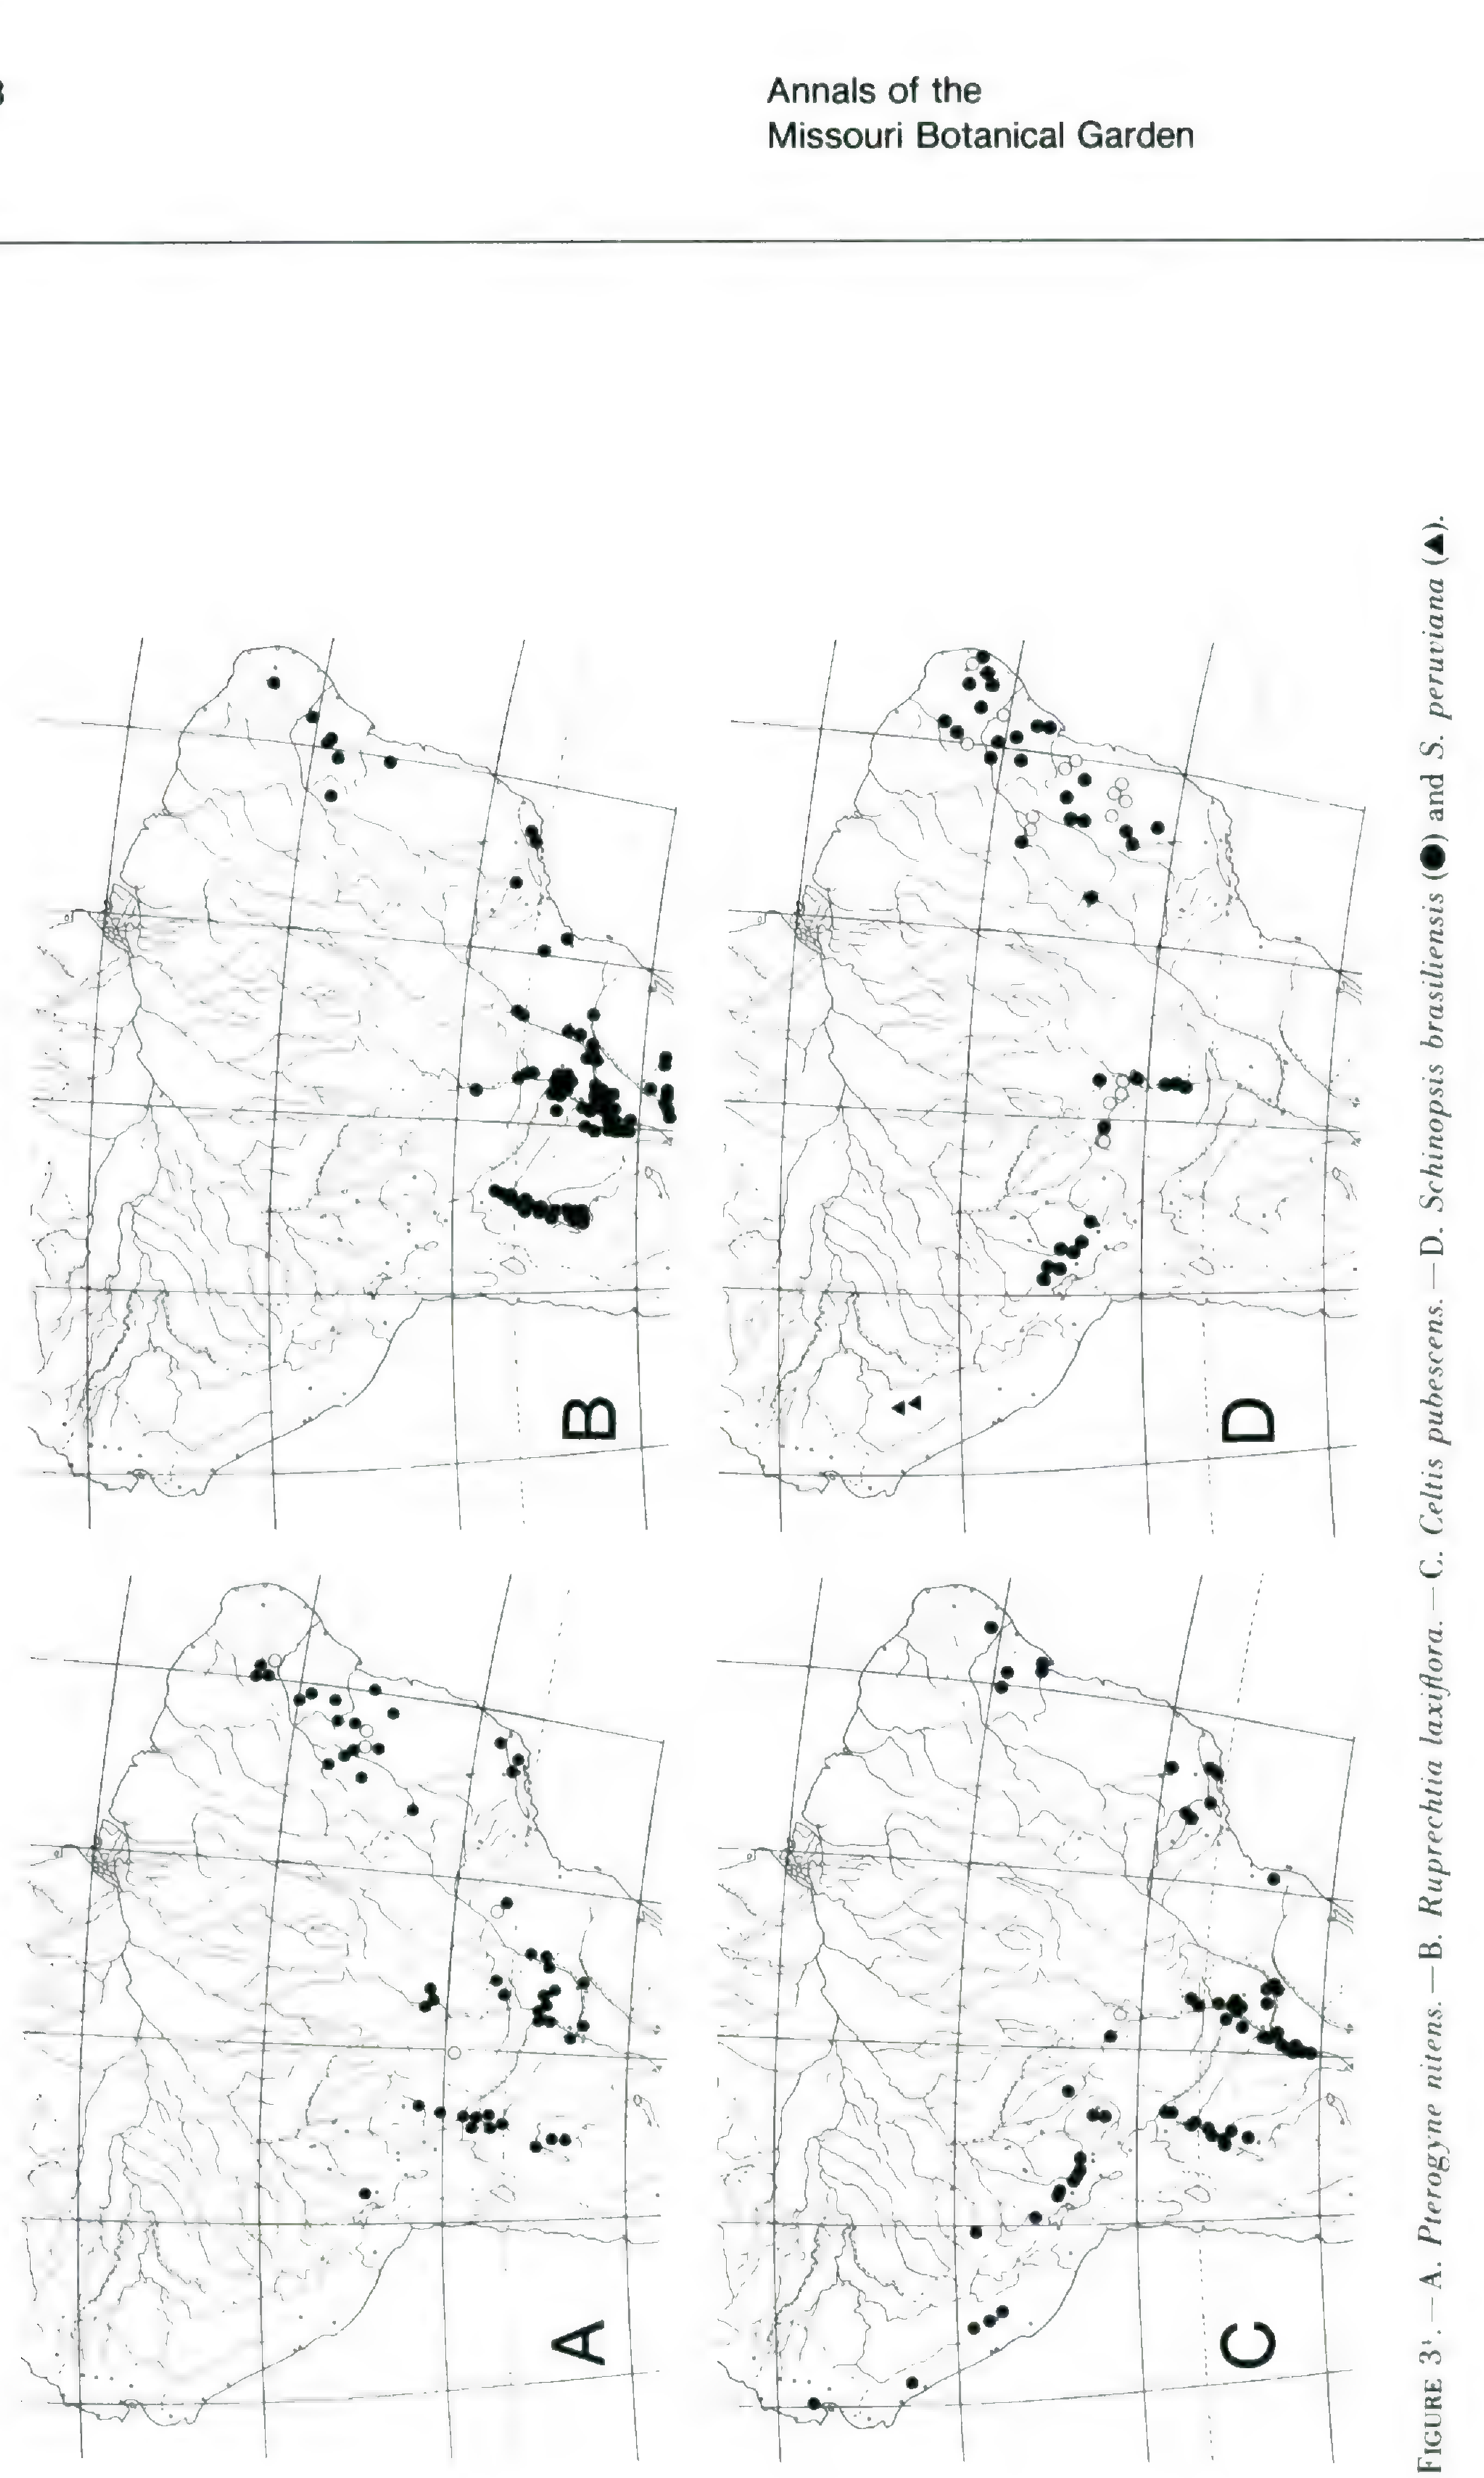

FIGURE 3[1].—A. *Pterogyne nitens*.—B. *Ruprechtia laxiflora*.—C. *Celtis pubescens*.—D. *Schinopsis brasiliensis* (●) and *S. peruviana* (▲).

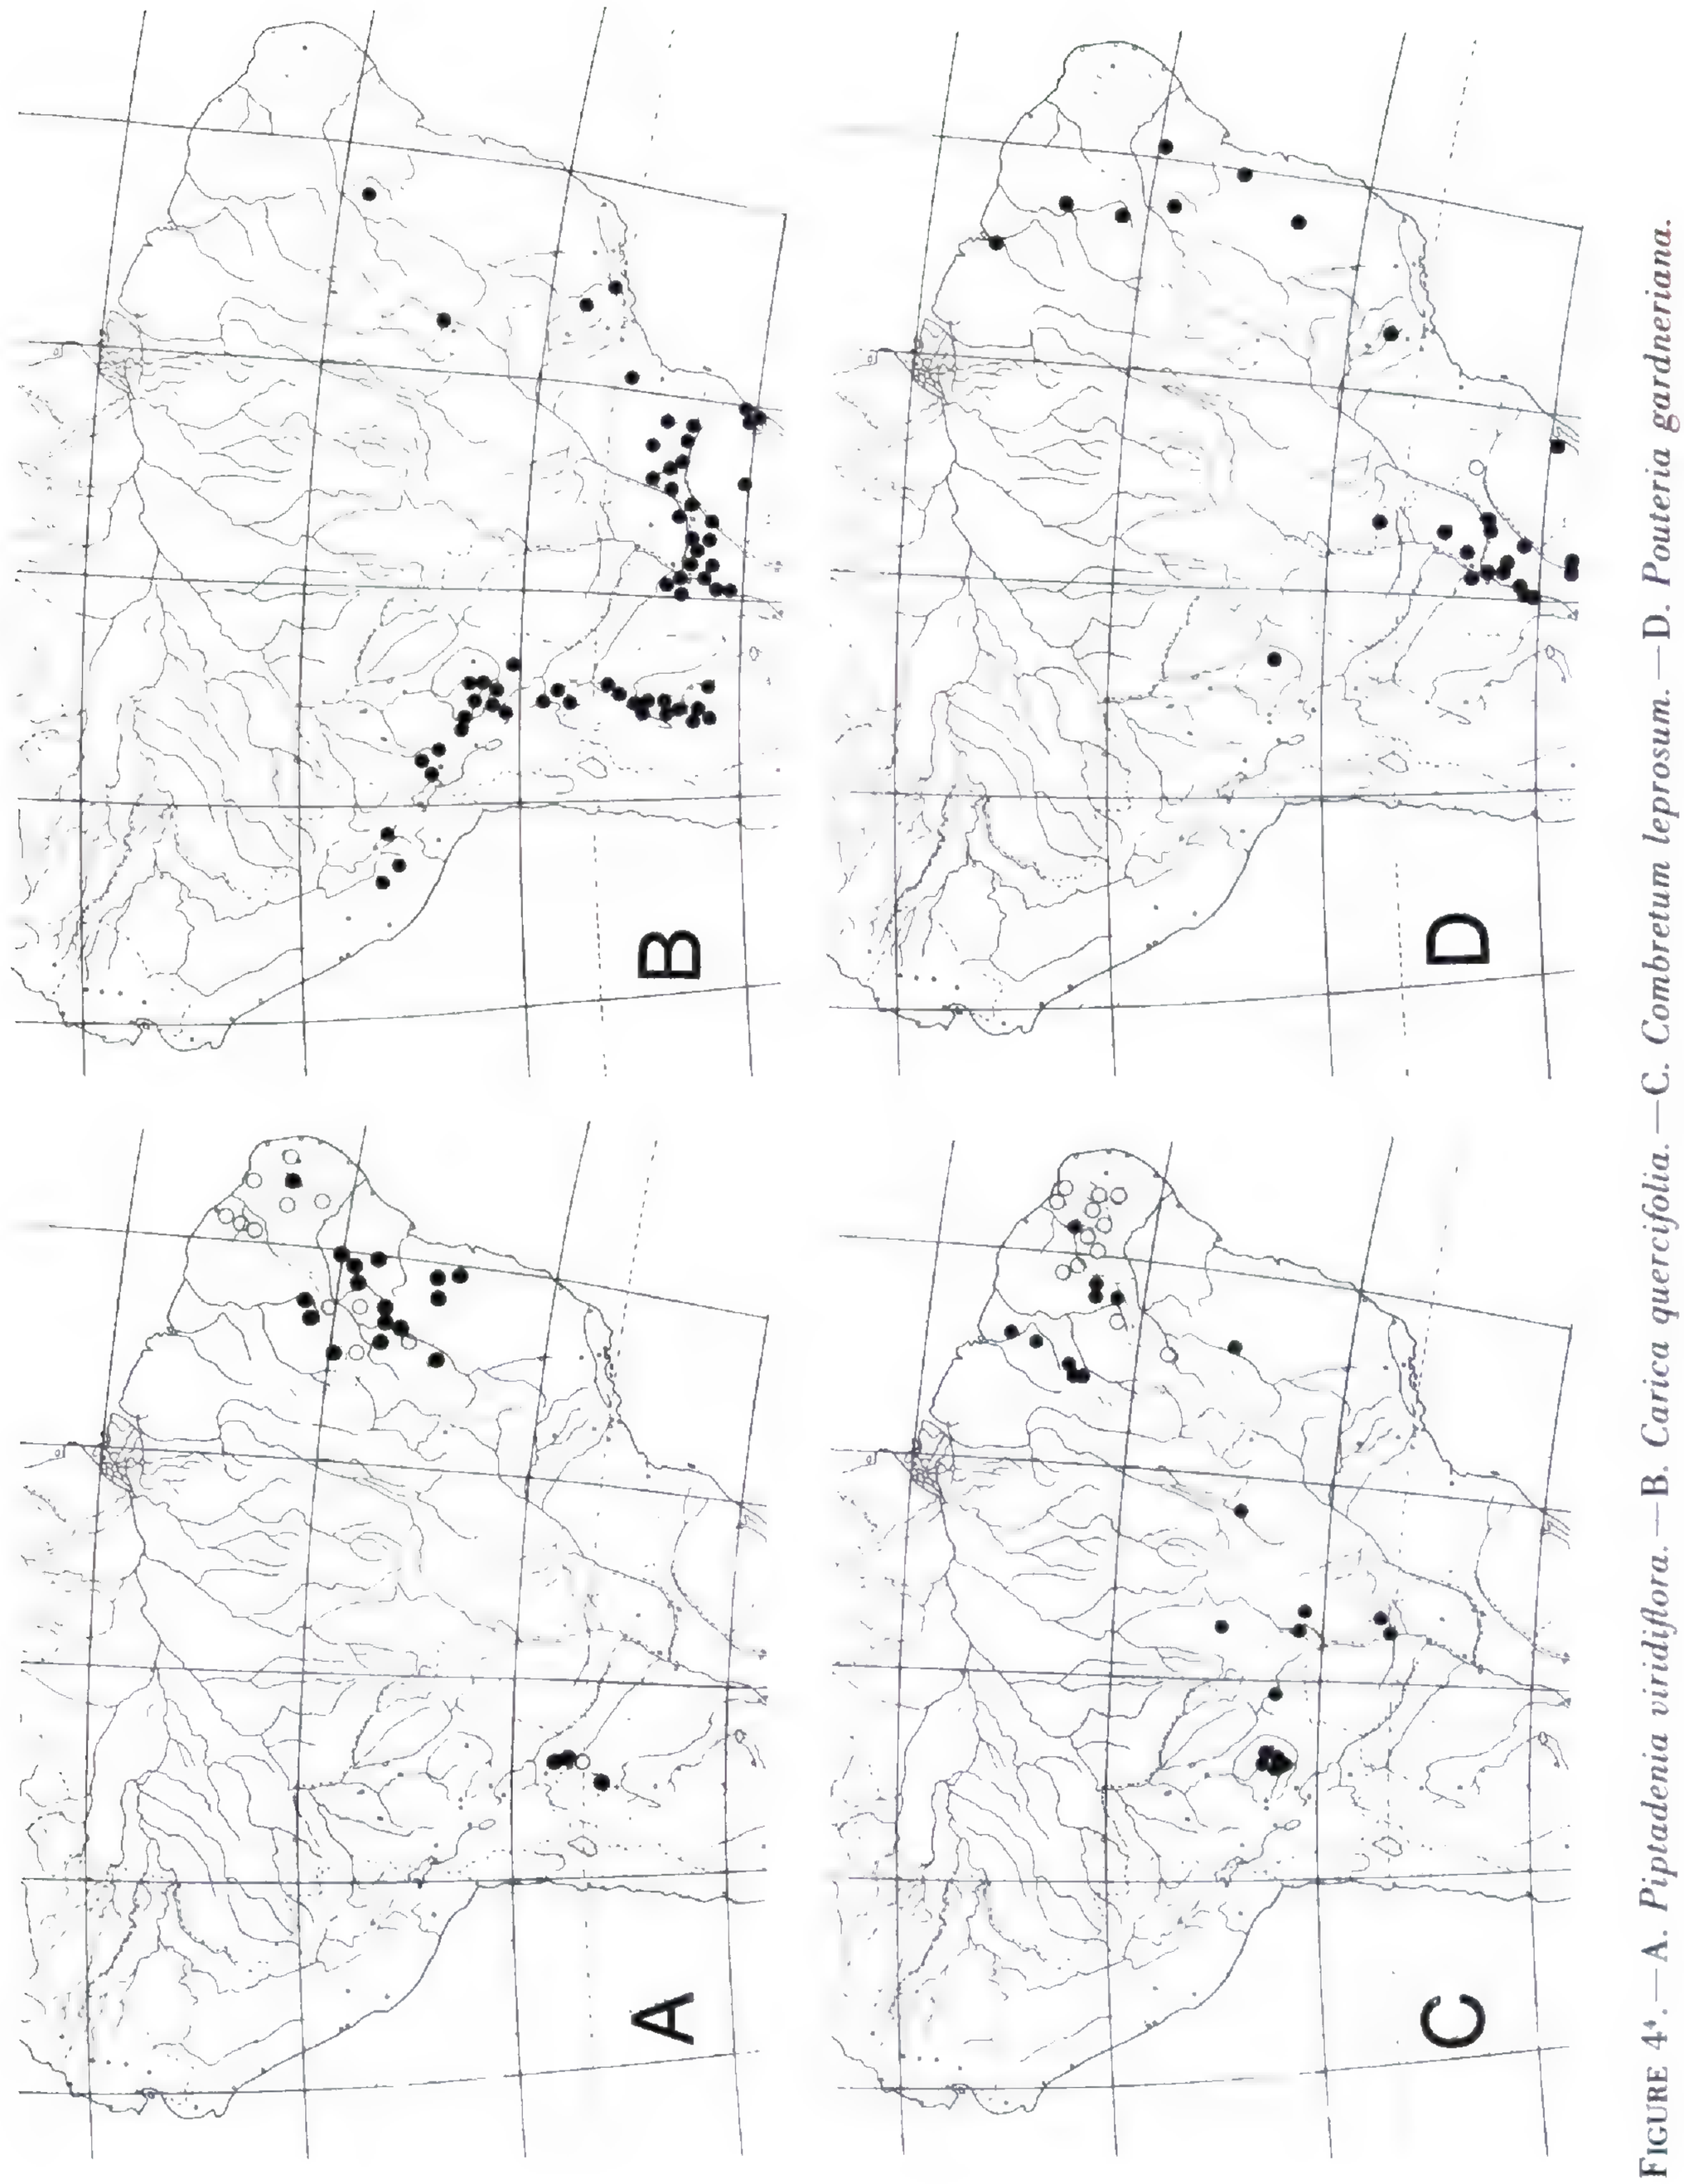

FIGURE 4*.—A. *Piptadenia viridiflora.* —B. *Carica quercifolia.* —C. *Combretum leprosum.* —D. *Pouteria gardneriana.*

4C). It is also common in Maranhão state in areas suspected of having links with the caatingas, and it has been collected in the River Paraguay valley and in Santa Cruz de la Sierra area, but seems to be missing from there to the south and northwest. The pattern followed by *Pouteria gardneriana* (D. C.) Radlk. (Sapotaceae) is somewhat more uncertain, since although it is well recorded in the caatingas and in the Paraguay–Paraná system, it is unclear whether it spreads into the Piedmont nucleus apart from one collection in Santa Cruz in Bolivia (Fig. 4D).

*Sterculia striata* A. St.-Hil. & Naudin (Sterculiaceae) is a rather different case (Fig. 5A), since it only marginally appears in tall, arboreal caatinga (Andrade-Lima, 1975; Ratter et al., 1978). It is much commoner in mesophilous forests within the cerrados expanse or in mesotrophic cerradão (Ratter et al., 1978, 1988), but it shuns the poor soils of the cerrado sens. str. It extends into the Amazon valley (Taroda, 1984) as well as to the River Paraguay area, particularly on calcium-rich soils (Ratter et al., 1988; Prado et al., 1992), and its westernmost collections come from the area of Santa Cruz.

The small bignoniaceous tree *Tabebuia caraiba* (Mart.) Burch. (synonymized with *T. aurea* (Manso) Benth. & Hook. in Gentry, 1992) has an unusual distribution in that it is common in the cerrados on typically poor-quality soils, but is also relatively common in the caatingas of Pernambuco (Andrade-Lima, 1954, 1960) and Bahia, and it can be found in the Amazon valley around Santarem. This species has also been frequently collected in the Paraguay River valley sector from Brazil to Argentina, while Ramella & Spichiger (1989) reported it for cerrado-like communities on top of the plateau in Cerro León. *Tabebuia caraiba* also appears occasionally in central Bolivia, including a specimen collected near Santa Cruz de la Sierra, thus conforming somewhat to the Pleistocenic Arc (Fig. 5B), although the main core area of this species is the central Brazilian cerrado area. Somewhat similar distributions, with extensive occurrence in typical cerrado, are shown by *Hymenaea martiana* Hayne (Leguminosae) and *Machaerium acutifolium* J. Vogel (Leguminosae) but both species lack the Amazonian extension (Fig. 5C, D). *Hymenaea martiana* spreads from the caatinga into the cerrado savannas in Goiás, the Federal District, and Minas Gerais, as well as occurring in the forests in the Paraguay River area. *Machaerium acutifolium* also occurs in the cerrados as well as the caatingas, and extends south into the Mata Atlântica in Rio de Janeiro, isolated "campo" areas in Minas Gerais and São Paulo, and in forests in eastern Paraguay. This latter species has a somewhat invasive–pioneer tendency, which may account for its more extended distribution.

A number of genera show vicariad species that occupy parts of the Pleistocenic Arc. One such case is *Brunfelsia* L. (Solanaceae). Recently, Plowman (1979) drew attention to the fact that *B. uniflora* (Pohl) D. Don forms a link between the older Andean species and the eastern Brazilian ones within section *Franciscea*. It has been collected in northern Venezuela, in Roraima (Brazil) and neighboring Guyana, also in the Yungas area of the eastern-facing slopes of the Andes in southwestern Bolivia and northwestern Argentina, to then reappear sporadically in the caatingas and more abundantly in the Atlantic forests and planalto forests in eastern Brazil. Two additional species, *B. pilosa* Plowman and *B. australis* Benth., are apparently derived from *B. uniflora*. *Brunfelsia australis*, previously treated as a subspecies of *B. uniflora*, fills in the southernmost gap corresponding to the Misiones nucleus in the distribution of its mother species in Paraguay and northeastern Argentina (Fig. 6A). *Brunfelsia uniflora* thus shows a similar but much more complete distribution pattern (Fig. 6B) to that of *Commiphora leptophloeos* (Mart.) Gillet (Burseraceae).

The genus *Patagonula* L. (Boraginaceae) seems to be endemic to the Pleistocenic Arc (Fig. 6C). This genus comprises only two species: *P. bahiensis* Moricand is endemic to the caatingas, whereas the type species, *P. americana* L., has been collected or reported for the forests in Paraná state in Brazil, the upper Uruguay River basin (Klein, 1972), eastern Paraguay, and northeastern Argentina in subtropical forests from Misiones to the eastern Chaco district (Cabrera, 1976; Lewis & Pire, 1981). It is also the third most important species in the Piedmont nucleus forests of northwestern Argentina and southern Boliva (Cabrera, 1976). Although *Patagonula* has not been reported from other areas of the Pleistocenic Arc, it would not be surprising for it to be encountered in the future in the rather poorly studied areas of Cerro León, the Santiago and Chiquitos ranges, or south of Santa Cruz de la Sierra.

The genus *Loxopterigium* Hook. f. (Anacardiaceae) presents five disjunct species in South America (Fig. 6D). The scarcely known *L. gutierrezii* Barkley was collected only once in the Caribbean sector of Colombia, while *L. sagotii* Hook. f. is better known from the Guianas. The tree *L. hu-*

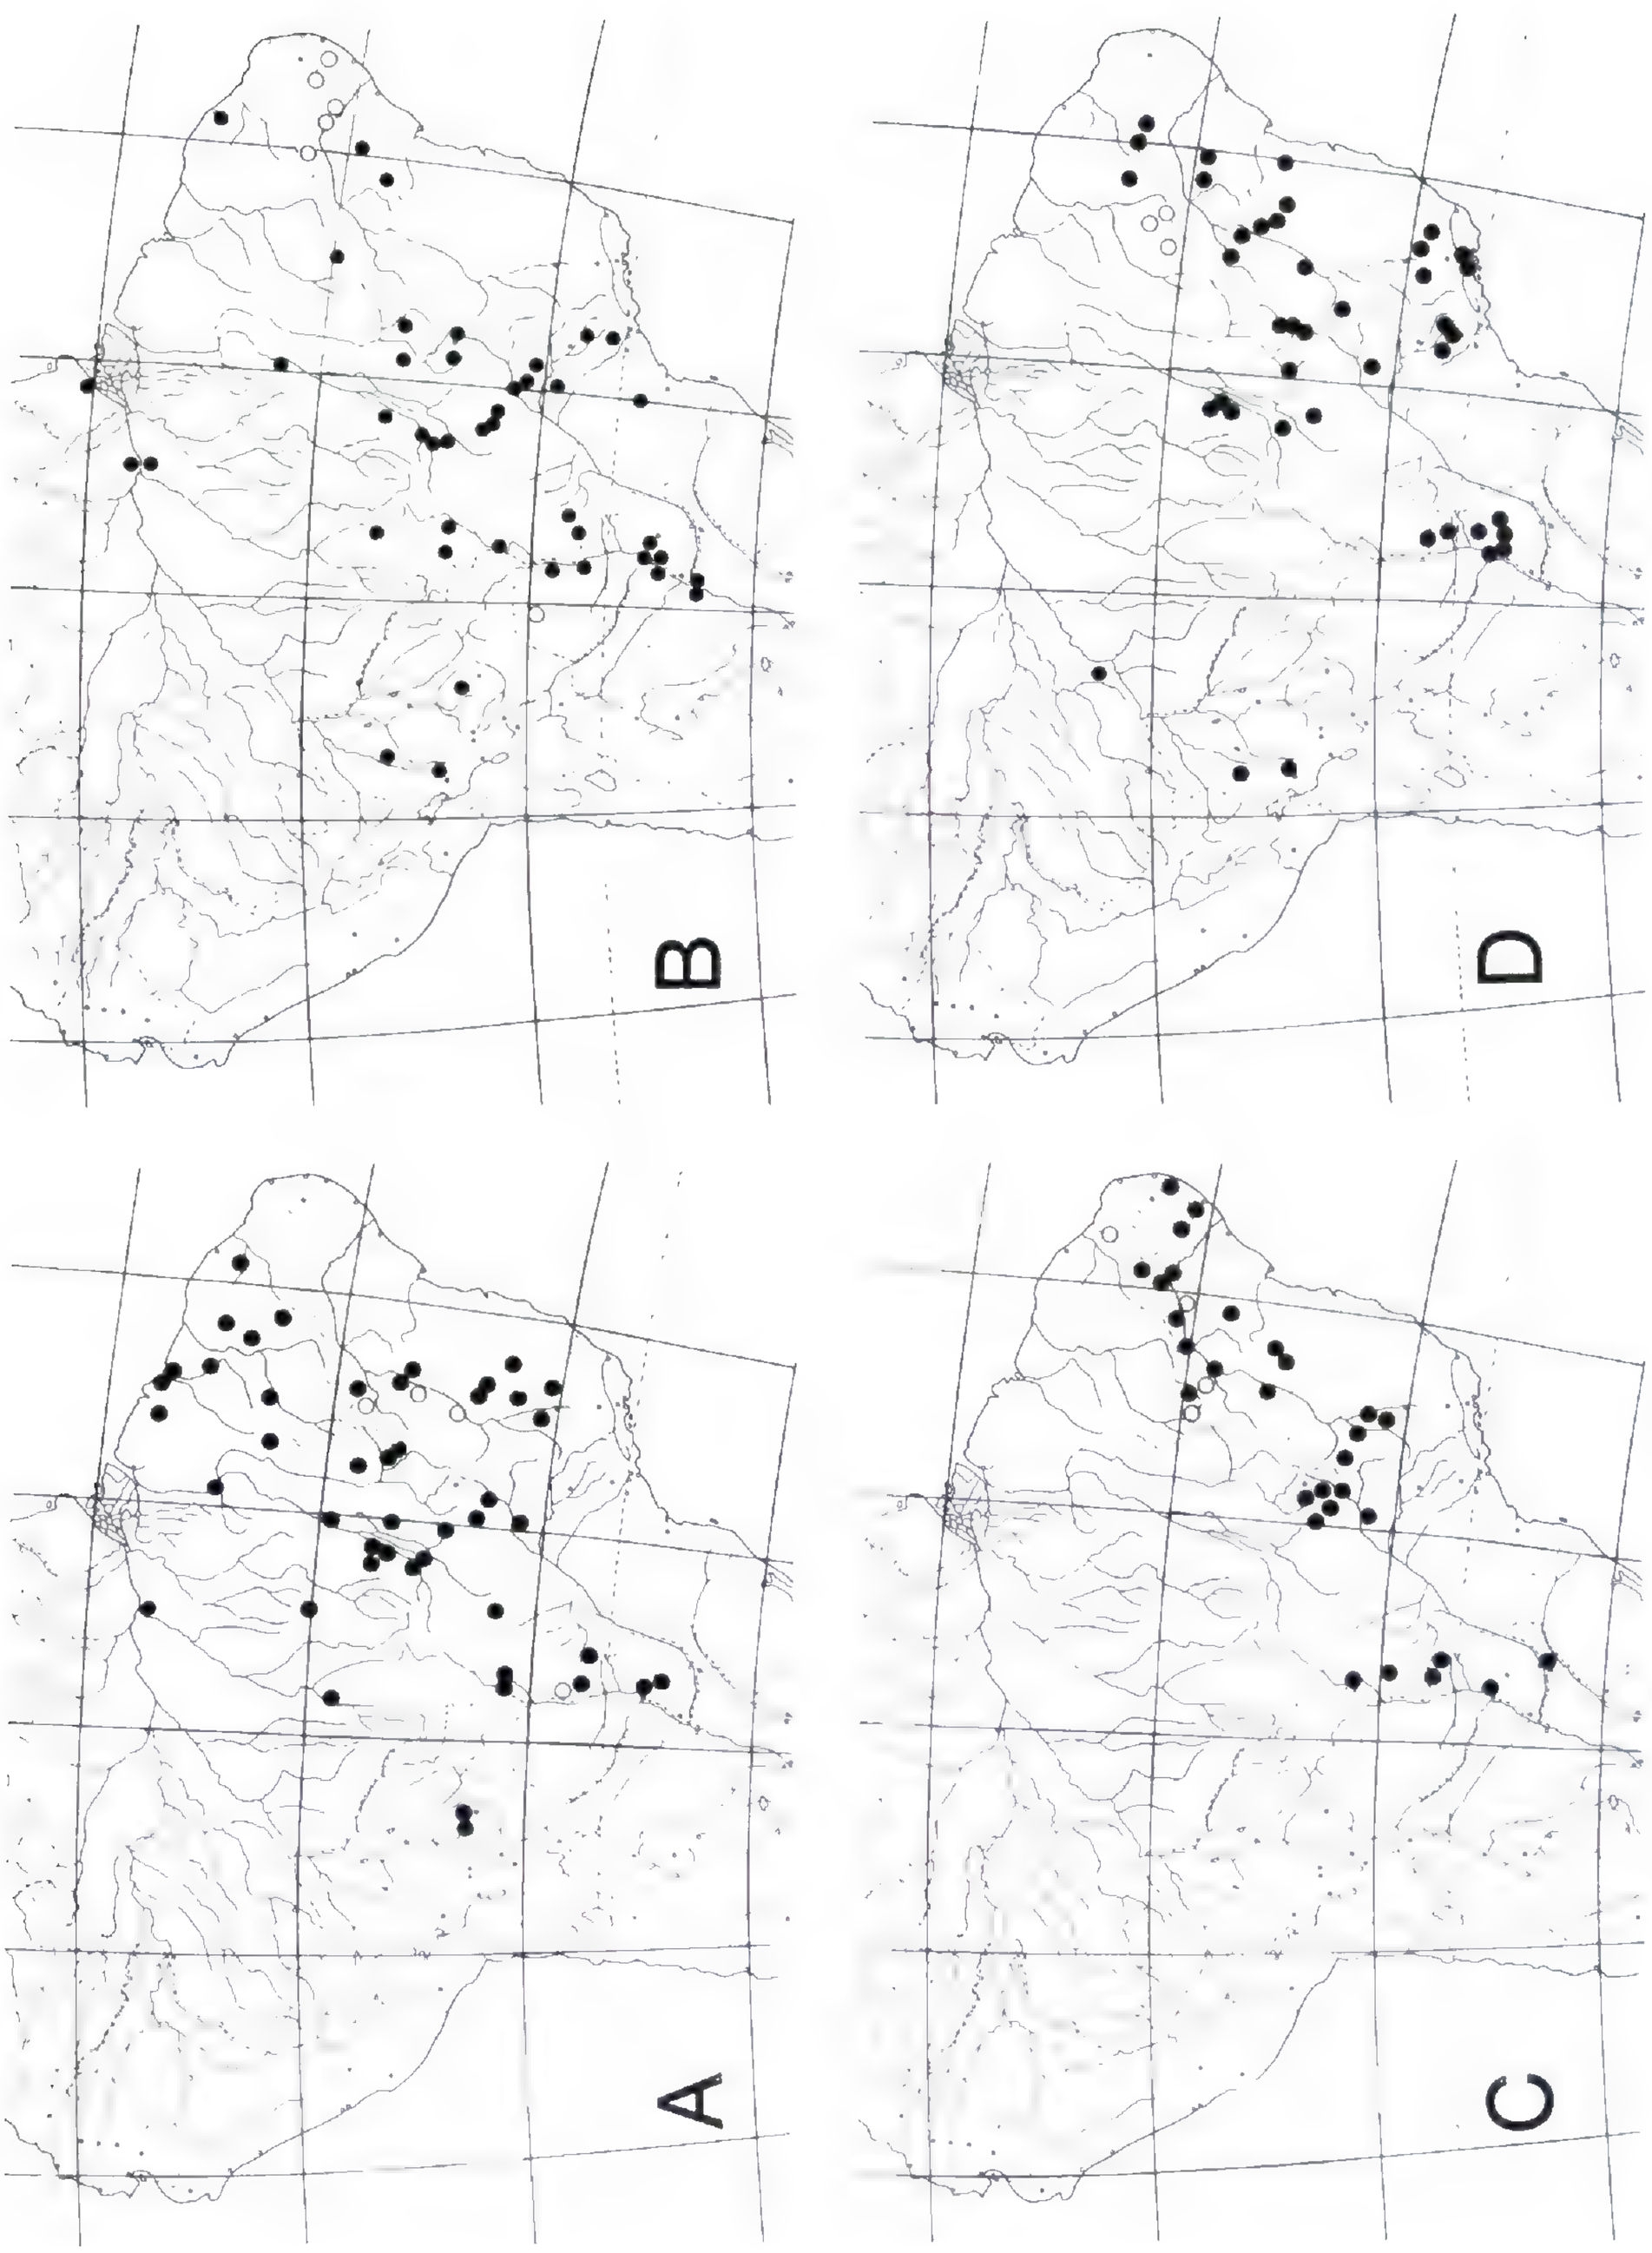

FIGURE 5[1]. —A. *Sterculia striata*. — B. *Tabebuia caraiba*. —C. *Hymenaea martiana*. —D. *Machaerium acutifolium*.

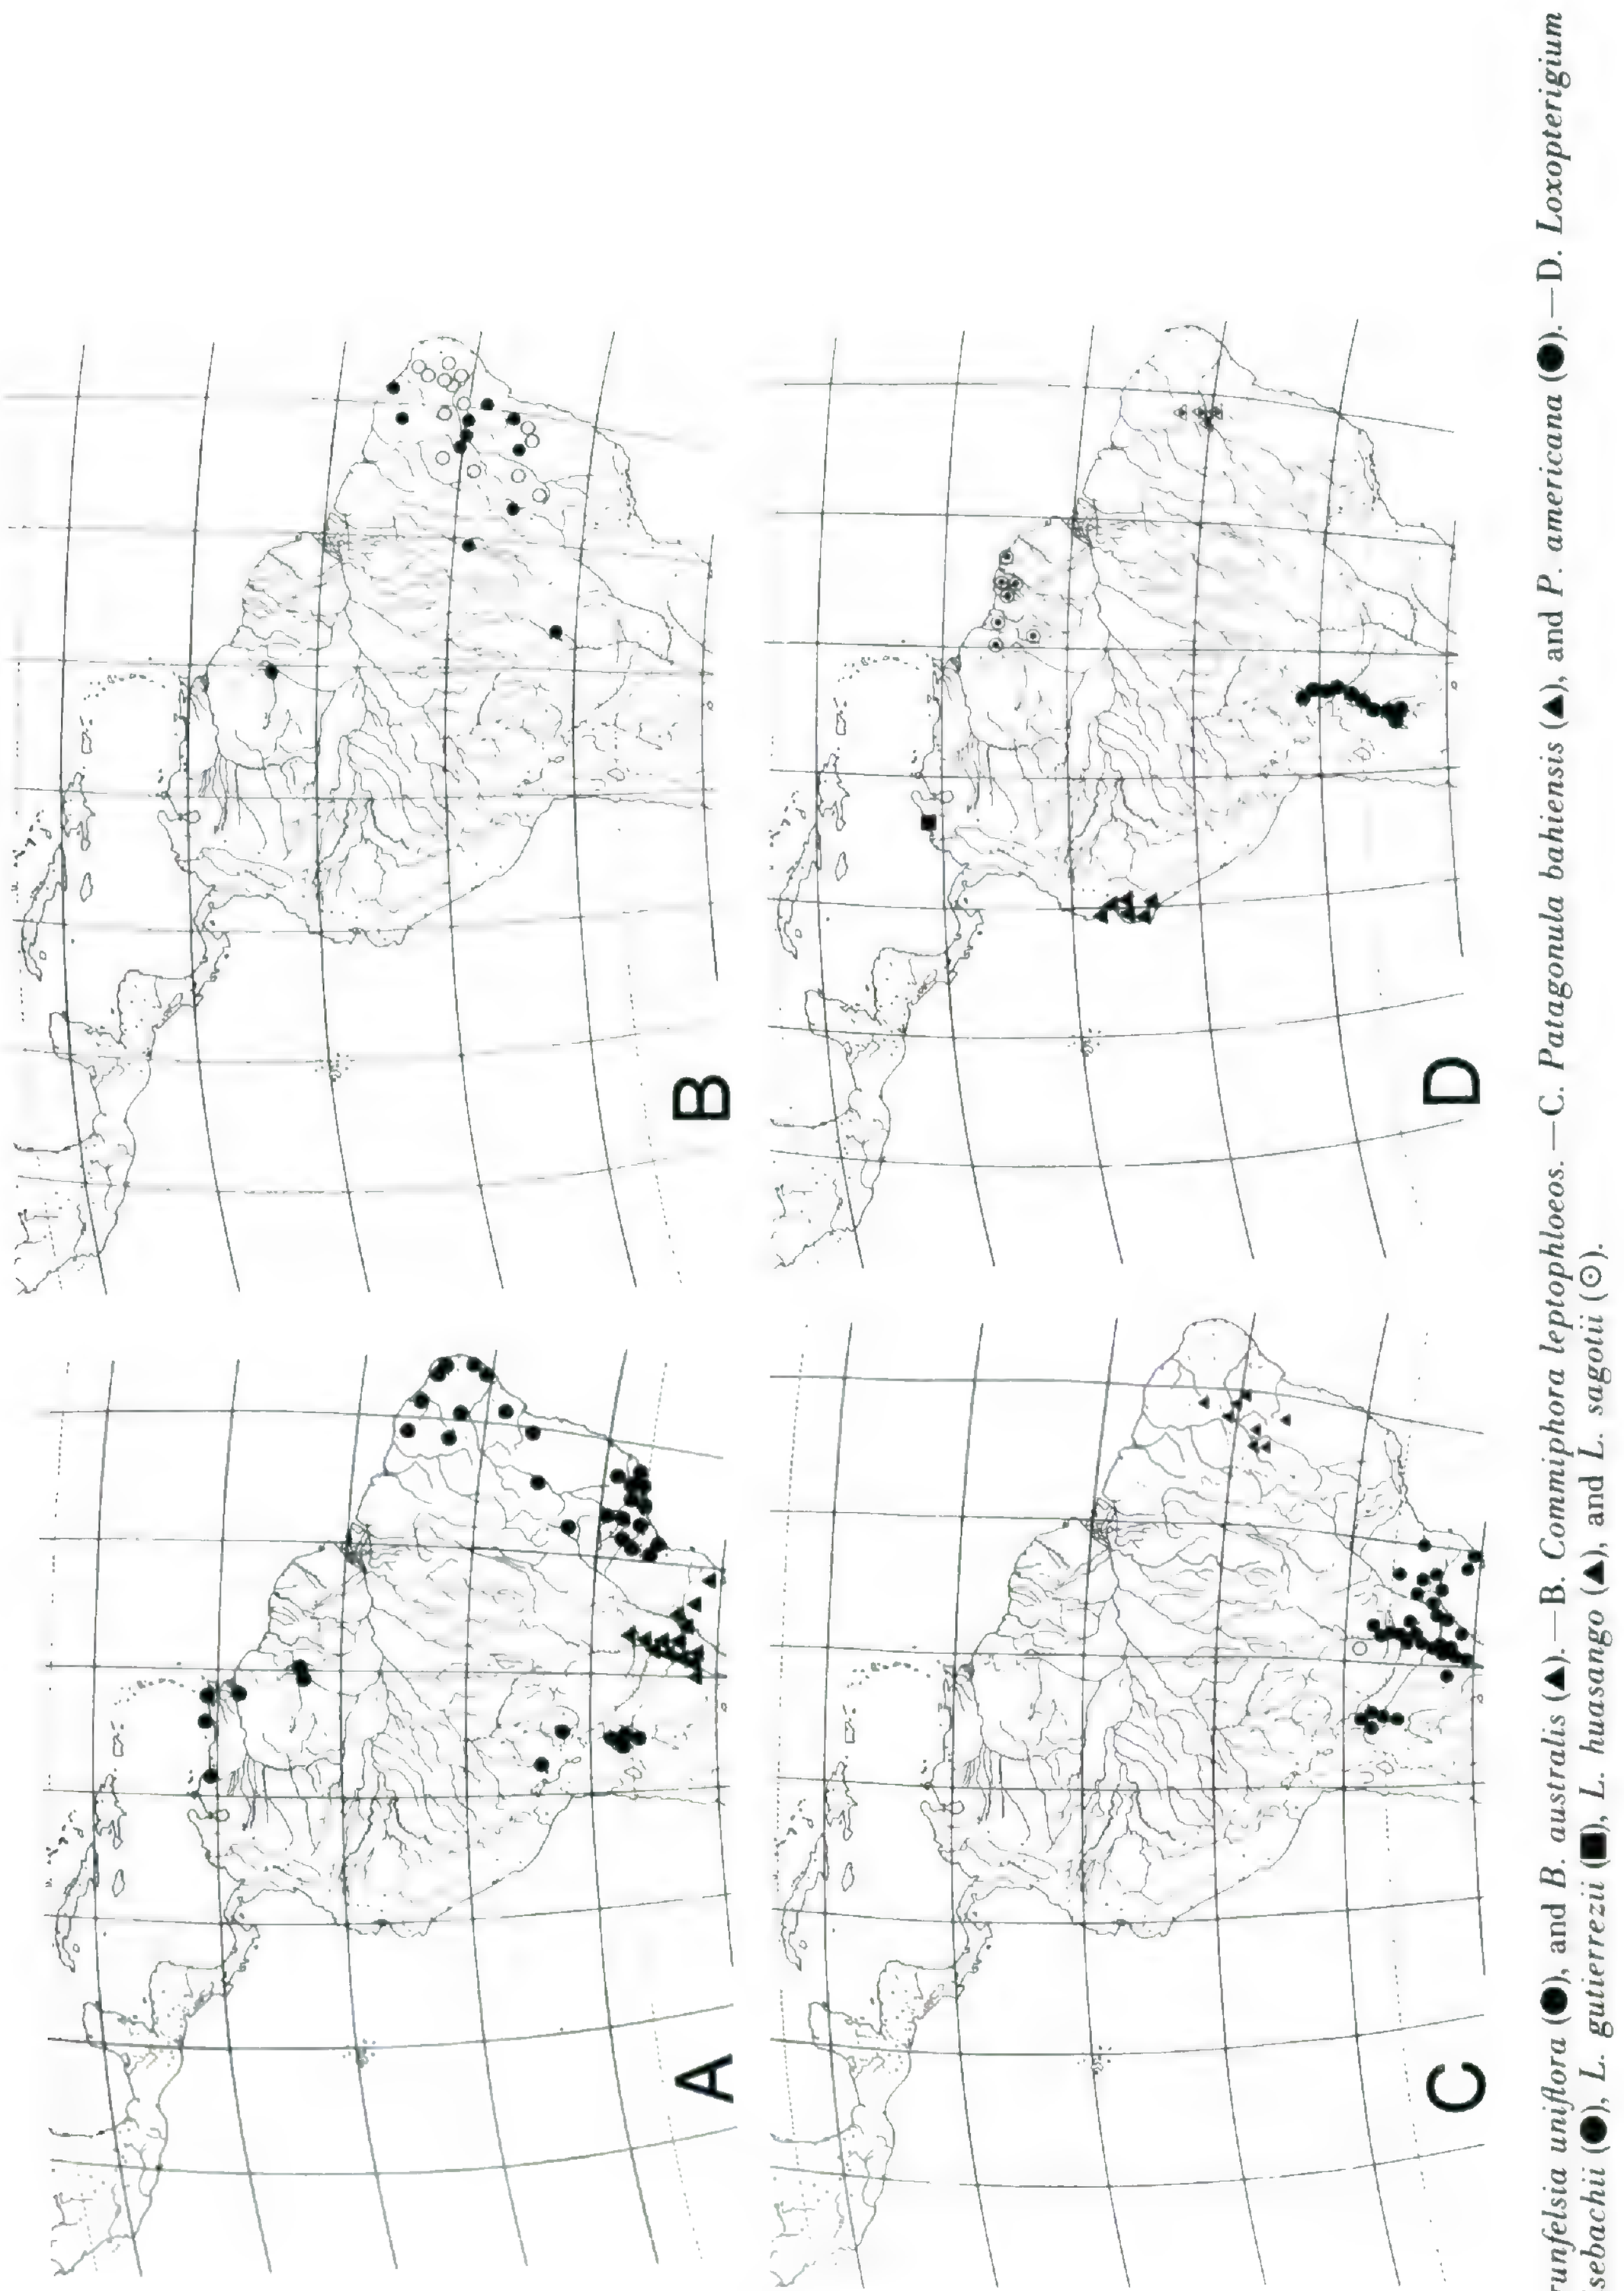

FIGURE 6[4].—A. *Brunfelsia uniflora* (●), and *B. australis* (▲).—B. *Commiphora leptophloeos*.—C. *Patagonula bahiensis* (▲), and *P. americana* (●).—D. *Loxopterigium gardnerii* (△), *L. grisebachii* (●), *L. gutierrezii* (■), *L. huasango* (▲), and *L. sagotii* (⊙).

*asango* Spruce appears only in seasonal semiarid to arid formations in coastal southwestern Ecuador and northern Peru, while the caatinga woodlands of a small area of Piauí and Bahia contain the few recorded populations of *L. gardneri* Engl. (= *Apterokarpos gardneri* (Engl.) Rizzini). Finally, *L. grisebachii* Hieron. & Lorentz ex Griseb. is an important member of the sub-Andean piedmont forests in northwestern Argentina and southern Bolivia, which separates chaco vegetation from the rain and cloud forests of the Yungas. In this case, therefore, the allopatric species within a small genus together comprise the familiar distribution pattern of this Seasonal Forests Arc in South America.

The unresolved taxonomic problem (see comments in Burkart, 1949, and Lewis, 1987) of the *Geoffroea striata* (Willd.) Morong–*G. spinosa* Jacq. (Leguminosae) complex provides another example of the Seasonal Forests Arc (Fig. 7A). In our experience, the diagnostic characters provided by Burkart (1949) fail to separate these alleged species clearly, and this complex is treated here as one polymorphic unit which, however, segregates well from the only other species of the genus, the typically but not exclusively chaquenian *G. decorticans* (Hook. & Arn.) Burkart. The *G. striata–spinosa* complex appears in northern Venezuela, western Ecuador and adjoining Peru, and in central Bolivia in the Yungas-like area of the Río Grande or Piraí, for the Andean related part, whereas in the lowlands there are essentially two nuclei: the Caatingas and Misiones. A similar pattern is followed by *Ipomoea carnea* Jacq. subsp. *fistulosa* (Mart. ex Choisy) Austin (Convolvulaceae), including some Caribbean islands, northern Colombia and Venezuela, the same sectors of Ecuador and Peru previously mentioned, and in riverine environments linked to the sub-Andean Piedmont forests in northwestern Argentina but where the exsiccata might be of plants escaped from cultivation (O'Donell, 1959). In the east of the continent it occurs in the Caatingas and Misiones nuclei, and some odd appearances in the Amazon River valley area (around Santarem and Belém) have to be taken into account (Fig. 7B). This pattern is also followed in part by *Peltophorum dubium* (Spring.) Taub. (Leguminosae), which has been recorded for seasonal forests in Venezuela, but is more frequent in the east of the continent, namely in the caatingas, in mesophilous forests in Minas Gerais, São Paulo and Paraná, in the upper Uruguay River valley in Santa Catarina, and it has been frequently collected in eastern Paraguay. Once again this species is entirely absent from the chaco, only to reappear in Yungas-like areas close to Santa Cruz de la Sierra in Bolivia (Fig. 7C).

A similar situation, but in this case with the component elements segregated as varietal taxa, occurs in the caesalpinioid *Senna spectabilis* (DC.) Irwin & Barneby (Irwin & Barneby, 1982). The variety *spectabilis* extends from coastal Venezuela to Andean valleys in the Mérida area of the same country and the Magdalena and Cauca river valleys in Colombia, and then reappears in seasonal formations in Ecuador and further south in dry valleys in the Peruvian Andes (Fig. 7D). This variety is also a conspicuous member of the Yungas forests in Bolivia, and of the deciduous piedmont forests in southern Bolivia and northwestern Argentina where it is called "carnaval." As usual in this kind of distribution pattern this tree is entirely absent from the Chaco, only to reappear in eastern Paraguay. The other taxon, variety *excelsa* (Schrader) Irwin & Barneby, is virtually restricted to the caatinga in northeast Brazil, where it is called "canafistula."

The shrub to small tree *Solanum granulosoleprosum* Dunal (Solanaceae) shows a similar distribution (Fig. 8A). It has been collected in northern Colombia and Guyana, is absent from the Amazon but reappears in the caatingas of Bahia and Minas Gerais, and further south in the mesophilous forests of Rio de Janeiro, Paraná, and Santa Catarina, and also extends into adjoining Paraguay and northeastern Argentina, particularly in the Austro-Brazilian Transitional forest (Prado, 1991). As usual, it is absent from the Chaco but occurs in the eastern slopes of the Andes in northwestern Argentina and Bolivia.

## Restricted Arc Distributions

Some caatinga species have relatively widespread distributions but do not show the full sequence of links with other seasonal formations as do most of the cases considered above. Such species can be considered as having a restricted distribution, in which the third Piedmont nucleus is either lacking or very fragmentary. Several examples occur in the genus *Aspidosperma* (Apocynaceae). One such case is *A. pyrifolium* Mart. (Fig. 8B), which has been reported for Cerro León in Paraguay (Ramella & Spichiger, 1989). It is a characteristic species of the caatingas that spreads extensively into Minas Gerais, but then there is a disjunction with the populations on the river Paraguay. There is also a puzzling exsiccatum from Faro (Marcondes-Ferreira, 1988), in the Pará state,

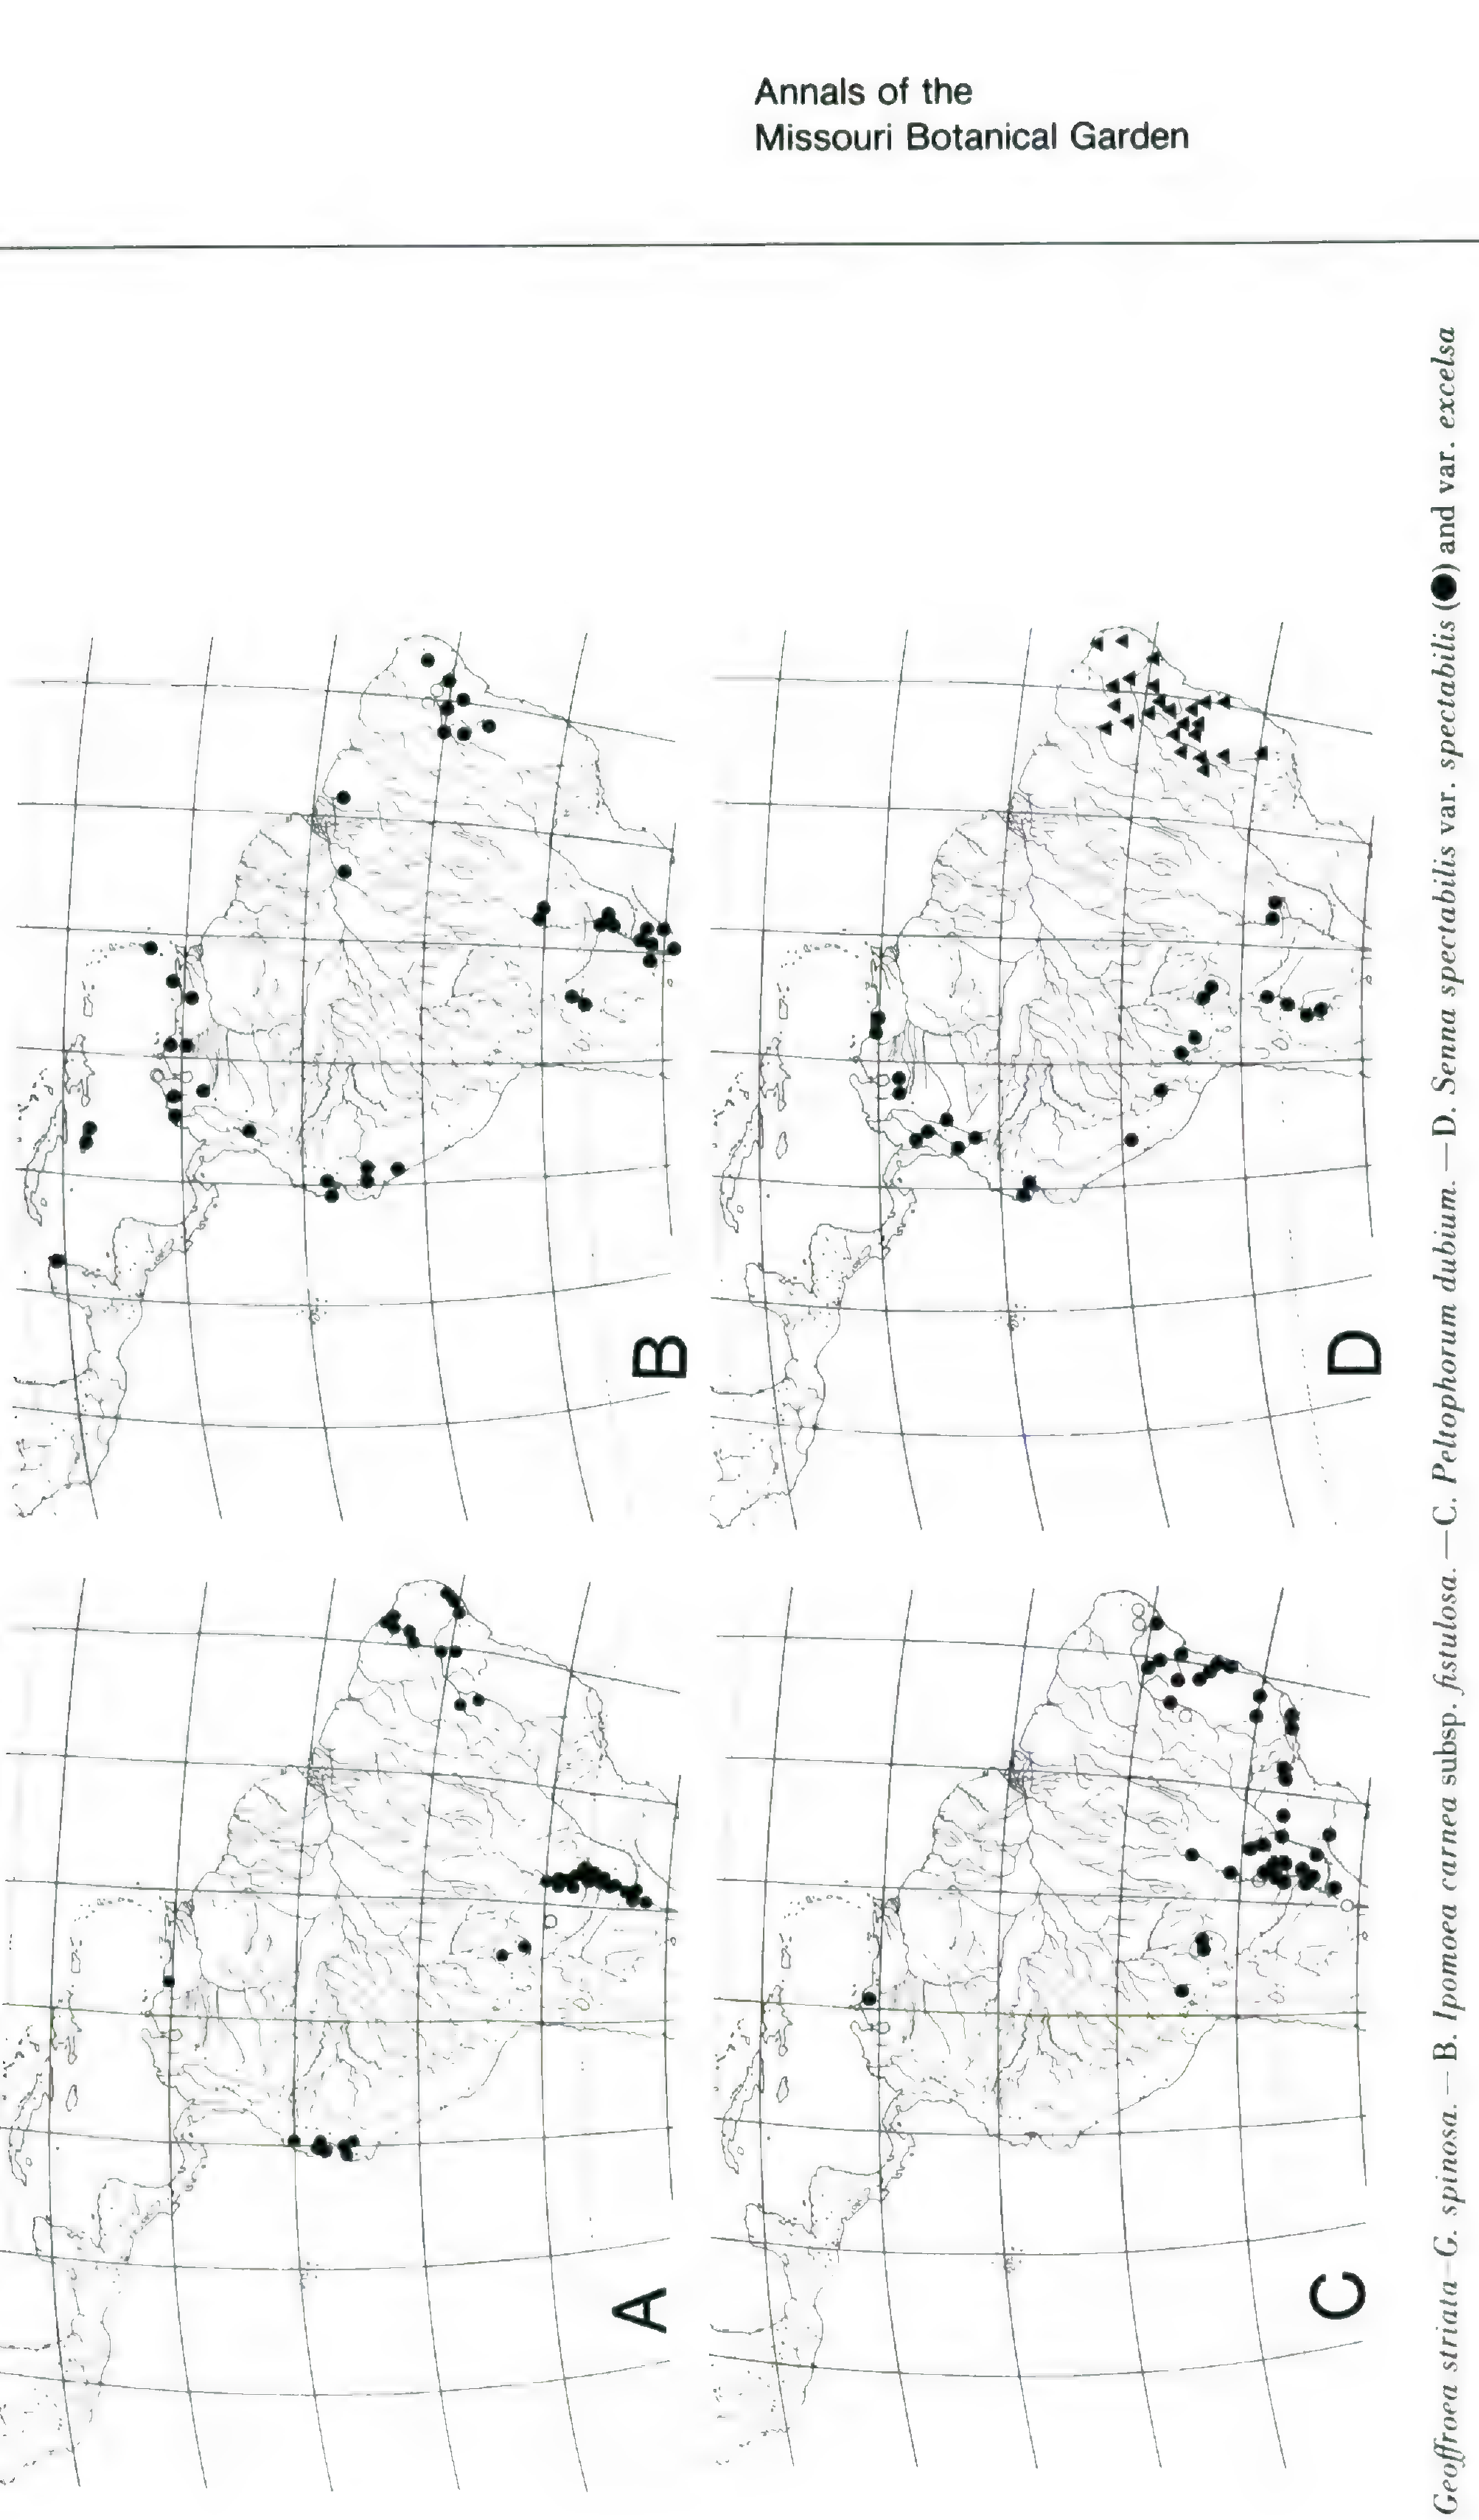

FIGURE 7.—A. *Geoffroea striata*–C. *Peltophorum dubium*.—D. *Senna spectabilis* var. *spectabilis* (●) and var. *excelsa* (▲).

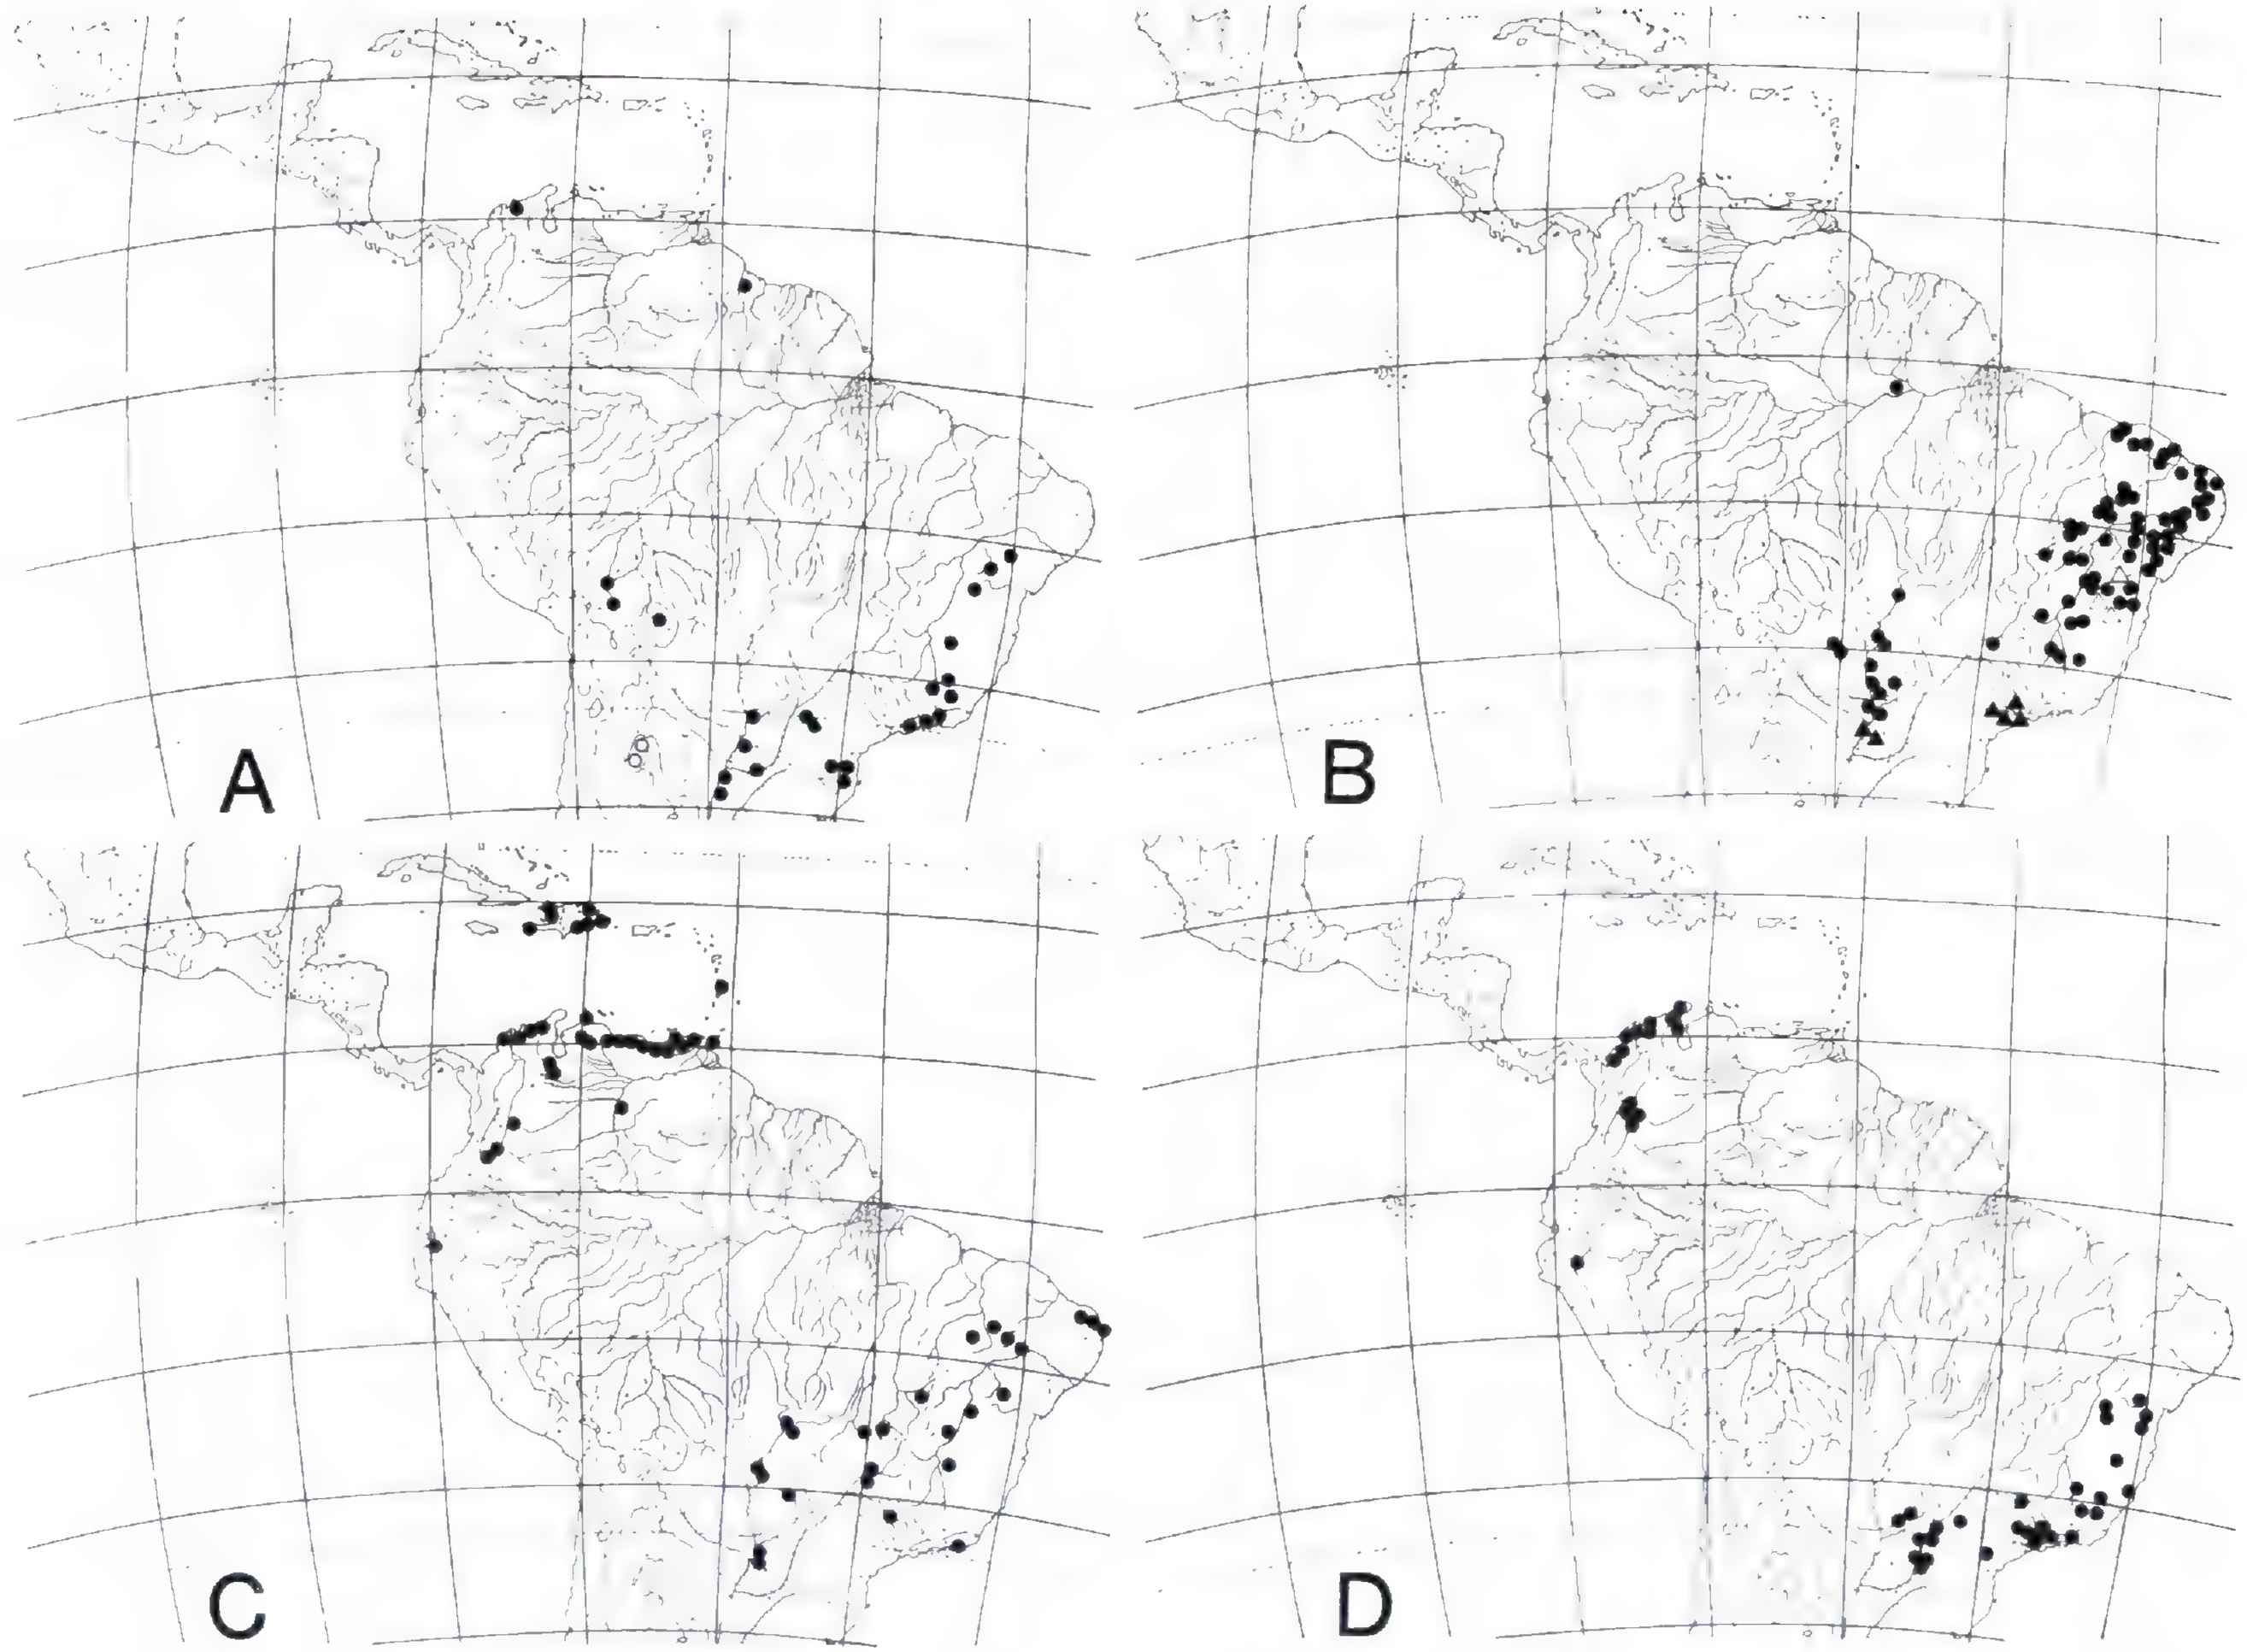

FIGURE 8[1].– A. *Solanum granuloso-leprosum*.—B. *Aspidosperma pyrifolium* (●), *A. riedelii* subsp. *riedelii* (▲) and subsp. *oliganthum* (△).—C. *Aspidosperma cuspa*.—D. *Aspidosperma polyneuron*.

a locality in a small sector of the Amazon valley where several other caatinga elements (Andrade-Lima, 1959) have also been collected (see further comments below). The tree *Aspidosperma riedelii* Müll. Arg., which has been treated by Marcondes-Ferreira (1988) as comprising two subspecies, subspecies *oliganthum* (Wood.) Marc.-Ferr., a Bahian endemic, and subspecies *riedelii* with two disjunct localities in the forests of São Paulo and in central Paraguay (Fig. 8B), shows a similar but more fragmented pattern. *Aspidosperma cuspa* (Kunth) Blake (Fig. 8C), which has been collected in the dry forests of Hispaniola and Martinique, is also a common tree in the dry Caribbean sectors of Colombia and Venezuela, countries in which it also extends to some dry, inter-Andean valleys. It reappears in southwestern Ecuador (Woodson, 1951), and at nearly the same latitude but on the opposite side of the continent in Rio Grande do Norte (northeast Brazil). A rather infrequent plant in the Caatingas nucleus, it is found scattered in the cerrado of central Brazil, and on rock outcroppings of the Cordillera de Altos in Paraguay (Marcondes-Ferreira, 1988). The taxonomically closely related *A. polyneuron* Müll. Arg. (Fig. 8D) parallels in part the distribution of *A. cuspa*, since it has been collected from the western half of the dry Caribbean sector and also in dry inter-Andean valleys in Colombia, but it has not been recorded so far from the eastern zone. No collections in Ecuador have been located, but it occurs in northern Peru in an area of similar vegetation to that of southwest Ecuador (Weberbauer, 1936; Harling, 1979). This species also occurs in the caatingas of Bahia (northeastern Brazil) and extends in a northeast-southwest arc through mesophilous forests in Minas Gerais, Espírito Santo, Rio de Janeiro, São Paulo, and Paraná, to Paraguay and a very reduced area in north Misiones (Argentina).

The valuable timber tree *Balfourodendron riedelianum* (Engl.) Engl. (Rutaceae) occurs in the caatingas (Fig. 9A) and extends south to the planalto forests in Saõ Paulo and Paraná states, along the upper Uruguay River valley, and reaching eastern Paraguay and northeastern Argentina. Rather similar, two-nuclei distributions are found in the soft-wooded tree *Phytolacca dioica* L. (Phytolaccaceae), *Alseis floribunda* Schott (Rubiaceae), and *Astronium concinnum* Schott (Anacardiaceae) (Fig. 9B–D).

Another group of woody species is absent from the caatingas but occurs in the Misiones and commonly also in the Piedmont nuclei within the Pleistocenic Arc. These include two sapindaceous genera: the monotypic *Diatenopteryx*, with *D. sorbifolia* Radlk. (Fig. 10A), and the ditypic *Diplokeleba*, with one species, *D. floribunda* N.E. Brown, which is abundant on the Paraguay–Paraná system, while the other, *D. herzogii* Radlk., is known only from the type collection in Cabezas, Bolivia (Fig. 10B), most likely from the deciduous forests frequent in that area (Coro, 1956). A similar distribution is found in *Ziziphus oblongifolius* S. Moore (Rhamnaceae) (Fig. 10C), which is a frequent shrub in the north of the Paraguay–Paraná system (Prado et al., 1992), and cited by Herzog (1910) for Bolivia and Escalante (1946) for Orán in Salta (Argentina). Three species that are restricted to the Misiones nucleus are *Astronium balansae* Engler (Fig. 9D), *Ziziphus guaranitica* Malme (Fig. 10D), and *Maytenus ilicifolia* (Celastraceae) (Fig. 11A). Another taxon restricted to a single nucleus is the monotypic genus *Athyana* Radlk. (Sapindaceae), with *A. weinmannifolia* (Griseb.) Radlk., which is endemic to the piedmont forests of northwestern Argentina and southern Bolivia (Fig. 11A). The kind of distributions that is restricted to the second and third nuclei is also illustrated by the elegant rubiaceous tree *Calycophyllum multiflorum* Griseb., the dominant and characteristic species of the palo blanco forest in the piedmont of the sub-Andean chains (Fig. 11B), to which it gives its vernacular name, and which is also common in the River Paraguay area and in the Cerro León (Ramella & Spichiger, 1989). Some isolated populations of *C. multiflorum* have been occasionally found within the Chaco sens. str. (Castellanos, 1958; Morello, 1967; Morello & Adámoli, 1974).

Finally, ca. 180 woody species are endemic to the Caatinga province (Prado, 1991). Examples include *Ziziphus joazeiro* Mart. and *Z. cotinifolia* Reissek (Rhamnaceae) (Fig. 10C), *Fraunhoffera multiflora* Mart. (Celastraceae), the congenerics *Auxemma oncocalyx* (Allemão) Taub. and *A. glazioviana* Taub. (Boraginaceae), *Spondias tuberosa* Arruda (Anacardiaceae), *Cordia leucocephala* Moric. and *C. dardani* Taroda (Boraginaceae), and *Hymenaea eriogyne* Benth. (Figs. 11C, D, 12A, B).

### Taxa with More Complex Distributions

It is of considerable interest that a number of caatinga species show links with the Amazonian area. The outlying records for *Commiphora leptophloeos* and *Aspidosperma pyrifolium* noted above are two such cases. A congeneric example

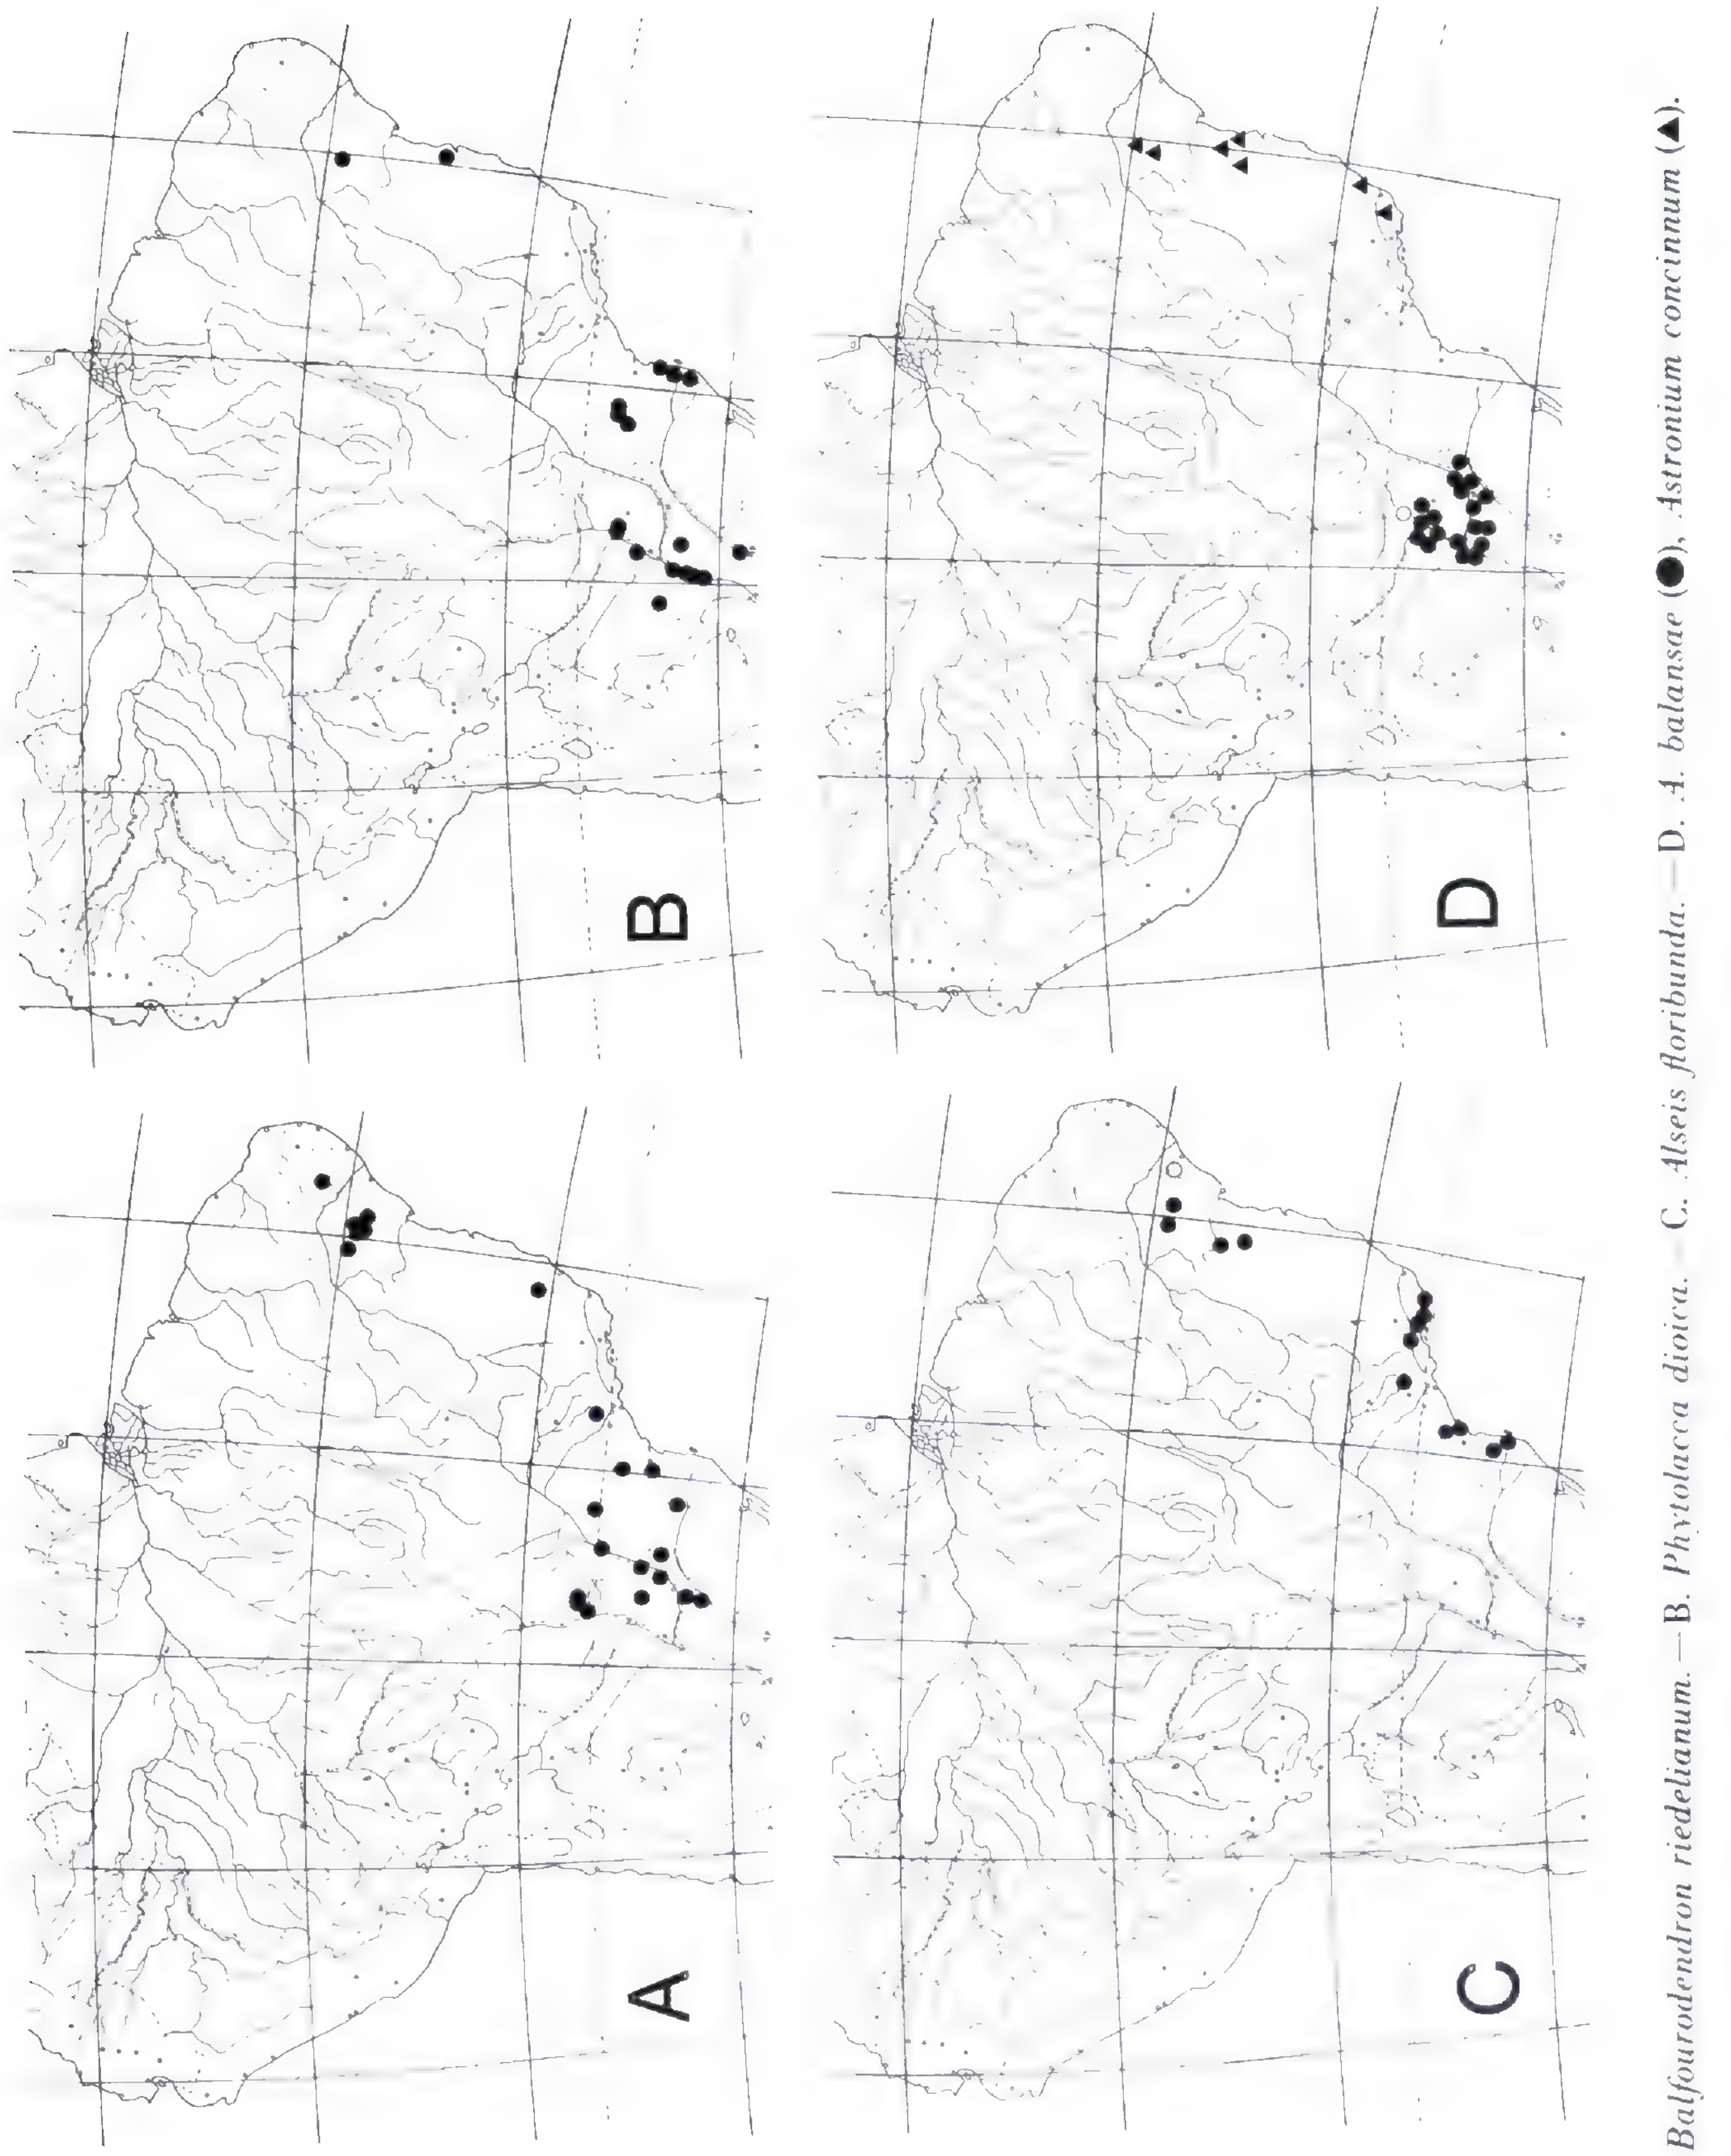

FIGURE 9.—A. *Balfourodendron riedelianum*.—B. *Phytolacca dioica*.—C. *Alseis floribunda*.—D. *A. balansae* (●), *Astronium concinnum* (▲).

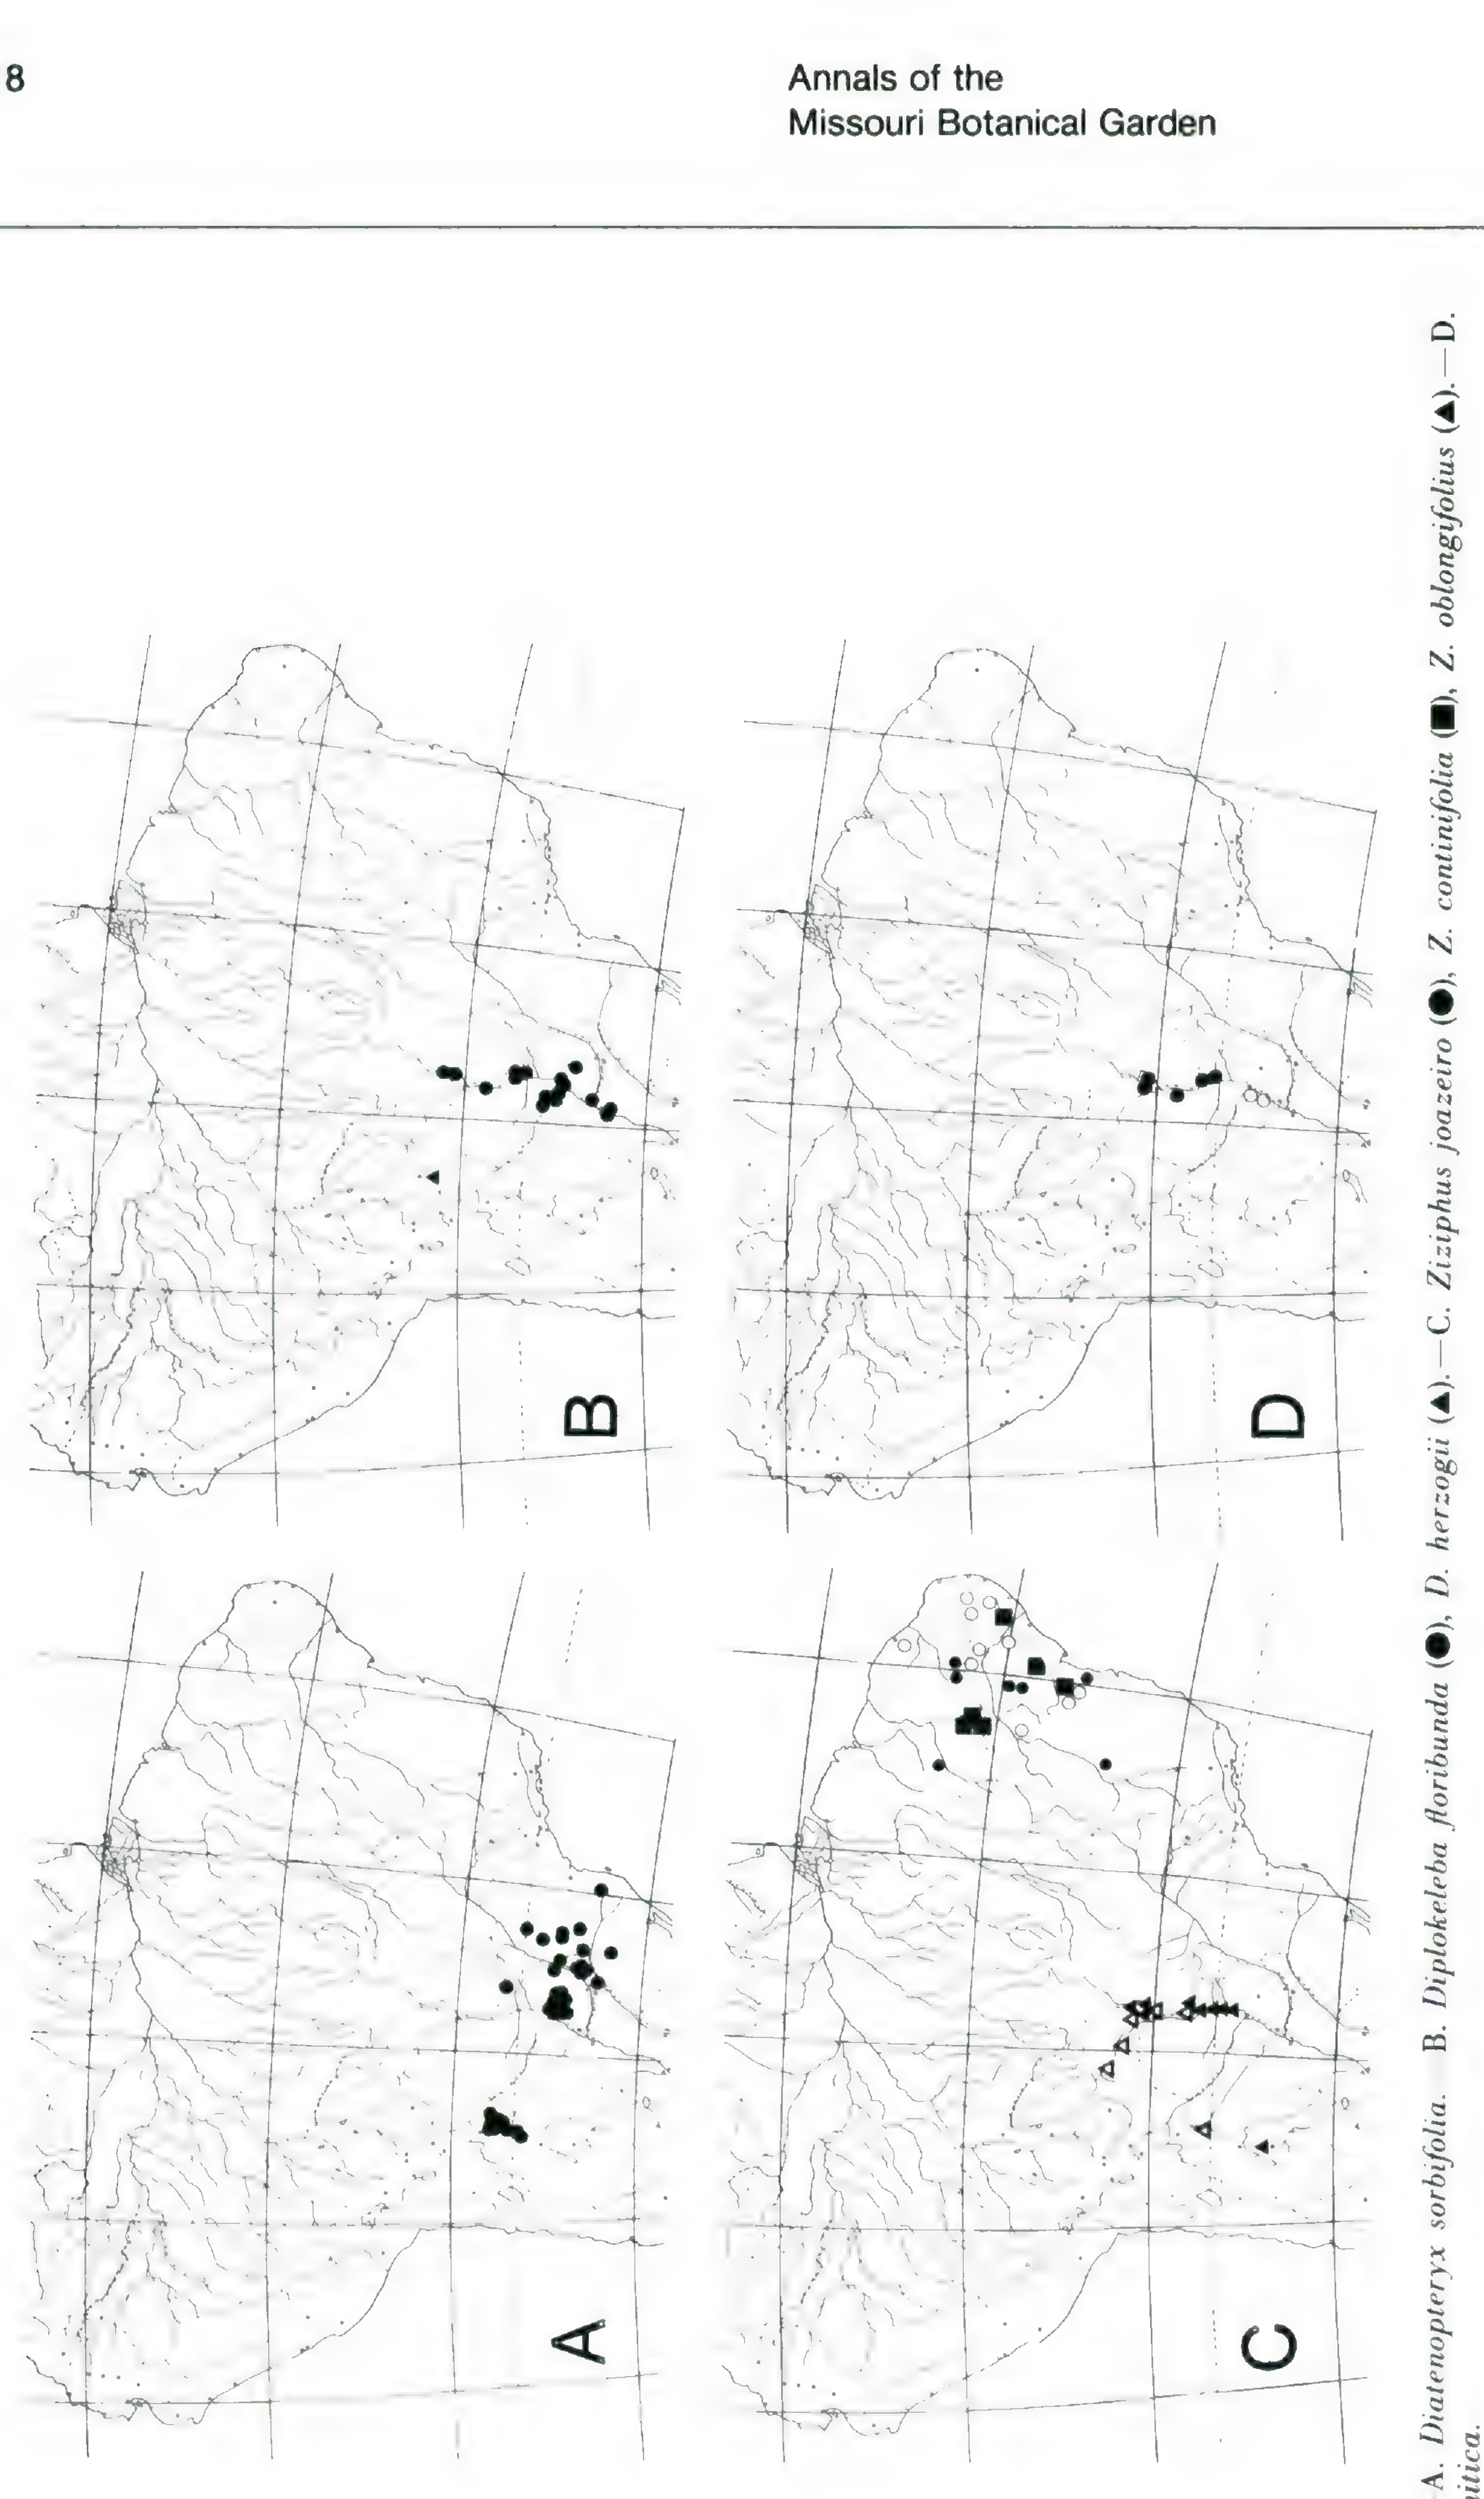

FIGURE 10[4].—A. *Diatenopteryx sorbifolia*. B. *Diplokeleba floribunda* (●), *D. herzogii* (▲).—C. *Ziziphus joazeiro* (●), *Z. continifolia* (■), *Z. oblongifolius* (▲).—D. *Ziziphus guaranitica*.

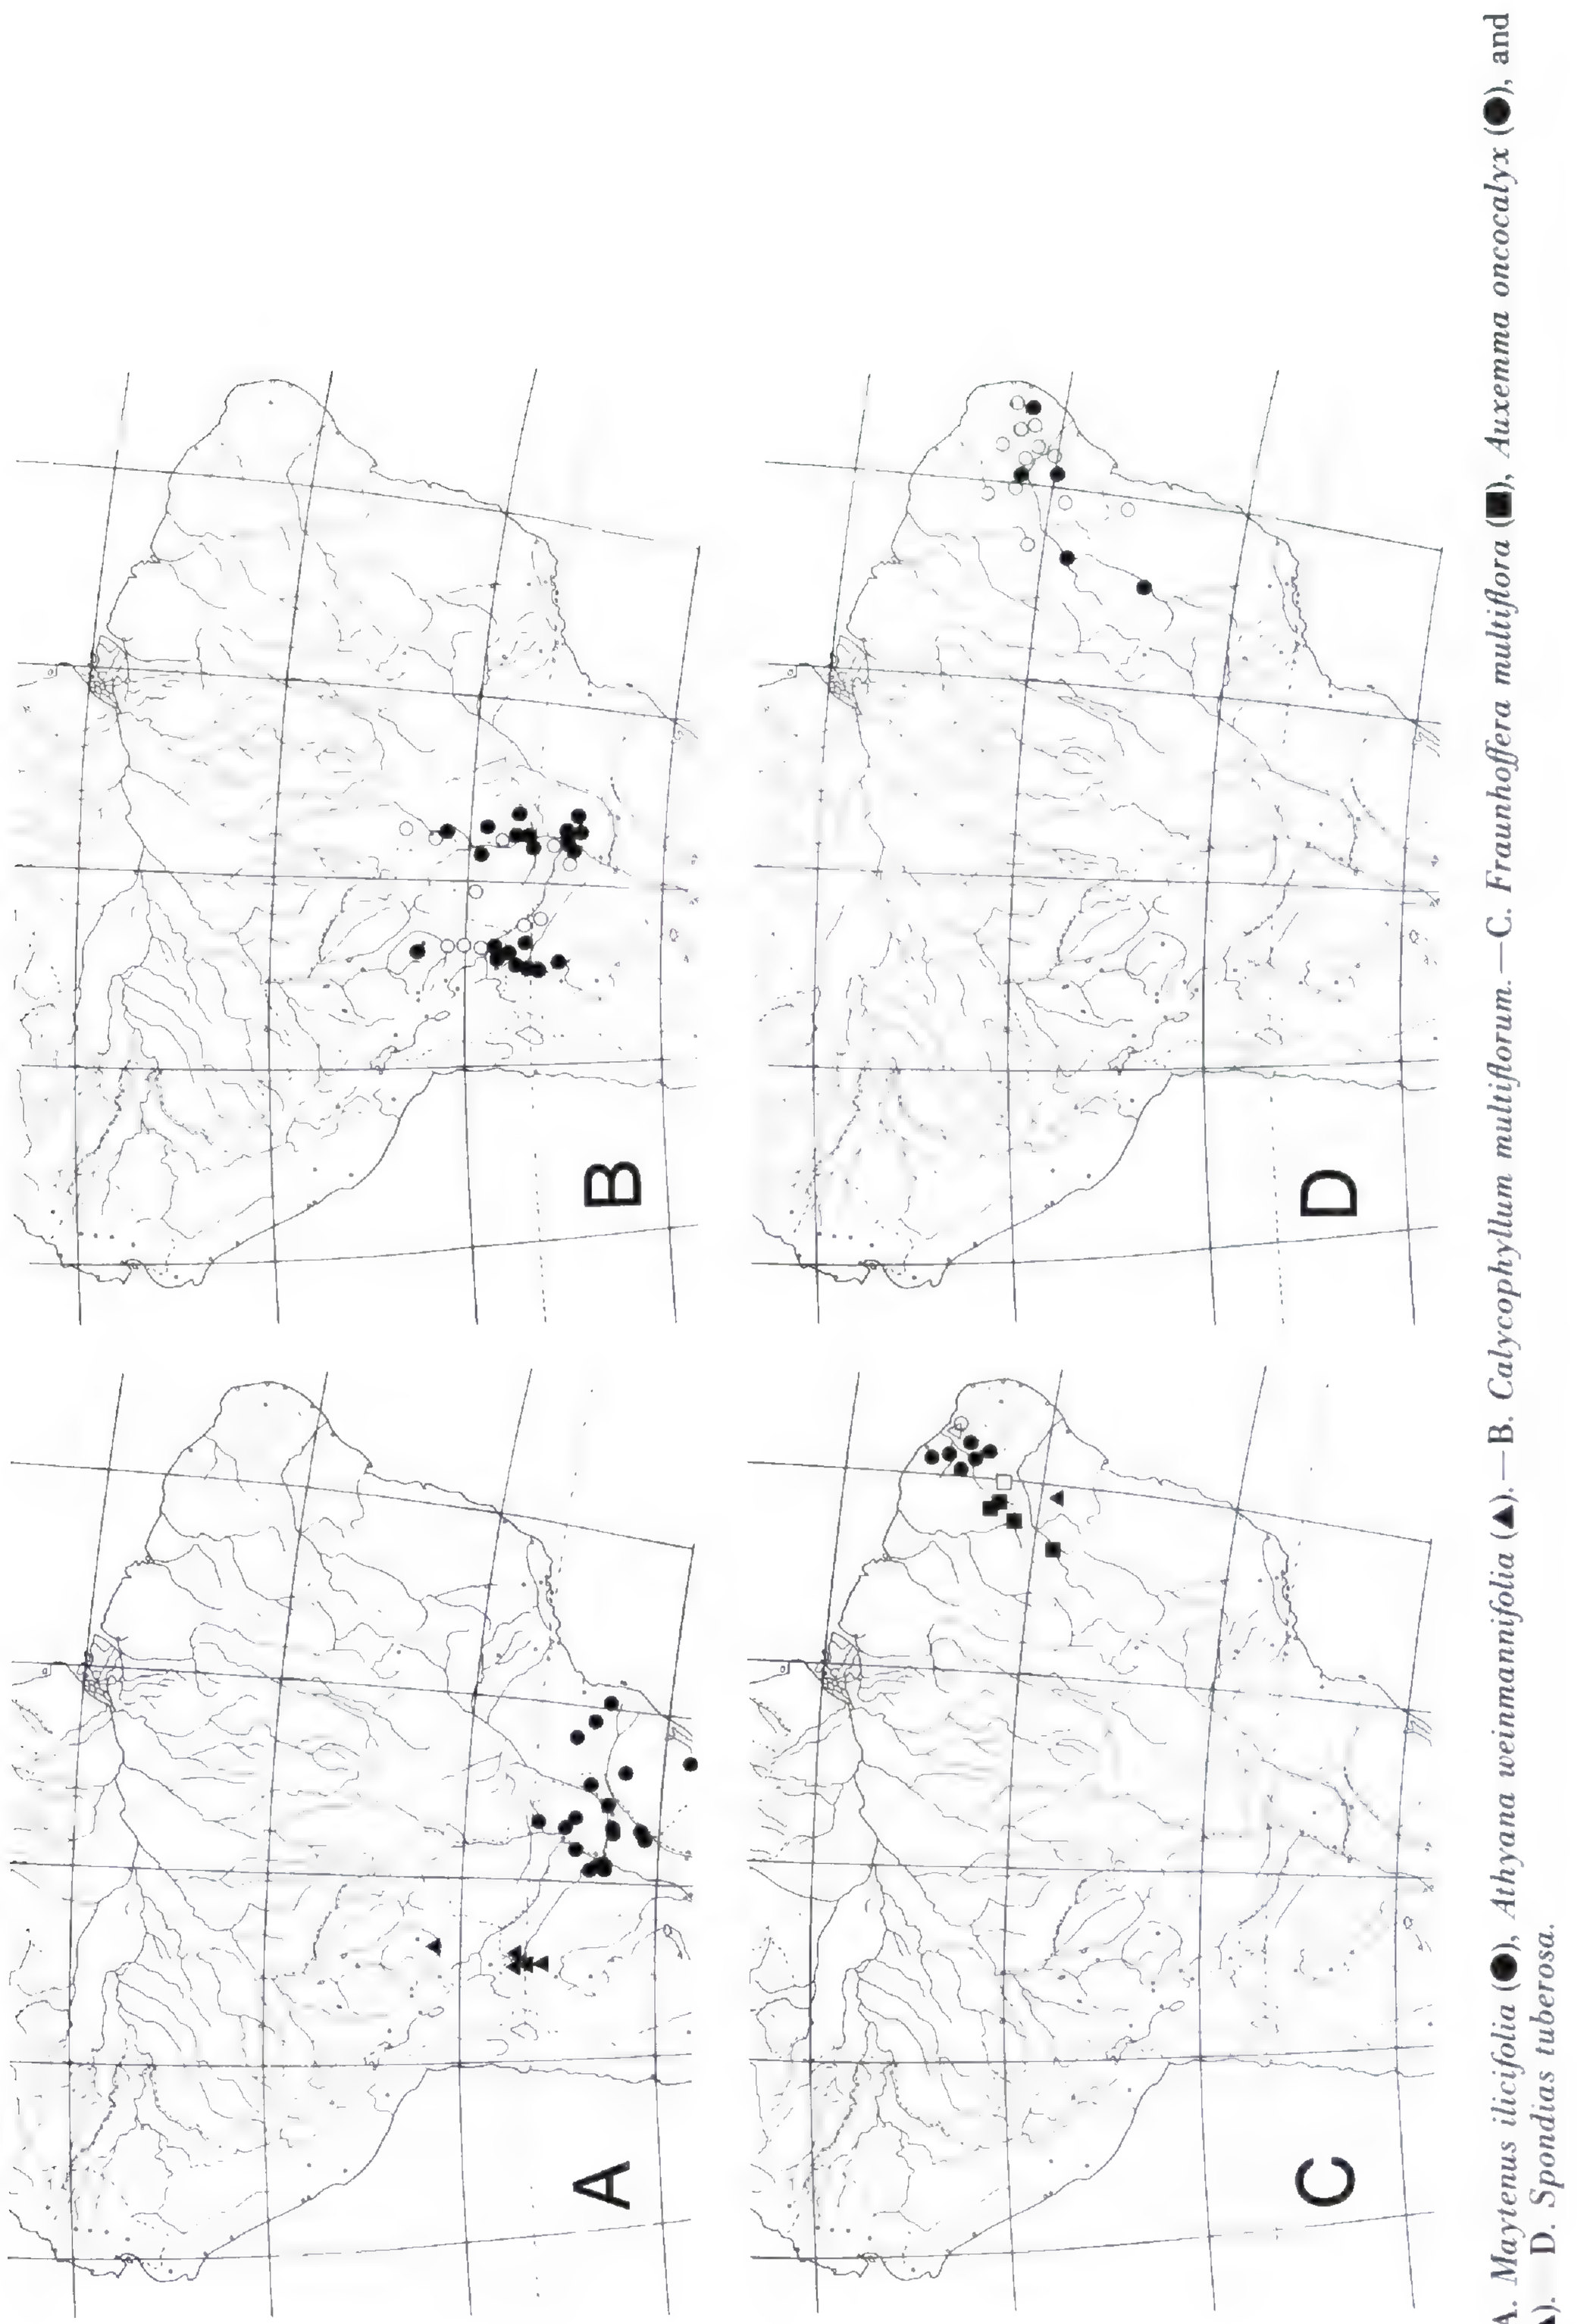

FIGURE 11[a].—A. *Maytenus ilicifolia* (●), *Athyana weinmannifolia* (▲).—B. *Calyophyllum multiflorum*.—C. *Fraunhoffera multiflora* (■), *Auxemma oncocalyx* (●), and *A. glazioviana* (▲).—D. *Spondias tuberosa*.

is *Aspidosperma discolor* A. DC., which occurs in Venezuelan Guayana and the Guianas, and which has been profusely collected in the lower and middle Amazon River valley and in Rondônia state, but it is also frequent in Bahian caatinga and in a central area of the cerrados (Fig. 12C). Another case is *Albizia polyantha* (A. Spreng.) Lewis (Leguminosae), which extends from the Guianas and Ilha de Maracá (Lewis & Owen, 1989), to the Amazon River valley and tributaries, and to the caatingas, the Paraguay–Paraná system and Cerro León (Fig. 12D). However, in a different category are species such as *Couepia uiti* (Mart. & Zucc.) Benth. (Chrysobalanaceae), which are essentially Amazonian elements, which extend via gallery forests into the cerrados and caatingas (Fig. 12B).

A number of species have more indistinct distribution patterns that include Amazonian localities. This sort of distribution is shown by a few caatinga species, although in each case they show fairly wide tolerance and also occur in more humid habitats. One such is *Coutarea hexandra* (Jacq.) K. Schum. (Rubiaceae), which also occurs along the Amazon River (Fig. 13A), and *Crateva tapia* L. (Capparaceae), which has been collected in the Amazon basin and also along the ephemeral watercourses in the caatingas (Fig. 13B). *Hymenaea courbaril* L. var. *courbaril* (Fig. 13C) and the outstanding caatinga tree *Tabebuia impetiginosa* (Mart. ex DC.) Standley (Fig. 13D) have similar distributions. Some such taxa are primarily restricted to seasonal habitats, such as *Myroxylon balsamum* (L.) Harms (Leguminosae) and *Poeppigia procera* C. Presl. (Leguminosae), although these species also appear in the Amazon (Fig. 14A, B), or as in the case of *Phyllostylon brasiliense* Capanema (Ulmaceae), in the Brazilian Atlantic rainforest (see distribution of the genus in Fig. 14C).

This distributional pattern is also followed (Fig. 14D) by another two-species complex: *Cordia alliodora* (Ruiz & Pav.) Oken–*C. trichotoma* (Vell.) Arráb. ex Steud. (Boraginaceae). Gibbs & Taroda (1983) studied this complex and concluded that both taxa should remain separate because of the different kinds of heterostylous conditions shown by plants of each species, together with differences in flower size, pollen grain size, and myrmecophily. However, these taxa have had a confusing history and have been treated as conspecific by some authors, while others have attempted to differentiate between them based on morphological characters such as leaf indumentum. This complex seems to show a high degree of ecological tolerance, with *C. alliodora* in particular showing fast-growing pioneer-type qualities, which may account for some aspects of its distribution. It extends from the semiarid Caribbean coast of Colombia and Venezuela, and the dry inter-Andean valleys of these countries, but also occurs in the more humid Orinoco River valley and even in the Amazon. From western coastal Ecuador and Peru, the distribution follows the more characteristic dry valley systems to reach the Yungas area in Bolivia. The specimens collected in northwestern Argentina in the sub-Andean Piedmont forests have been traditionally attributed to *C. trichotoma*, but from Gibbs & Taroda's (1983, fig. 1) point of view they must be regarded as *C. alliodora*, based both on morphology and geographical range. The specimens in the eastern half of the complex distribution are nearly all considered *C. trichotoma*, which thus extends from the caatingas, where this species can appear not only in the "sertão" but also in the wetter hills ("brejos"), to mesophilous forests on the Brazilian planalto (Minas Gerais, São Paulo, Paraná, and Santa Catarina), eastern Paraguay and northeastern Argentina.

Some species, such as *Platypodium elegans* Vogel (Leguminosae), that are more typical of the central Brazilian cerrado vegetation seem to partially shadow this distributional pattern (Fig. 15A). This species is a canopy tree in seasonal forest in Panama (Porter, 1973), and it is also present in Venezuela, but it then disappears in the whole of north and central South America to reappear in the caatingas, the cerrado in Goiás, Mato Grosso, Minas Gerais, and São Paulo, and further extends into eastern Paraguay and eastern Bolivia. Likewise, the anacardiaceous tree *Astronium fraxinifolium* Schott (Fig. 15B) is found in northern Colombia and Venezuela, and although it is absent from the caatingas sens. str., it has been recorded in semideciduous communities on higher ground within the general caatinga area. In central Brazil, it has been considered one of the indicator species of mesotrophic cerradão by Ratter et al. (1977), and it also extends to eastern Paraguay and central Bolivia. There is a surprising collection of this species in the Cañadón Platanillos, in central Paraguayan chaco, which must undoubtedly be linked to one of the watercourses that cross this region in a general west-east direction.

Finally, it should be emphasized that the distributions of the only three woody species (*Parkinsonia aculeata* L., *Sideroxylon obtusifolium* (Roem. & Schult.) Pennington, and *Ximenia americana* L.) that are common to the chaco and caatingas are meaningless in this context, since all three species have widespread distributions and

occur in diverse vegetation types. *Parkinsonia aculeata* (Leguminosae) is a very widespread ruderal plant whose ecological amplitude includes the Pacific coastal desert of Peru and the arid Monte province of Argentina (Fig. 15C). *Sideroxylon obtusifolium* (Sapotaceae) shows some fidelity to the seasonal formations, but together with the other two species it also occurs in temperate areas of South America (Fig. 15D). These species are also exceptional in that in addition to the chaco, they spread into areas such as Monte, or even Patagonia in the case of *Ximenia americana* (Olacaceae) (see map in Sleumer, 1984).

## Conclusions

The 80 or so taxa mapped in this analysis are all woody components of a series of dry seasonal woodland formations that occur in South America. This is a vegetation that seems to be mainly restricted to relatively mineral-rich soils. The present-day distributions of these species are considered to comprise fragmentary remnants of the once extensive forests that probably characterized the dry climatic maxima of the Pleistocene, and which are likely at that time to have extended into the Amazonian region, and also to have percolated into the Andean region, perhaps via the "Marañon gap," and established further links with the Caribbean–Guajira province, through northwestern Peru and eastern Ecuador.

The extant fragments of this seasonal woodland vegetation have their main nuclei in the Caatingas, Misiones, and Piedmont areas. Effectively, the woody and succulent flora of the caatingas comprises ca. 437 species, of which 228 species are certainly nonendemics (Prado, 1991). Of these, some 62 species (27%) show floristic affinities to the Pleistocenic Arc type distribution, whilst no other coherent distribution patterns were evident for the remaining nonendemic species. Equally notable, some 51 species (19.4%) of the ca. 263 woody and succulent species found in the piedmont forests of northwestern Argentina and southern Bolivia are also found in the caatingas, while a further 42 (16%) piedmont species show links with the Misiones nucleus and calcareous woodlands peripheral to the Brazilian cerrados (Prado, 1991).

Characteristically, these species distributions present a lacuna in the area of the chaco, and only sparse representation in the cerrado, with most seemingly cerrado representatives of this group actually restricted to calcareous outcrops. Indeed, the essentially distinct nature of typical Brazilian cerrado vegetation from other seasonal, semideciduous woodlands is striking, in sharp contrast to the clear floristic links between such seasonal woodland and the rather distinctive vegetation of the calcareous islands within the cerrado general area, as first emphasized by Ratter et al. (1978).

The caatinga-type seasonal woodlands also show intriguing links with some areas in the Amazonian, as well as the Caribbean and Venezuelan–Central American, regions, and with some species having isolated populations surviving in dry valleys of the east slopes of the Andes. It is unfortunate that, probably because of their occurrence on agriculturally desirable, good-quality soils, these seasonal forests in South America have suffered considerable devastation in the past, and continue to bear the brunt of agricultural expansion in the region. This applies particularly in the case of the piedmont woodlands of northwestern Argentina, and to the isolated areas of "mata calcárea" on base-rich outcrops scattered within the Brazilian cerrado area. A coherent conservation policy for selected areas of these seasonal forests areas is urgently needed.

# DIVERSITY PATTERNS AND BIOMASS OF EPIPHYTIC BRYOPHYTES AND LICHENS ALONG AN ALTITUDINAL GRADIENT IN THE NORTHERN ANDES[1]

*Jan H. D. Wolf*[2]

## Abstract

The difficult accessibility of the canopy of tropical rainforests is probably one of the main reasons why information about the nonvascular tree crown flora is scarce. In this paper full attention is paid to the epiphytic bryophytes and lichens of 59 bark type selected canopy trees, divided over 15 sites along an altitudinal transect ranging from 1,000 to 4,130 m in the Central Cordillera, Colombia. Species-area curves indicated that sampling at each investigated site (altitude) was adequate within the restrictions imposed by the sampling method. Ordination analysis revealed that altitude as a complex ecological factor explained most of the variation in the data. Alpha and beta diversity patterns along the gradient were different for mosses, liverworts, and macrolichens. As to liverworts, species richness reached its peak of approximately 100 taxa per altitude at a mid-altitudinal range from 2,550 m to 3,190 m. The distribution of individual taxa showed that the belt of greatest liverwort richness coincides with a contact transition zone. Several hypotheses (mass effect, ecological equivalency, and species overlap) predict highest species diversity at such a transition zone. All are based on the assumption that community composition results from between community interactions rather than from within community (niche) relationships. The validity of this presumption is further indicated by the low number of liverwort taxa (20.5%) exclusive to the belt of greatest richness, assuming that habitats are saturated. Species turnover appears greater for bryophytes on this tropical mountain than on temperate mountains in North America. The general increase in biomass of nonvascular canopy subsamples with altitude coincides with a rise in humidity.

The study of species diversity (species richness) is a central theme in both theoretical and applied ecology. Following Whittaker (1977), point diversity is defined as the species richness of a single subsample taken on a host tree and alpha diversity as the number of species of all the subsamples taken at four host trees per altitude. Beta diversity may be defined as the extent of species replacement along an environment gradient (MacArthur, 1965; Whittaker, 1960, 1972, 1977).

Origin and maintenance of local diversity may be explained in two ways: as a result from (1) processes (niche relations among species) within the community (MacArthur, 1965; Whittaker, 1977; Connell, 1978; Huston, 1979), or from (2), at least in part, propagule influxes from neighboring sites (Shmida & Wilson, 1985). Slack (1977) and Watson (1980) suggested that in bryophyte communities species diversity results more from successful colonization and establishment than from competition-related interactions.

It is generally accepted that tropical regions are richer in species than temperate areas (e.g., Pianka, 1966), but documentation of diversity patterns within the tropics is still rare (Gentry, 1982), in particular for nonvascular plants (Maury-Lechon et al., 1984). Species richness studies of various organisms along altitudinal gradients in the tropics have demonstrated three major patterns: (1) A decrease of species richness with altitude for woody

[1] The assistance with identification is gratefully acknowledged of B. H. Allen, A. Aptroot, S. P. Churchill, J-P. Frahm, D. Griffin III, R. Grolle, R. Moberg, J. Váña, D. H. Vitt, K. Yamada, and R. H. Zander. Special thanks for the identification of numerous collections is forwarded to H. Sipman (lichens), G. B. A. van Reenen (mosses), S. R. Gradstein (liverworts), and the late H. Inoue (*Plagiochila*). Valuable comments during the whole study period were provided by A. M. Cleef and T. van der Hammen. I thank S. R. Gradstein, M. J. A. Werger, and an anonymous reviewer for comments on earlier versions of the manuscript. I thank the staff of the Instituto de Ciencias Naturales (COL), Bogotá, for cooperation while visiting their research facility. Finally, this study would not have been possible without the tireless field assistance of J. Klomp. The study was supported by grant W84-236 of the Netherlands Foundation for the Advancement of Tropical Research.

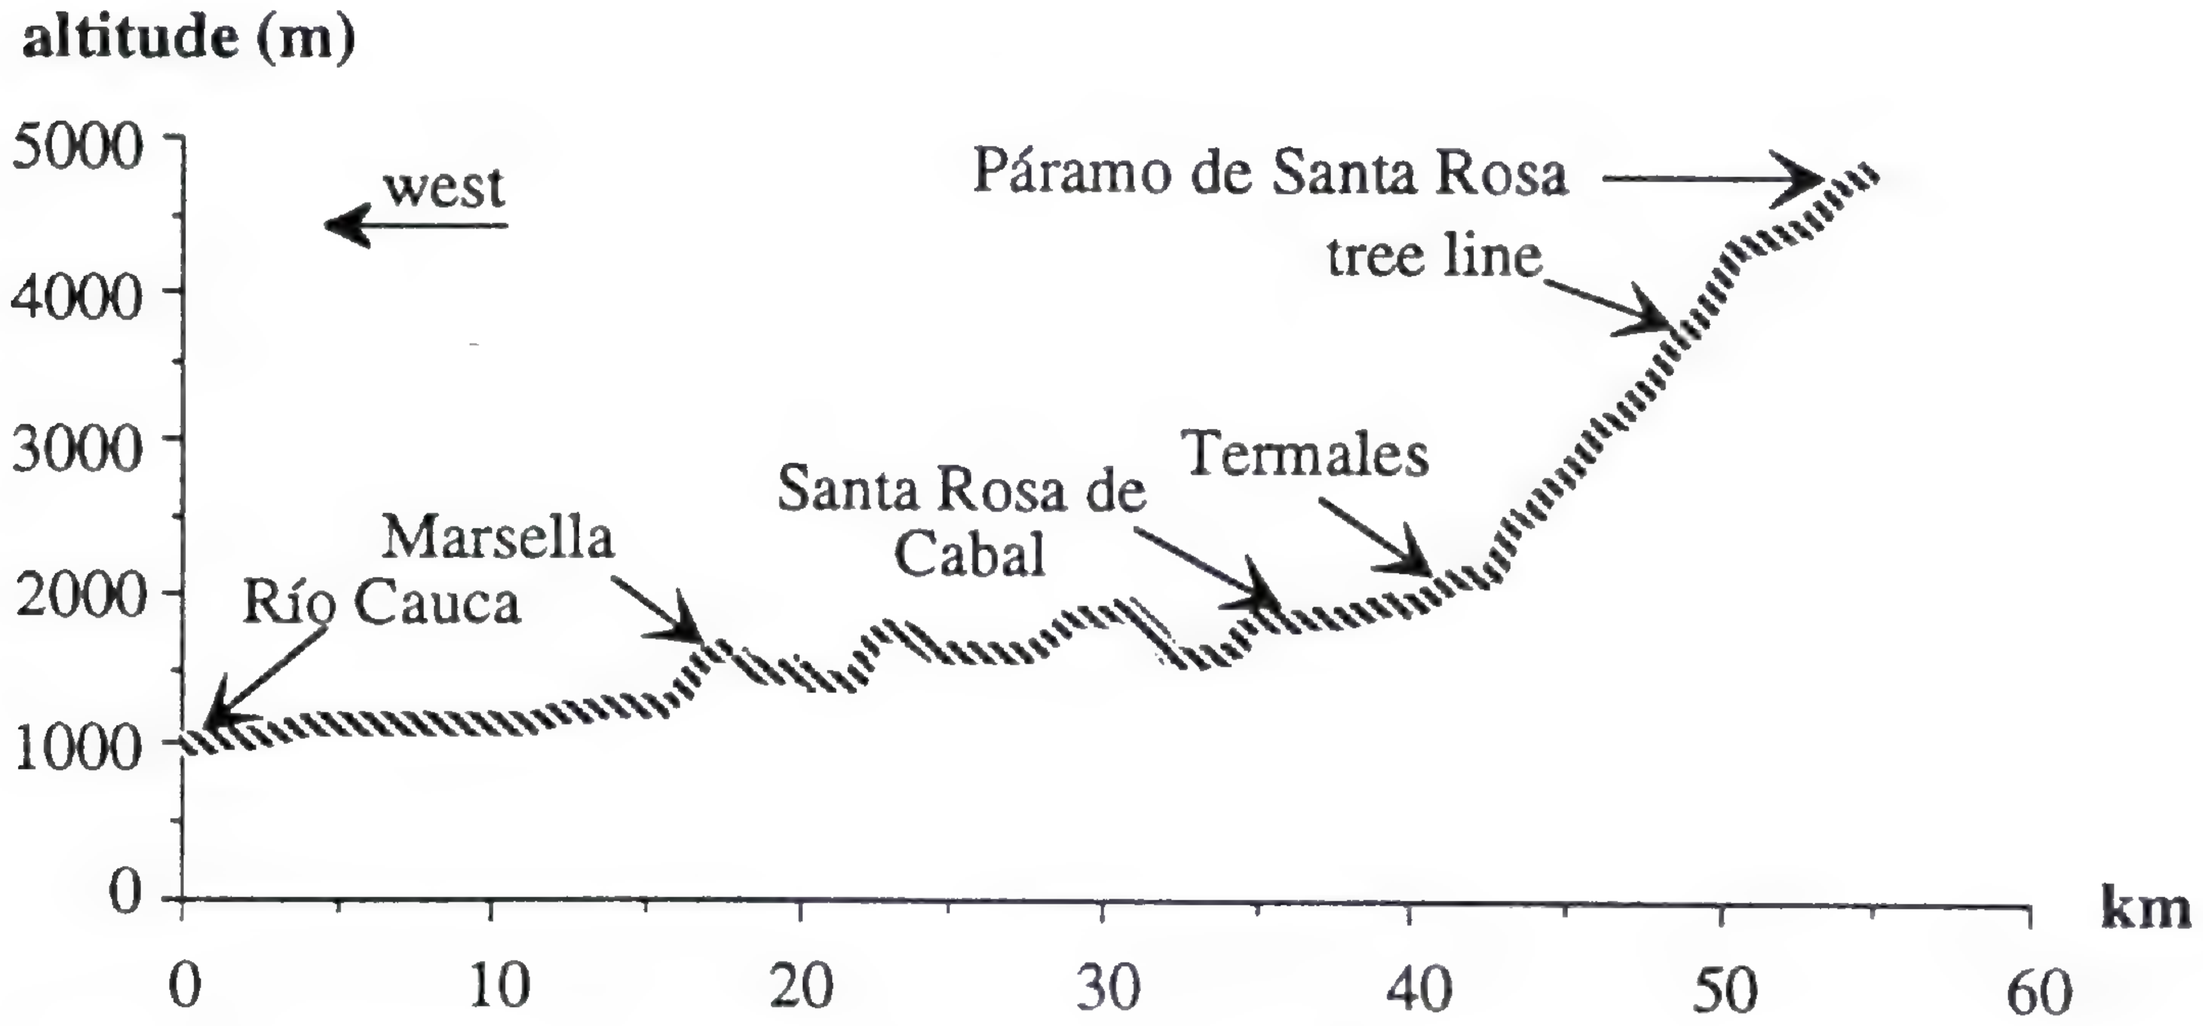

FIGURE 1. Longitudinal section of the west slope of the TPN-transect; redrawn from Thouret (1983).

phanerogams (Gentry, 1988), herpetofauna of leaf litter (Scott, 1976; Fauth et al., 1989), and anuran amphibians (Duellman, 1988). (2) A maximum of species richness at higher altitudes for mosses (Gradstein & Frahm, 1987; Frahm, 1987a), liverworts (Gradstein & Weber, 1982), bryophytes (Gradstein et al., 1989), and lichens (Sipman, 1989). The latter two studies were conducted along the transect treated in this study and included both terrestrial and epiphytic (mainly tree base) sampling. (3) A maximum of species richness at intermediate altitudes for birds (Terborgh, 1977), insects (Janzen, 1973), vascular epiphytes (Sugden & Robins, 1979, and assumed by Gentry & Dodson, 1987), bryophytes (Enroth, 1990), and liverworts (Wolf, 1989). Gradstein & Pócs (1989) also documented higher bryophyte (excluding epiphylls) species numbers at intermediate (1,500–2,600 m) altitudes in the Sierra Nevada de Santa Marta. Highest cover values of both terrestrial and epiphytic (1–3 m) bryophytes were found at Santa Marta at altitudes over 2,600 m (van Reenen & Gradstein, 1983). The increase of nonvascular epiphytes with altitude is a common feature of tropical mountain areas worldwide (Grubb, 1977; Grubb et al., 1963; Pócs, 1980; Frahm, 1987b), and it has been suggested that it is paralleled with an increase in species richness (Richards, 1984, 1988).

Beta diversity, which focuses on the qualitative differences between habitats, has received much less attention than alpha diversity. As far as I know, only two studies on beta diversity of cryptograms along an altitudinal gradient are available, both concerning bryophytes in temperate North America (Slack, 1977; Lee & La Roi, 1979). Other studies (Robinson et al., 1989; Oksanen, 1983) addressed the difference in response of bryophytes and lichens along other than altitudinal gradients.

The aim of this paper is the recording and assessment of species richness, distribution, and biomass of epiphytic bryophytes and lichens along an altitudinal transect in the northern Andes. The possible role of interactions between sites within the altitudinal macro-gradient on epiphytic species richness will be examined. For the first time in tropical mountains full attention was paid to the flora of the forest canopy.

## Study Area

The study was carried out along an altitudinal transect (1,000–4,130 m) on the western slope of the Colombian Central Cordillera (ca. 4°50′N, 75°30′W) in the watershed of the Río Otún. This transect is known from previous ecological studies as the "Transecto Parque Los Nevados" (van der Hammen et al., 1983, 1989; Veneklaas, 1990; Vis, 1989). Data on the bryophyte and lichen flora of the study area are provided by van Reenen (1983), Gradstein et al. (1989), and Sipman (1989).

The mountain slope is not steep from the Río Cauca valley floor at 1,000 m up to Termales at ca. 2,000 m altitude (Fig. 1). Above, there is a sudden increase in slope. The upper tree line is found at 3,700 m, but locally at higher elevations a dwarf forest (6–8 m) dominated by *Polylepis sericea* Wedd. and *Diplostephium violaceum* Cuatrec. may be present.

The watershed exhibits a bimodal yearly distribution of rainfall, coinciding with the passing of

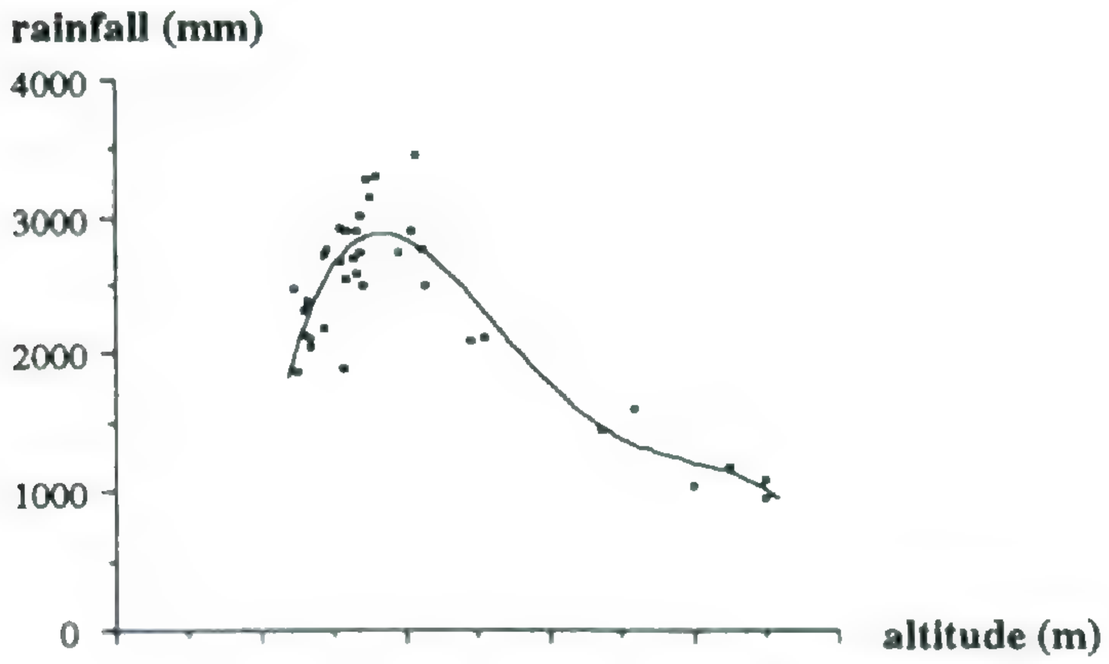

FIGURE 2. Annual rainfall distribution per altitude, after van de Weert et al. (1986).

the Intertropical Convergence Zone (Pérez, 1983). Rainfall data for a period of over 20 years from nearby meteorological stations, Matecaña Airport (1,342 m) and El Cedral (2,120 m), show that local rainfall exceeds 100 mm/month, even during the "dry" season (van der Weert et al., 1986).

Differences in precipitation and air humidity data from meteorological stations in the area seem to be largely correlated with differences in altitude. Based on climatic data from more than 40 stations at altitudes of 1,020–4,500 m, van de Weert et al. (1986) found a linear decrease of mean daily temperature in the watershed with altitude (0.63°C/100 m) and an annual precipitation maximum at around 2,000 m (Fig. 2).

## METHODS

Fieldwork was carried out from August 1985 to December 1986 and during the second half of 1988.

Diurnal variation of temperature and relative humidity at different altitudes (1,725 m, 2,150 m, 2,460 m, 2,970 m, 3,370 m, and 3,670 m) was recorded by Lambrecht thermohygrographs hung in white-painted, wooden, collapsible housing that was open at the bottom and had slots at the sides, allowing good aeration but avoiding sunlight at the measuring equipment. The housing was placed outside the forest at 2 m above ground level. At 3,370 m, where a clearing was not available, the thermohygrograph was placed about 1 m above the tree canopy hanging from an upright pole tied in the tree crown. As hair extension in the hygrograph is maximal at 95% relative humidity, humidity values higher than 95% could not be recorded.

Even though time of registration was limited to 2–3 weeks per site, the small seasonal variations in temperature and relative humidity (van der Weert et al., 1986) permitted a good impression of diurnal patterns.

Hemispherical photographs (167°) were taken with a superwide angle lens mounted on the front of the 24-mm lens of a standard 35-mm camera, to determine light conditions within the forest. Two perpendicular levels attached to the camera body permitted precise vertical canopy photographs. Diffuse site factors (Anderson, 1964), which provide a reasonably accurate estimate of the mean percentage of diffuse light passing through the canopy, were determined from the photographs using the method described by Anderson (1964). The amount of direct sunlight at the sites was not estimated, since data on the variation in periods of sunshine along the transect were not available.

### SAMPLING

At altitudinal intervals of ca. 200 m four trees were selected for investigation. Selected trees had to be (1) full-grown with their crowns reaching the average tree crown level (canopy); (2) of a common species in the forest; and (3) without a scaling, very hard, very smooth, or very coarse bark (at 4,130 m an exception was made for dominant *Polylepis* trees, which have a flaky bark). Additionally, they were not to be located near the edge of the forest, near a stream, on very steep terrain, on a ridge or in a gulley, or next to a previously sampled tree. Taxonomical affinity of host trees was not considered. Host-preference of epiphytes is often regarded of minor importance in wet montane tropical forests (e.g., Richards, 1984; Smith, 1982).

An effort was made to locate forests where disturbance was minimal. At 1,000 m it was not possible to find forests not disturbed by humans, but also at higher altitudes (e.g., at 2,130 and 2,460 m) much forest seemed disturbed, as evidenced by fast-growing "weedy" tree species like *Brunellia occidentalis* Cuatrec., *Solanum inopinum* Ewan, and by treeferns (Cyatheaceae). Since in these higher forests disturbance by humans was not apparent, these trees appear to form a natural element of the forest, perhaps due to the frequent occurrence of landslides (pers. obs.).

Epiphytic, excluding epiphyllous, vegetation was sampled on 59 trees (only three trees at 1,000 m). On each tree ca. 10 subsamples were taken at habitats such as tree base, trunk, inner crown, middle crown, and the outer branches, wherever a clear change in structure or in species quality of the epiphytic vegetation occurred along the vertical within-tree gradient. Subsamples taken on branchlets in the outer tree crown covered a smaller

area than on tree bases; subsample area varied from a few to over 20 $dm^2$. Branches were sampled above and aside only, epiphytes growing in the rain shadow underneath were excluded. Prior to removal from the bark of each subsample as a whole, information was gathered about the location, plot size, and percent cover of the dominant species relative to the area of the upper half-cylinder of the branch segment. The epiphyte communities are described in detail in Wolf (1993a, b).

A first impression of the species composition of 596 subsamples taken was obtained in the field laboratory in order not to miss tiny bryophyte species that are easily overlooked when dry. Subsequently, organic debris was separated and all subsamples were oven-dried at 70°C, weighed (excluding phanerogams), and sent to the laboratory in the Netherlands, where they were reexamined for hitherto not-found species and to check the field identifications. Biomass in this study is defined as the (dry) weight of living plants, excluding accumulated suspended organic soil. Parts of plants were assumed to be living whenever they were recognizable as plant structures and included brownish bryophyte bases of tall turf-forming species.

Some 1,600 botanical collections were deposited in the Herbarium of the Instituto de Ciencias Naturales (COL), Bogotá, with duplicates in the Herbarium of the University of Utrecht (U). Some duplicates were sent to specialists for identification.

Each tree was climbed using slightly modified rope climbing techniques, as described by Perry (1978a) and ter Steege & Cornelissen (1988). With a hunting bow, an arrow with a nylon line attached was shot through the tree crown and the tree was climbed with jumars along a mountaineering rope.

## SPECIES IDENTIFICATION

Species identification is problematical for groups of organisms that have not been adequately treated systematically. For the lichens this concerns in particular the genera *Sticta*, *Lobaria*, *Leptogium*, and *Usnea* and for bryophytes some members of the Lejeuneaceae (subfamily Lejeuneoideae), Plagiochilaceae, and Bryaceae. Some unidentified species were given provisional names (e.g., *Lejeunea* sp. *A*. *Lejeunea* sp. *B*) and included as such in the analysis; others could not be recognized as individual species and were grouped in higher taxonomic ranks (e.g., *Sticta* spp.; Lejeuneaceae). Furthermore, species were grouped when they could only be differentiated from their close allies in a fertile state, like most sterile crustose lichens, but also some bryophytes, e.g., *Omphalanthus filiformis* (Sw.) Nees and *O. platycoleus* Herz (Gradstein et al., 1981). Finally, two pleurocarpous moss species, *Ctenidium malacodes* Mitt. and *Mittenothamnium reptans* (Hedw.) Card, and all species of the crustose lichen family Graphidaceae were lumped, because they could only be separated after detailed microscopic investigation and were regularly found to grow intermixed.

The resulting amount of species-grouping into higher taxonomic ranks may be roughly estimated from the variety within each rank. Thus, for example, the 65 taxa of Lejeuneaceae used in the analysis are believed to represent ca. 70% of total Lejeuneaceae species present.

Nomenclature follows recent checklists of liverworts (Gradstein & Hekking, 1979), mosses (Churchill, 1989), and lichens (Sipman, 1989) or the latest taxonomic works, when available.

## DATA COMPUTATION

To make a meaningful evaluation of alpha and/or beta species diversity patterns, two requirements should be met:

(1) Adequate sampling. Minimum area (cumulative species vs. number of subsamples) curves were constructed (Fig. 3) and the rapid leveling of the curves shows that the minimum area of epiphytic bryophytes and lichens is small, agreeing with Gradstein et al. (1990), who found that sampling of epiphytic bryophytes in mixed tropical lowland forest of French Guiana yielded only few (1–3) additional species per tree when more than five trees were sampled.

(2) Establishment that the gradient under investigation, i.e., altitude, is indeed the major environmental factor determining species distribution. For that purpose, ordination analysis, using presence/absence data of species, was carried out using Detrended Correspondence Analysis, DECORANA (Hill, 1979; Hill & Gauch, 1980). A graphic representation of the first two axes is shown in Figure 4. The first axis of ordination of the sites shows a relatively high eigenvalue (0.652), suggesting the presence of a clear species gradient indicating the site variation. The second axis has a much lower eigenvalue (0.259), thus most variation can be explained by the gradient corresponding with the first axis. Eigenvalues of the third and fourth axes are 0.163 and 0.107, respectively.

Since the Spearman's rank coefficient for correlation calculated between the ordination rankings of the sites along the first axis of ordination and altitude was highly significant ($R = 0.993$; $P <$

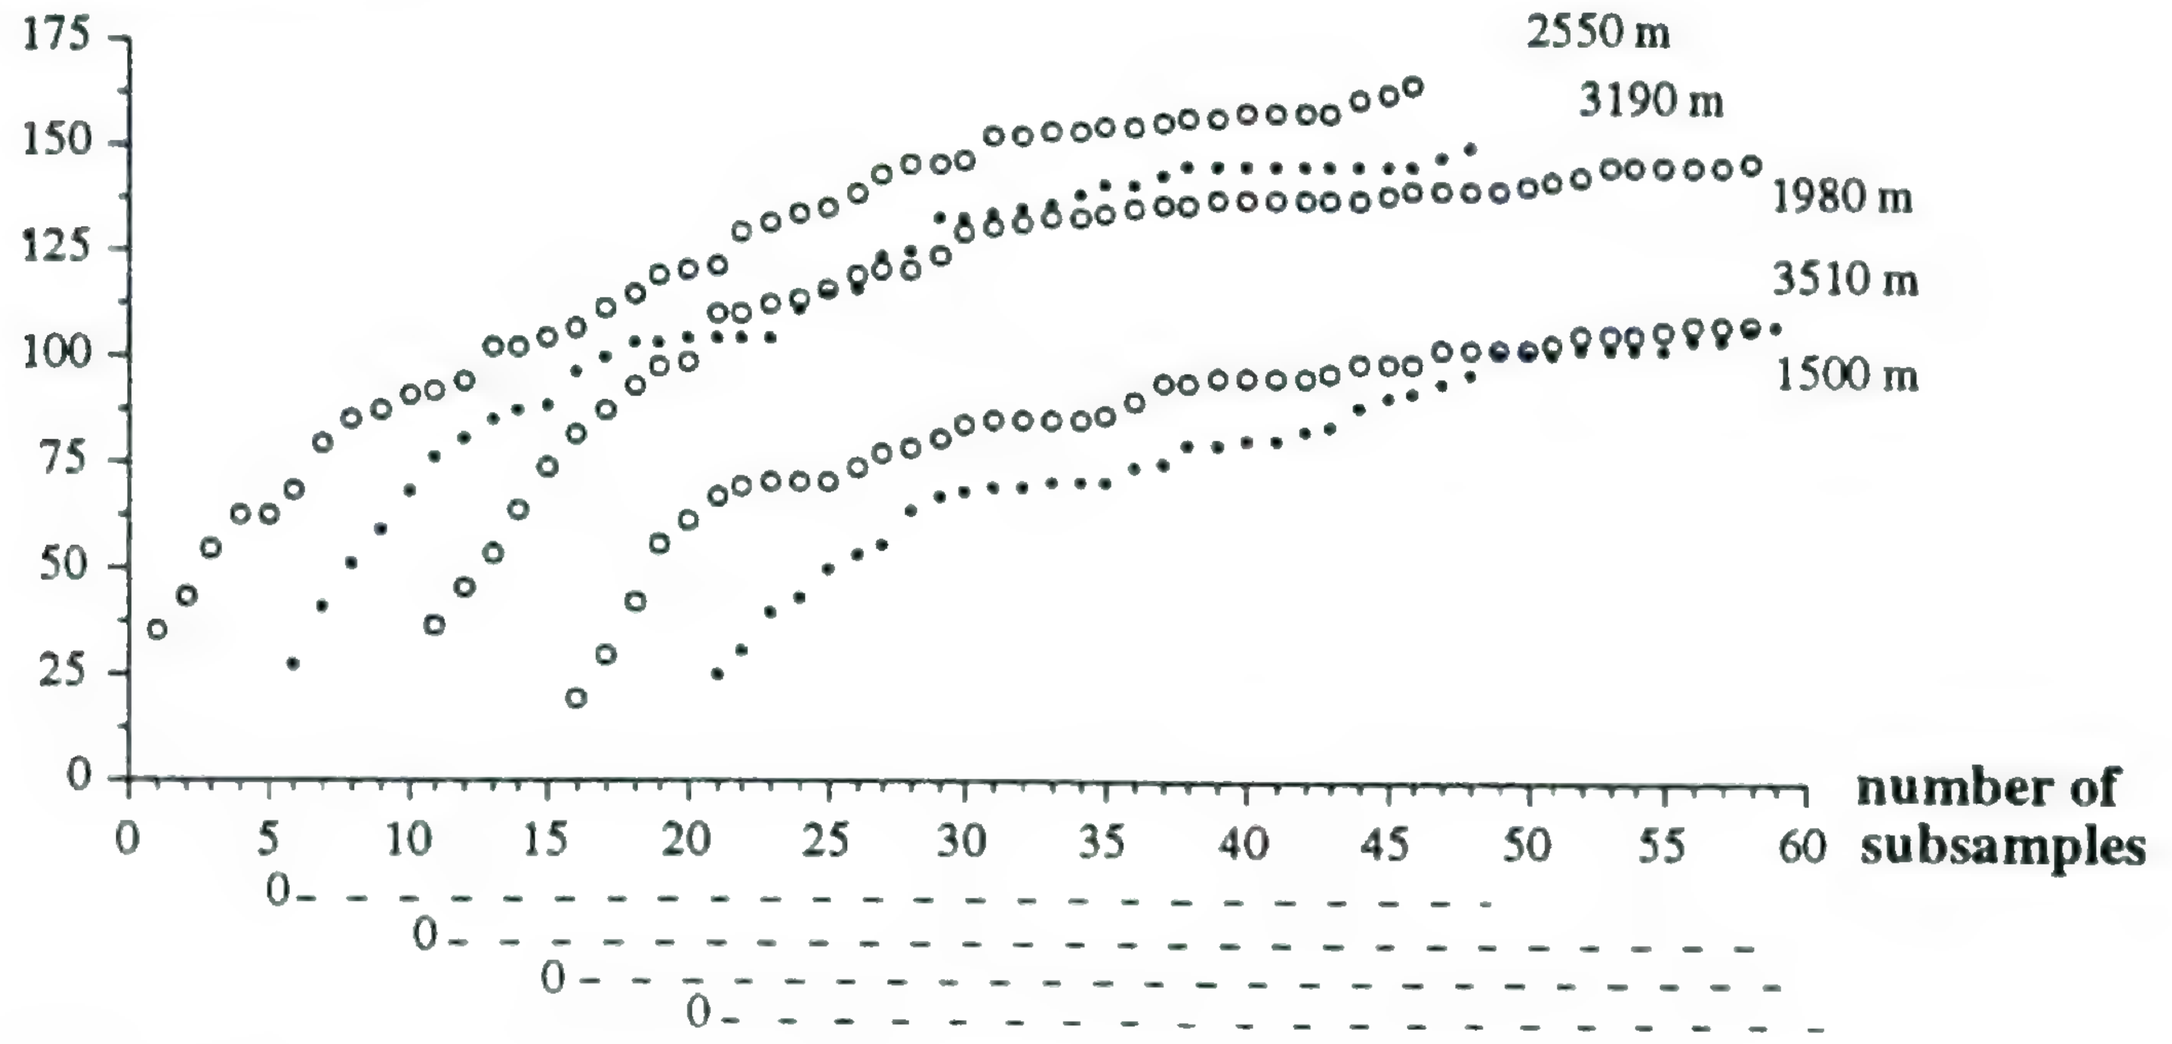

FIGURE 3. Cumulative species vs. number of subsamples (in random order) curves. The subsamples were taken on four trees per altitude.

0.001), it can be concluded that the variation in altitude explains most of the variation in the data. Therefore, it is felt permissible to consider species distribution to be continuous between highest and lowest altitudes where species were found. For further calculations this assumption was made, following Wilson & Shmida (1984).

Ordinations, using DECORANA, were performed for all data again, but also for macrolichens, bryophytes, mosses, and liverworts separately. The sites at 1,000 m and at 4,130 m were excluded, the lower site being much influenced by humans and the higher site, an outlier on the second axis in the first ordination (Fig. 4), not being part of the montane hillside forest. Crustose lichens were not considered because of the presence of many sterile unidentifiable species.

For unidimensional gradients the position of the sites on the first axis, as generated by DECORANA, has been shown to be a reliable estimate of beta diversity (Økland, 1986). Beta diversity was furthermore quantified using Sørensen's Coefficient of Community (1948) and a measure proposed by Wilson & Shmida (1984), which combines features of measures proposed by Cody (1975) and Whittaker (1960):

Sørenson (1948)

$$\text{C. C. Sørenson} = 2s/(a + b)$$

Wilson & Shmida (1984)

$$\text{"beta turnover"} = [g(H) + l(H)]/2\alpha;$$

where s = number of species found at both sites, a = number of species at site A, b = number of species at site B, g(H) and l(H) are number of species gained or lost respectively over the gradient, and $\alpha$ = average site richness.

Wilson & Shmida (1984) recommended the use of their index when sample (site) data can be arranged along a single overriding gradient, as in our case.

Previous studies on beta diversity of bryophytes have used the number of half changes in community composition along an elevational gradient (coenocline in the terminology of Whittaker), following Whittaker (1960). For reasons of compatibility the same method was used. Coefficients of Community, CC (Sørensen, 1948), were calculated for sites at different intervals along the coenocline.

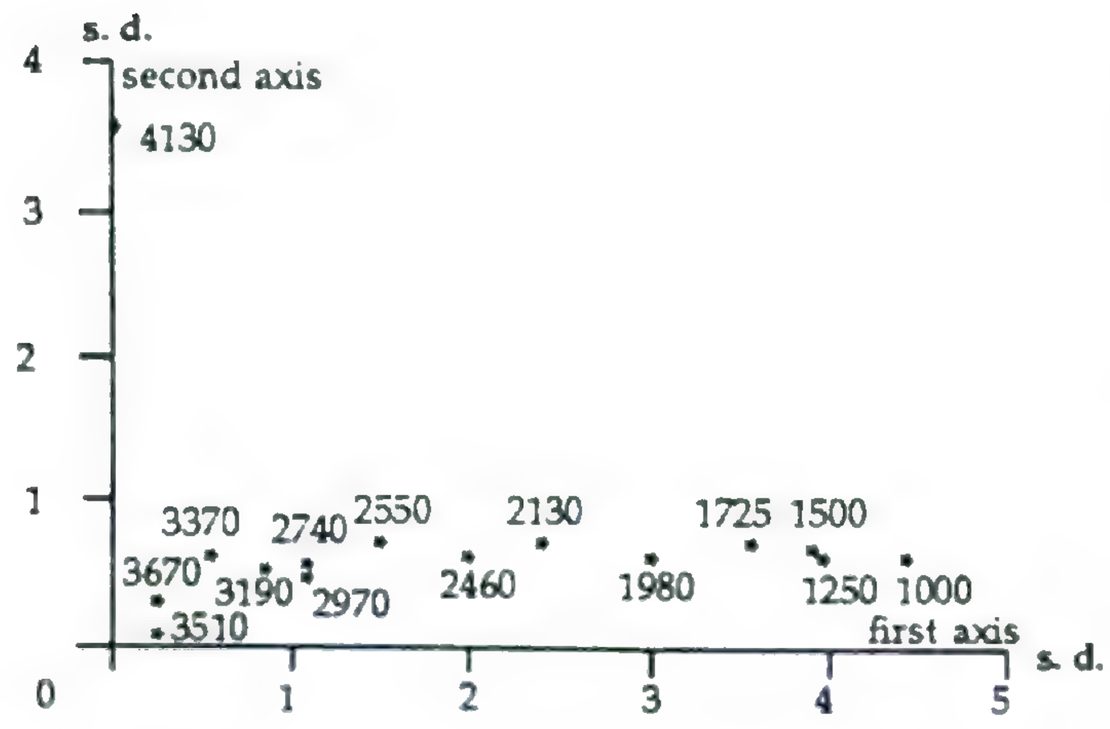

FIGURE 4. Distribution of sites over the first two axes generated by Detrended Correspondence Analysis; the scale of the axes are standard deviation units (s.d.). Eigenvalue first axis: 0.652; second axis: 0.259.

A log linear regression of these site similarities (%) against distance along the gradient permits the calculation of $CC_0$ at zero distance. In all cases regression was calculated using the first 5 points on the graph only. Beta diversity in half changes over an ecological distance of z intervals (in our case 1,000 m altitudinal difference) is then calculated as $\beta = (\log CC_0 - \log CC_z)/\log 2$. To evaluate differences in species turnover between lower and higher elevations, the altitudinal coenocline was divided into two sections. The lower part had the site at 1,250 m as reference stand and the higher part the site at 3,670 m.

## Results and Discussion

### CLIMATE

Day climate diagrams, following Ellenberg (1975) and including vapor pressure deficits, of the six stations along the transect (1,725–3,670 m) are based on hourly readings (Fig. 5). With increasing altitude, diurnal rhythms become less pronounced, a well-known pattern in equatorial montane forests (Walter, 1964), and a marked increase in humidity (hatched area) is notable above ca. 2,400 m as further shown by humidity conditions during daylight hours only (Fig. 6). Rainfall and humidity do not exhibit a linear relationship with altitude. Between about 2,000 m and 2,500 m there is a maximum in rainfall and a notable increase in humidity with altitude, which corresponds with the increase in slope of the transect (Fig. 1). Local wind circulation patterns may account for the observed humidity and rainfall pattern: in the early morning hours anabatic winds rise from the valley floor along the hillside and while rising, clouds may be formed through condensation, on a typical day resulting in precipitation during the early afternoon at an altitude of about 2,100 m (van der Weert et al., 1986). Accordingly, at higher altitudes sunshine was much rarer than in the valley and when it occurred it was during early morning hours and during late afternoons, when the clouds had passed onward (pers. obs.). During the night a drop in relative humidity, without an expected rise or even associated with a drop in temperature, was often observed (Fig. 7). This phenomenon, noted as far down the slope as 2,450 m and also known at the Sierra Nevada de Santa Marta, Colombia (van der Hammen, 1984), might be explained assuming the passing of a "dry" descending catabatic wind from the high (>5,000 m) snow-capped hinterlying volcanoes. These winds warm while descending, but apparently do not take up much moisture, perhaps due to the lack of bushy vegetation at higher elevations.

The distribution of tree base diffuse site factors (Anderson, 1964) with altitude shows that about 90–95% of the diffuse light is intercepted by the canopy (Fig. 8). Near the tree line at 3,670 m and at the *Polylepis*-dominated dwarf forest at 4,130 m the forest canopy is more open, with diffuse site factors of about 15% and 30%, respectively.

### BIOMASS PATTERNS

The biomass per unit surface area of the epiphytic tree crown subsamples (excluding phanerogams) varies considerably at a given altitude (Fig. 9A), but generally increases with altitude in agreement with quantitative measurements of bryophyte abundance in the forest understory along altitudinal gradients in Colombia (van Reenen & Gradstein, 1983) and Peru (Frahm, 1987c).

High bryophyte biomass values in the tropics have been attributed to rainfall above 100 mm per month (Pócs, 1980), and to foggy conditions (Grubb & Whitmore, 1966; Ellenberg, 1975). Frahm (1987c) observed a direct relationship between the biomass of epiphytic bryophytes in northeast Peru and the amount of radiation. The maximum recorded biomass value at a tree trunk by Frahm was 1.4 g/dm$^2$, while in this study the maximum bryophyte dry weight at the trunk base was 16 g/dm$^2$ (at 3,670 m). The climatic data presented from the Peruvian transect suggest that the local climate is notably drier than in our area, which predictably would result in lower bryophyte biomass values.

The rise in epiphytic biomass with altitude displays a marked increase around ca. 2,400 m that is not correlated with a sudden change in rainfall (Fig. 2), diffuse site factors (Fig. 8), or temperature (van de Weert et al., 1986), but coincides with an observed rapid increase of humidity above the 2,400 m mark (Figs. 5, 6). Ecophysiological research on bryophytes confirms the importance of moisture availability to bryophytic growth. Hosokawa et al. (1964) demonstrated for several epiphytic bryophytes a positive relationship between photosynthetic rate and relative humidity at equal light conditions. Because bryophyte photosynthesis is relatively insensitive to low temperatures (Dilks & Proctor, 1975), decreasing temperature should not negate the positive effects of high humidity on growth at higher elevations.

Long periods of high humidity not only allow for long periods of photosynthetic activity, but they also reduce the risk of desiccation. The latter factor

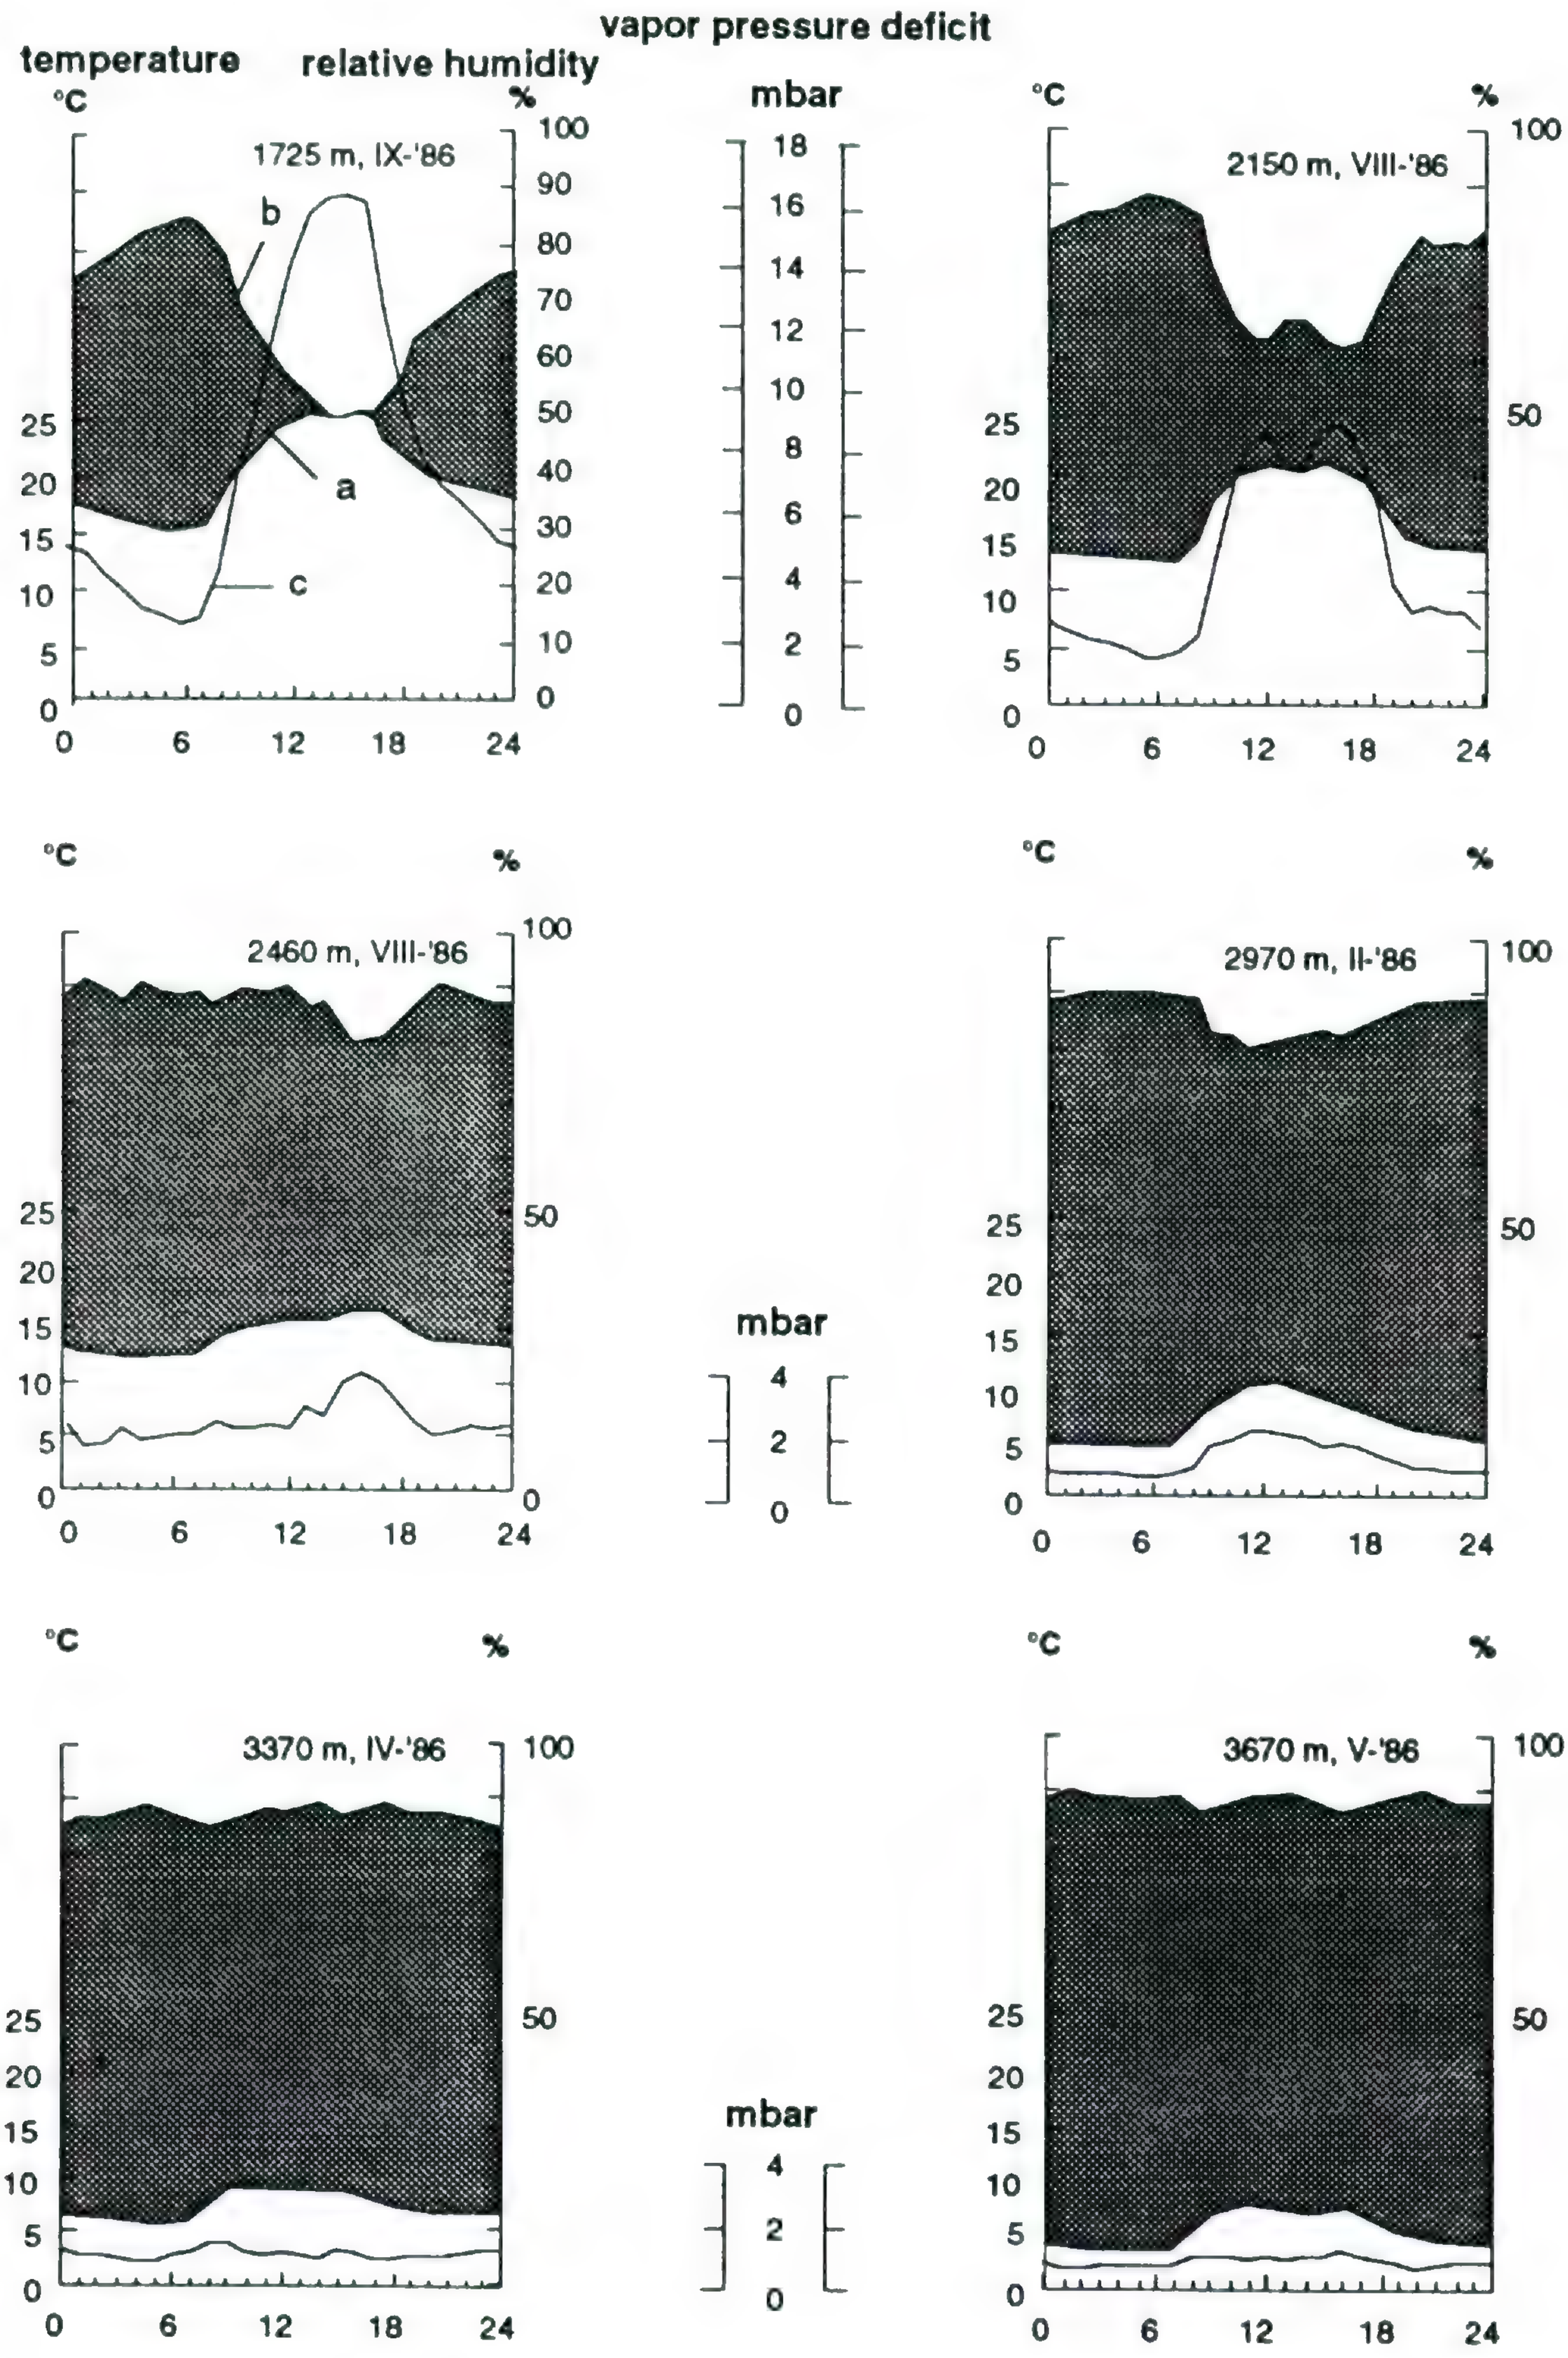

FIGURE 5. The daily course of temperature (a), relative humidity (b), and (derived) vapor pressure deficit (c) at different altitudes, based on hourly readings during 12 (1,725 m; 2,150 m; 2,460 m; 2,970 m) or 18 days (3,370 m; 3,670 m). Presentation following Ellenberg (1975).

- mean relative humidity (%)

FIGURE 6. Humidity conditions, as exemplified by three moisture indexes, in relation to altitude, based on hourly readings during daylight hours (06.00–18.00 hr.). Means of 12 (1,725 m; 2,150 m; 2,460 m; 2,970 m) or 18 days (3,370 m; 3,670 m).

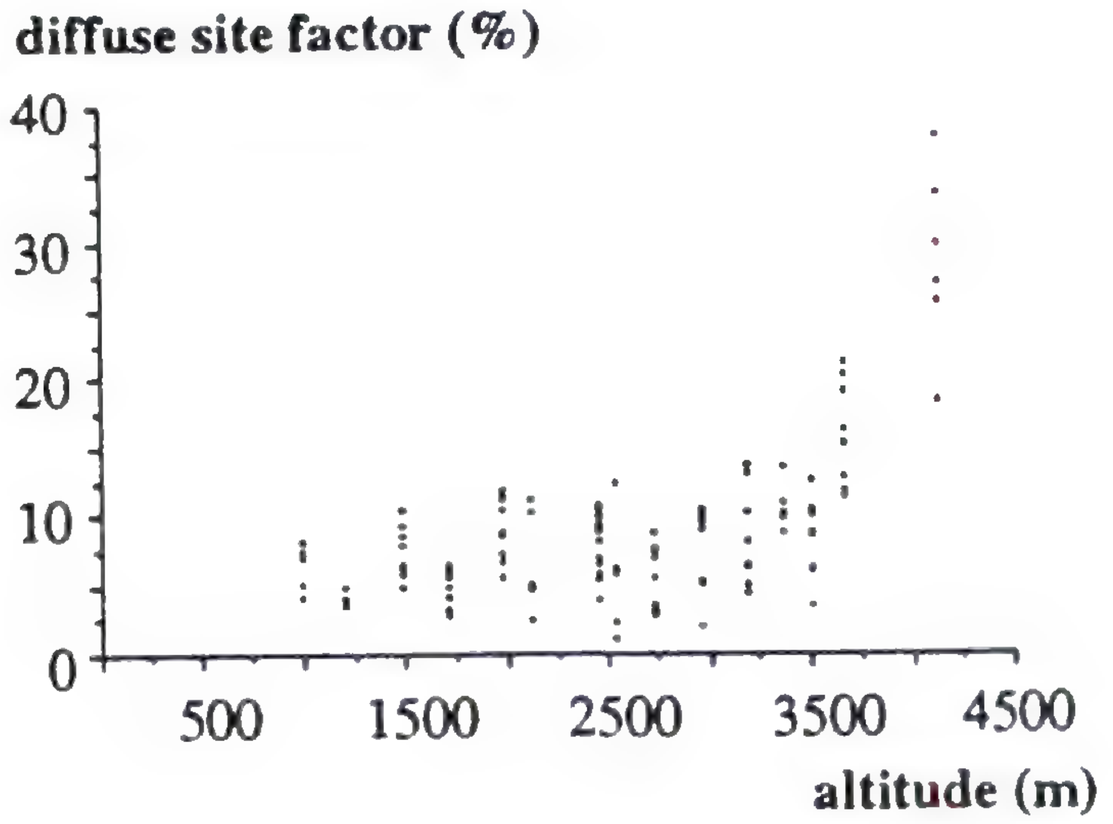

FIGURE 8. Mean percentage of diffuse light cut off by the canopy, expressed as diffuse site factors (Anderson, 1964) and calculated from hemispherical photographs taken at the bases of the investigated trees.

allows for the development of bryophyte growth forms that may attain a thick epiphytic layer (Fig. 9B) and hence a great biomass per surface area, such as tall turfs and pendents (Richards, 1984).

Another factor may be the greater life expectancy of the substrate. At higher elevations the productivity of the forest is lower (Grubb, 1977; Veneklaas, 1991) and therefore the trees are presumably older. $C^{14}$ analysis of the core wood at breast height of a 15-m-tall *Weinmannia mariquitae* Szyszyl. (Cunoniaceae) tree at 3,700 m altitude revealed a most probable age of 215 (±15) years (Hofstede et al., 1993).

Lichen biomass values were not determined separately from bryophytes, but were supposedly highest at altitudes below 2,500 m, due to the regular occurrence of large foliose growth forms, e.g., *Sticta* spp., at lower altitudes.

## EPIPHYTIC SPECIES NUMBERS

In total, 473 taxa (108 mosses, 187 liverworts, and 178 lichens) are recognized in the subsamples. Based on the amount of species grouping, these taxa are estimated to represent ca. 90% of the species present (with estimated species numbers of 113 for mosses, 220 for liverworts, and 198 for lichens, excluding an unknown number of crustose lichens).

Lichens may be subdivided into three main growth forms: foliose (110 taxa), fruticose (30 taxa), and crustose lichens (38 taxa). Crustose lichens include leprose (thallus powdery) and some squamulose (e.g., *Pannaria rubiginosa* (Ach.) Bory) forms. Fruticose lichens include filamentous (e.g., *Coenogonium* sp.) and loosely attached foliose growth forms with a thallus diameter of < 2 mm (e.g., *Everniastrum catawbiense* (Degel.) Hale). Squamulose growth forms are included with the foliose lichens, when the squamules regularly are

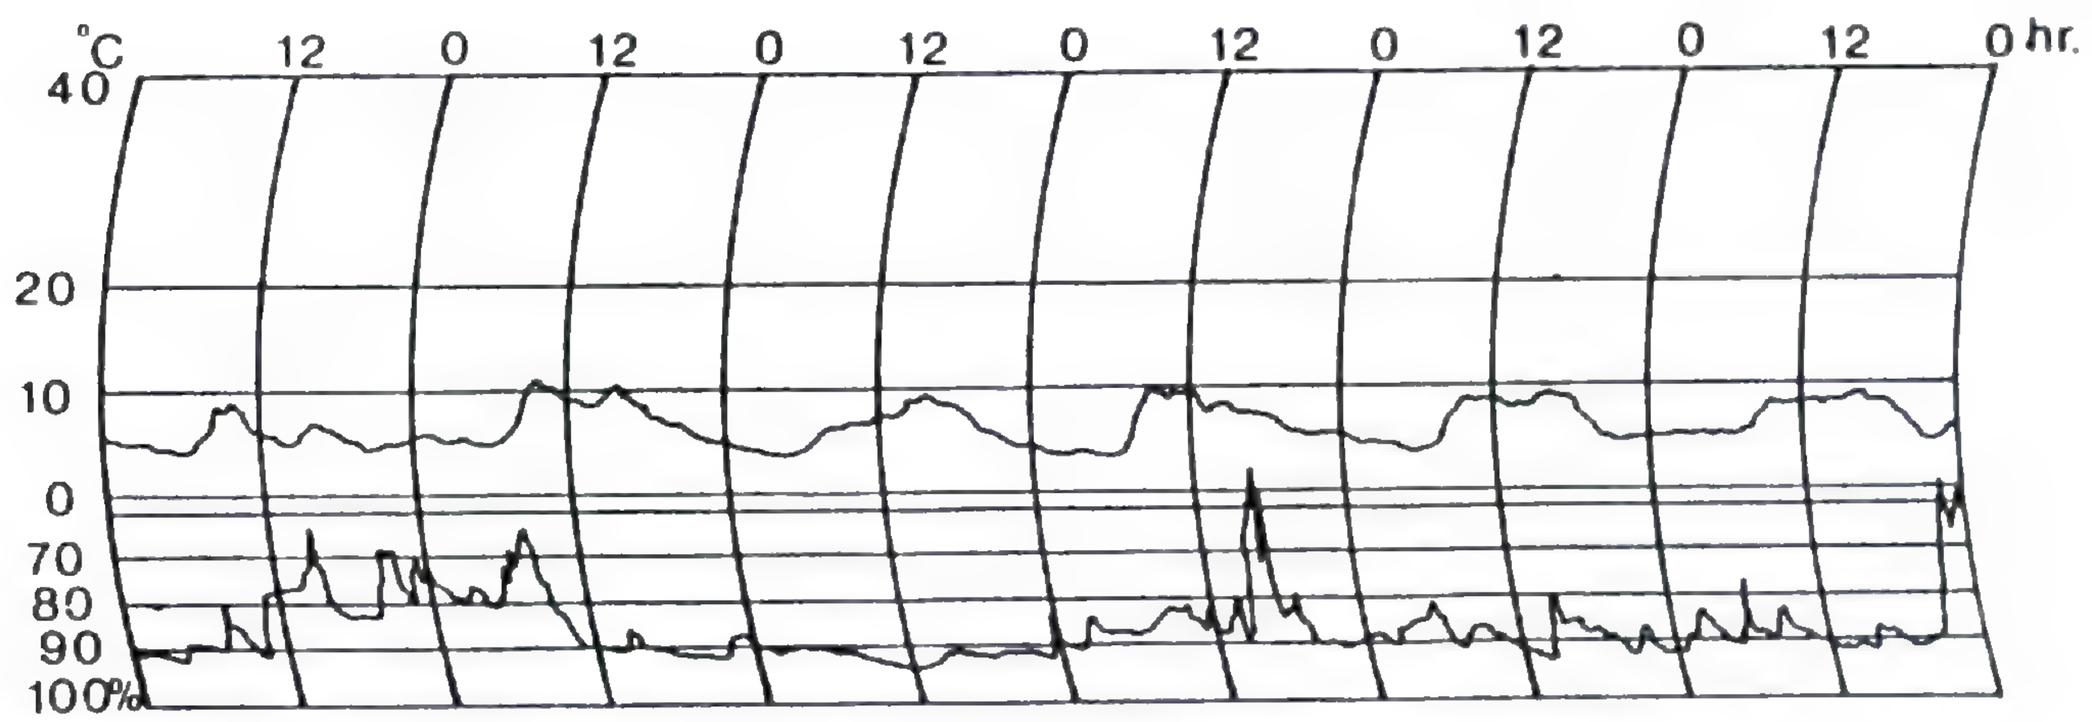

FIGURE 7. Thermohygrograph reading, TPN-transect, 9–15 May 1986, altitude 3,670 m.

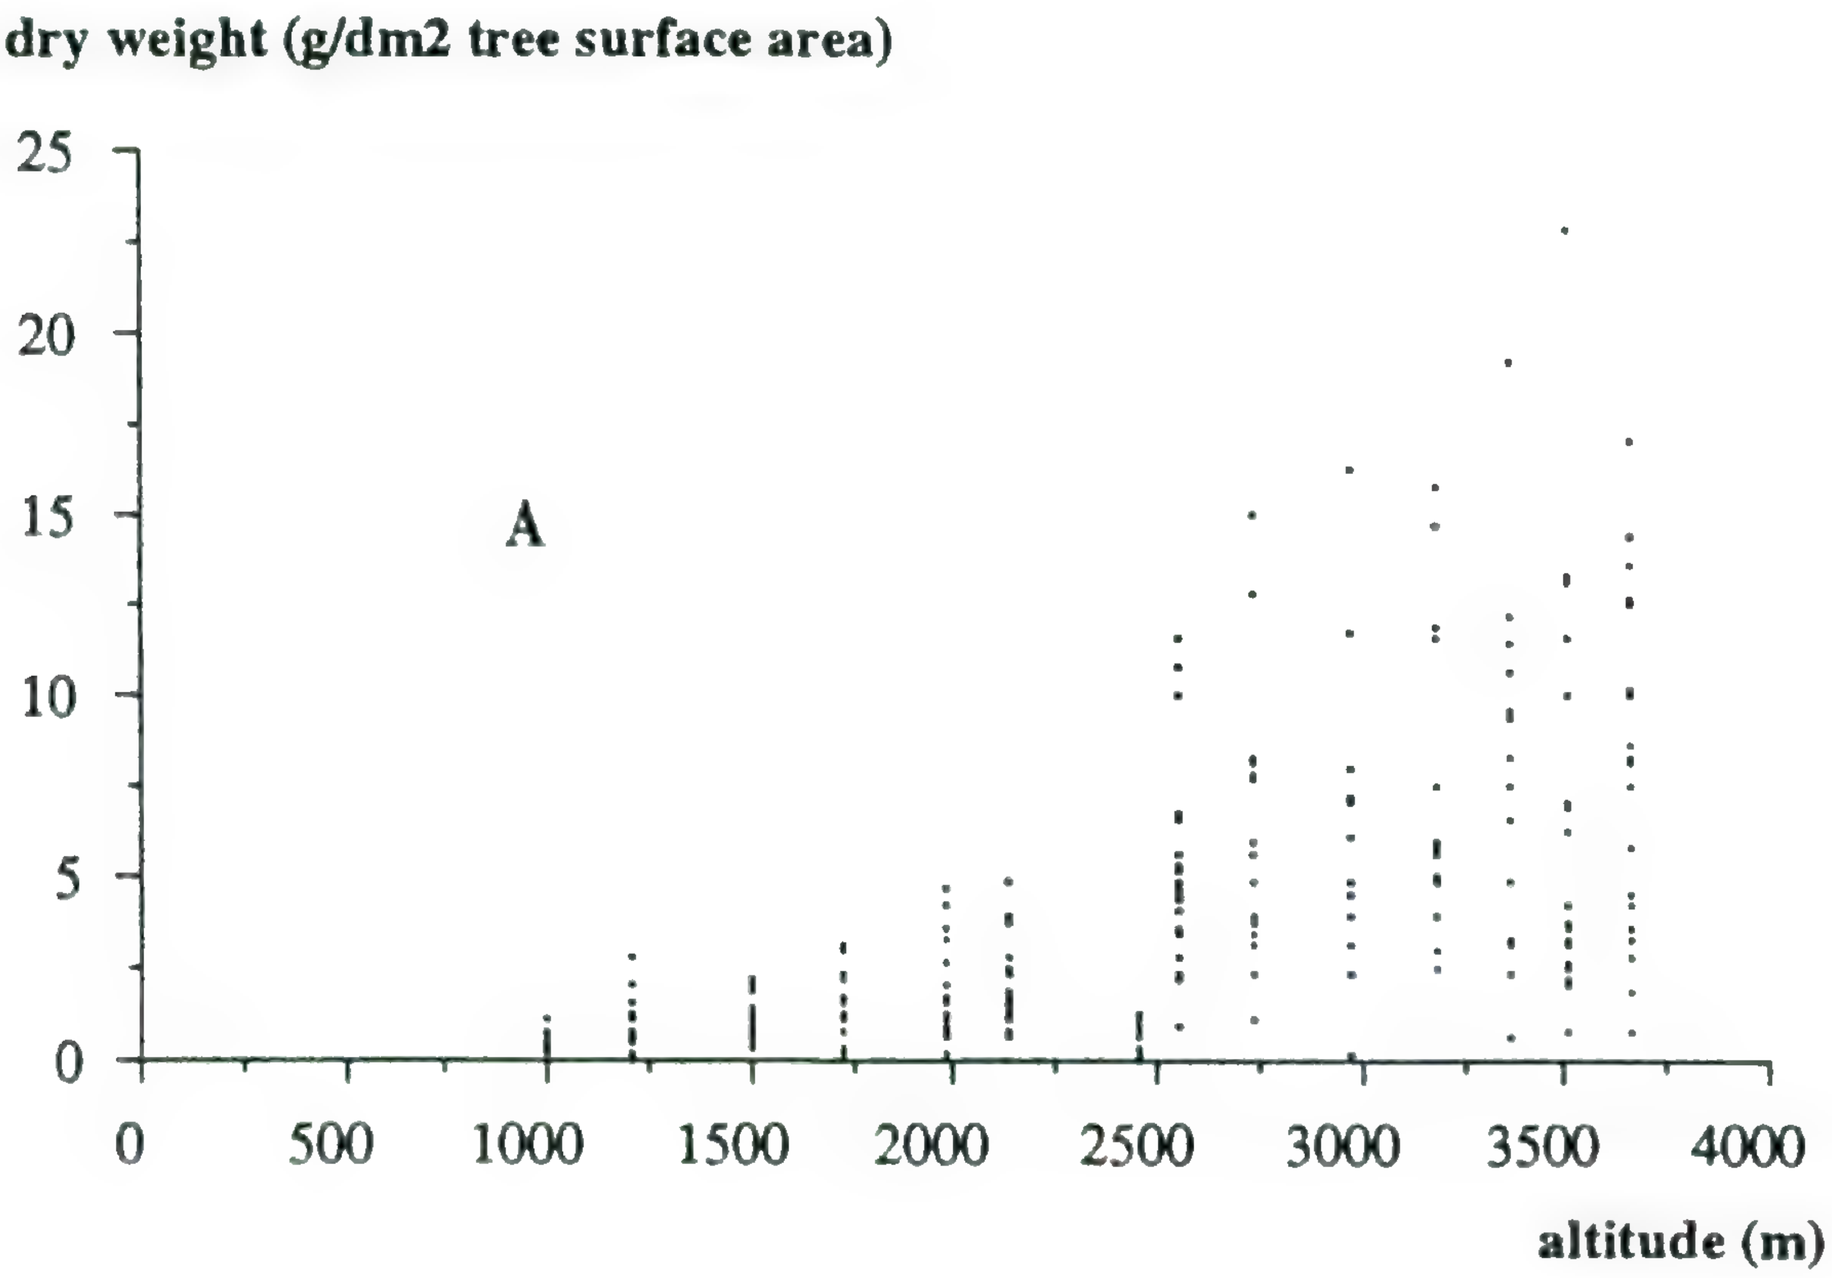

FIGURE 9. Biomass (A) and thickness (B) of the (living) epiphytic bryophyte layer. Each dot represents a subsample taken at the inner and middle parts of the branches within the canopy.

> 0.5 cm (e.g., *Normandina pulchella* (Borr.) Nyl.).

For many organisms the tropical region is richer in species than the temperate zone (e.g., Pianka, 1966). This may not apply to bryophytes and lichens, however. For example, recorded moss species numbers for the British Isles, Europe, the Guianas, and tropical America are, respectively, 700 (Smith, 1978), 1,084 (Corley et al., 1981), 234 (Florschütz-de Waard, 1991), and between 1,000 and 1,500 according to a rough estimation (Frahm & Gradstein, pers. comm.). Liverwort species numbers recorded for the same geographical areas are, respectively, 300 (Smith, 1990), 350 (Grolle, 1983), 375 (Gradstein & Hekking, 1989), and ca. 1,200 (Gradstein, 1988). Even though the number of bryophyte species in the tropics is likely to increase with continued exploration, it appears

TABLE 1. Epiphytic bryophyte and macrolichen richness in a temperate deciduous forest (Sweden), lowland tropical rainforest (Guianas), and montane tropical rainforest (Colombia): (1) from Sjögren (1961); (2) from Cornelissen & Ter Steege (1989); (3) from Montfoort & Ek (1990); (4) this study. Within the tropical areas sampling included the tree crown and in the Guianas epiphyllous species.

| | Number of trees sampled | Mosses | Liver-worts | Total bryophytes | Macro-lichens |
|---|---|---|---|---|---|
| Sweden; deciduous forest (1) | many | 78 | 17 | 95 | — |
| Guyana; dry evergreen *Eperua* spp. forest (2) | 11 | 28 | 53 | 81 | 33 |
| Guyana; mixed lowland rainforest (2) | 5 | 28 | 60 | 88 | 19 |
| French Guyana; mixed lowland rainforest (3) | 4 | 43 | 61 | 104 | 21 |
| Colombia; montane rainforest; 1,500 m (4) | 4 | 22 | 36 | 58 | 49 |
| Colombia; montane rainforest; 2,550 m (4) | 4 | 33 | 102 | 135 | 51 |
| Colombia; montane rainforest; 3,510 m (4) | 4 | 19 | 63 | 82 | 37 |

that temperate areas are richer in bryophytes (British Isles 1,000 species) than tropical lowland rainforest (Guianas 609 species). The higher relative contribution of liverworts to bryophyte species richness in the tropics (tropical America ca. 50%) than in temperate areas (Europe ca. 25%) is confirmed by data on epiphytic bryophyte diversity (Table 1). Total epiphytic bryophyte species numbers are similar in temperate Sweden, the tropical Guianas, and in Colombia, but species numbers in the tropics are likely to be higher due to the restrictive sampling methods used. Records on species numbers of lichens in the tropics are still incomplete. Sipman (1989) estimated lichen richness in the transect to be of the order of 600–900 species, compared to 1,355 recorded species for the British Isles (James, 1965).

Comparing bryophyte species numbers recorded on similar numbers of host trees in situations of near saturated species area curves (Table 1), at least for epiphytes no support is given for earlier assumptions (Richards, 1984, 1988) that wet montane tropical forests are richer in bryophyte species than tropical lowland rainforests (but epiphyllous species were not included in this study). Epiphytic macrolichen richness appears to be greater in tropical montane forest than in lowland forest.

In addition to limitations imposed by the restrictive sampling method by tree size, bark type, and location, bryophyte and lichen species numbers in general should be looked at with care for two reasons.

First, there is justification for treating epiphytic and terrestrial cryptogams separately, not only because epiphytic species are ecologically different, but also because, in particular in the lowland tropics, terrestrial sampling is likely to be biased. Tropical lowland forests have low cover percentages of terrestrial bryophytes, possibly partly due to the smothering effect of leaf litter and partly due to the combination of low light intensities and high temperatures (Richards, 1984; Frahm, 1987c). Species richness estimations of lowland areas are likely to be highly influenced by factors such as gaps, road banks, and fallen trees. Bias in sampling may largely be avoided by sampling of the epiphytic flora growing on trees within the forest only. Furthermore, terrestrial substrates are more likely to differ from each other structurally, chemically, and in terms of water availability than epiphytic sites, and thus habitat heterogeneity is more likely to cause noise in diversity patterns.

Second, epiphytic sampling should include systematic investigation of the forest canopy. In the lowland rainforest of the Guianas, over 50% of the epiphytic bryophyte species may be found exclusively in the canopy (Gradstein et al., 1990). Moreover, a more open forest may permit the descent of typical canopy species to the forest floor, confusing altitudinal species diversity patterns when only the forest floor is sampled. The reported rise in number of species of lichens (Sipman, 1989) and bryophytes (Gradstein et al., 1989) near the upper tree limit in the investigated transect, based on both terrestrial and epiphytic (0–3 m) sampling, can possibly be ascribed to the occurrence of canopy species near ground level, together with the influx of typical terrestrial páramo species.

## ALPHA DIVERSITY PATTERNS

The altitudinal distribution of 473 bryophyte and lichen taxa is presented in Table 2. Bryophyte and lichen richness patterns along the transect selected for study are not identical (Fig. 10). Whereas bryophyte richness shows a clear maximum between 2,550 m and 3,190 m, numbers of taxa of lichens decrease slightly between 1,500 m

TABLE 2. Recorded taxa and their distribution along the altitudinal transect. "X" = actual record; "•" = presumed occurrence; (# . . . refers to collection number).

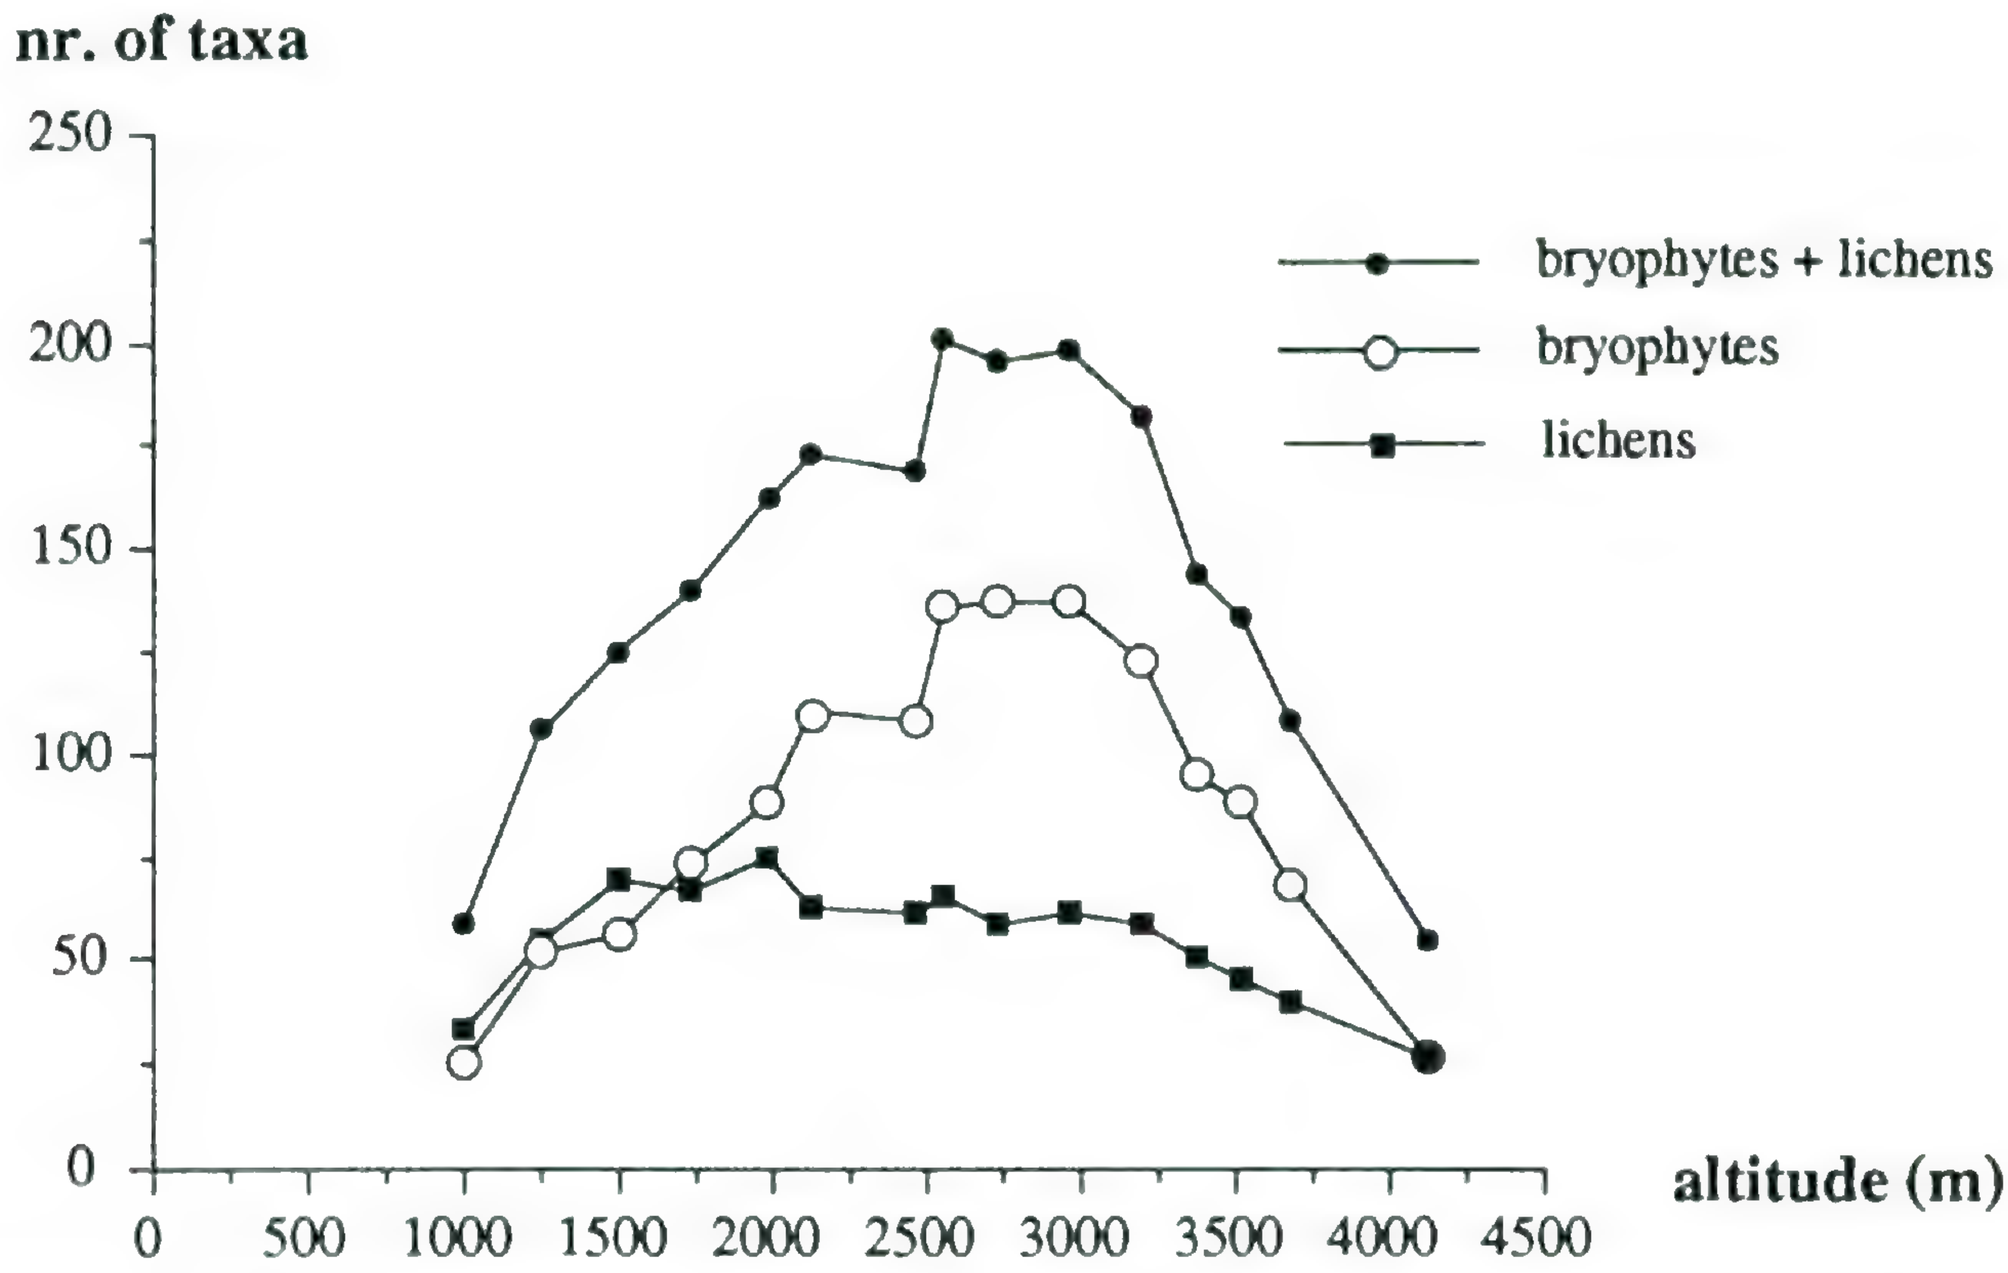

FIGURE 10. Distribution pattern of bryophyte and lichen richness in relation to altitude, as derived from Table 2.

and 3,200 m and substantially at higher altitudes. While foliose and crustose lichen taxa numbers tend to drop with altitude, fruticose lichen numbers increase up to an altitude of about 3,400 m (Fig. 11). The bryophyte curve (Fig. 12) is mainly determined by the liverwort component, whereas mosses exhibit very much the same distribution as the overall lichen pattern.

The mosses : liverworts ratio has been repeatedly correlated to humidity (Gradstein et al., 1989; van Reenen & Gradstein, 1983) and the data on epiphytic bryophytes, including canopy species, for altitudes up to ca. 3,200 m confirm the hypothesis that the contribution of liverworts to overall bryophyte diversity increases with humidity.

Liverworts are an important element, in terms

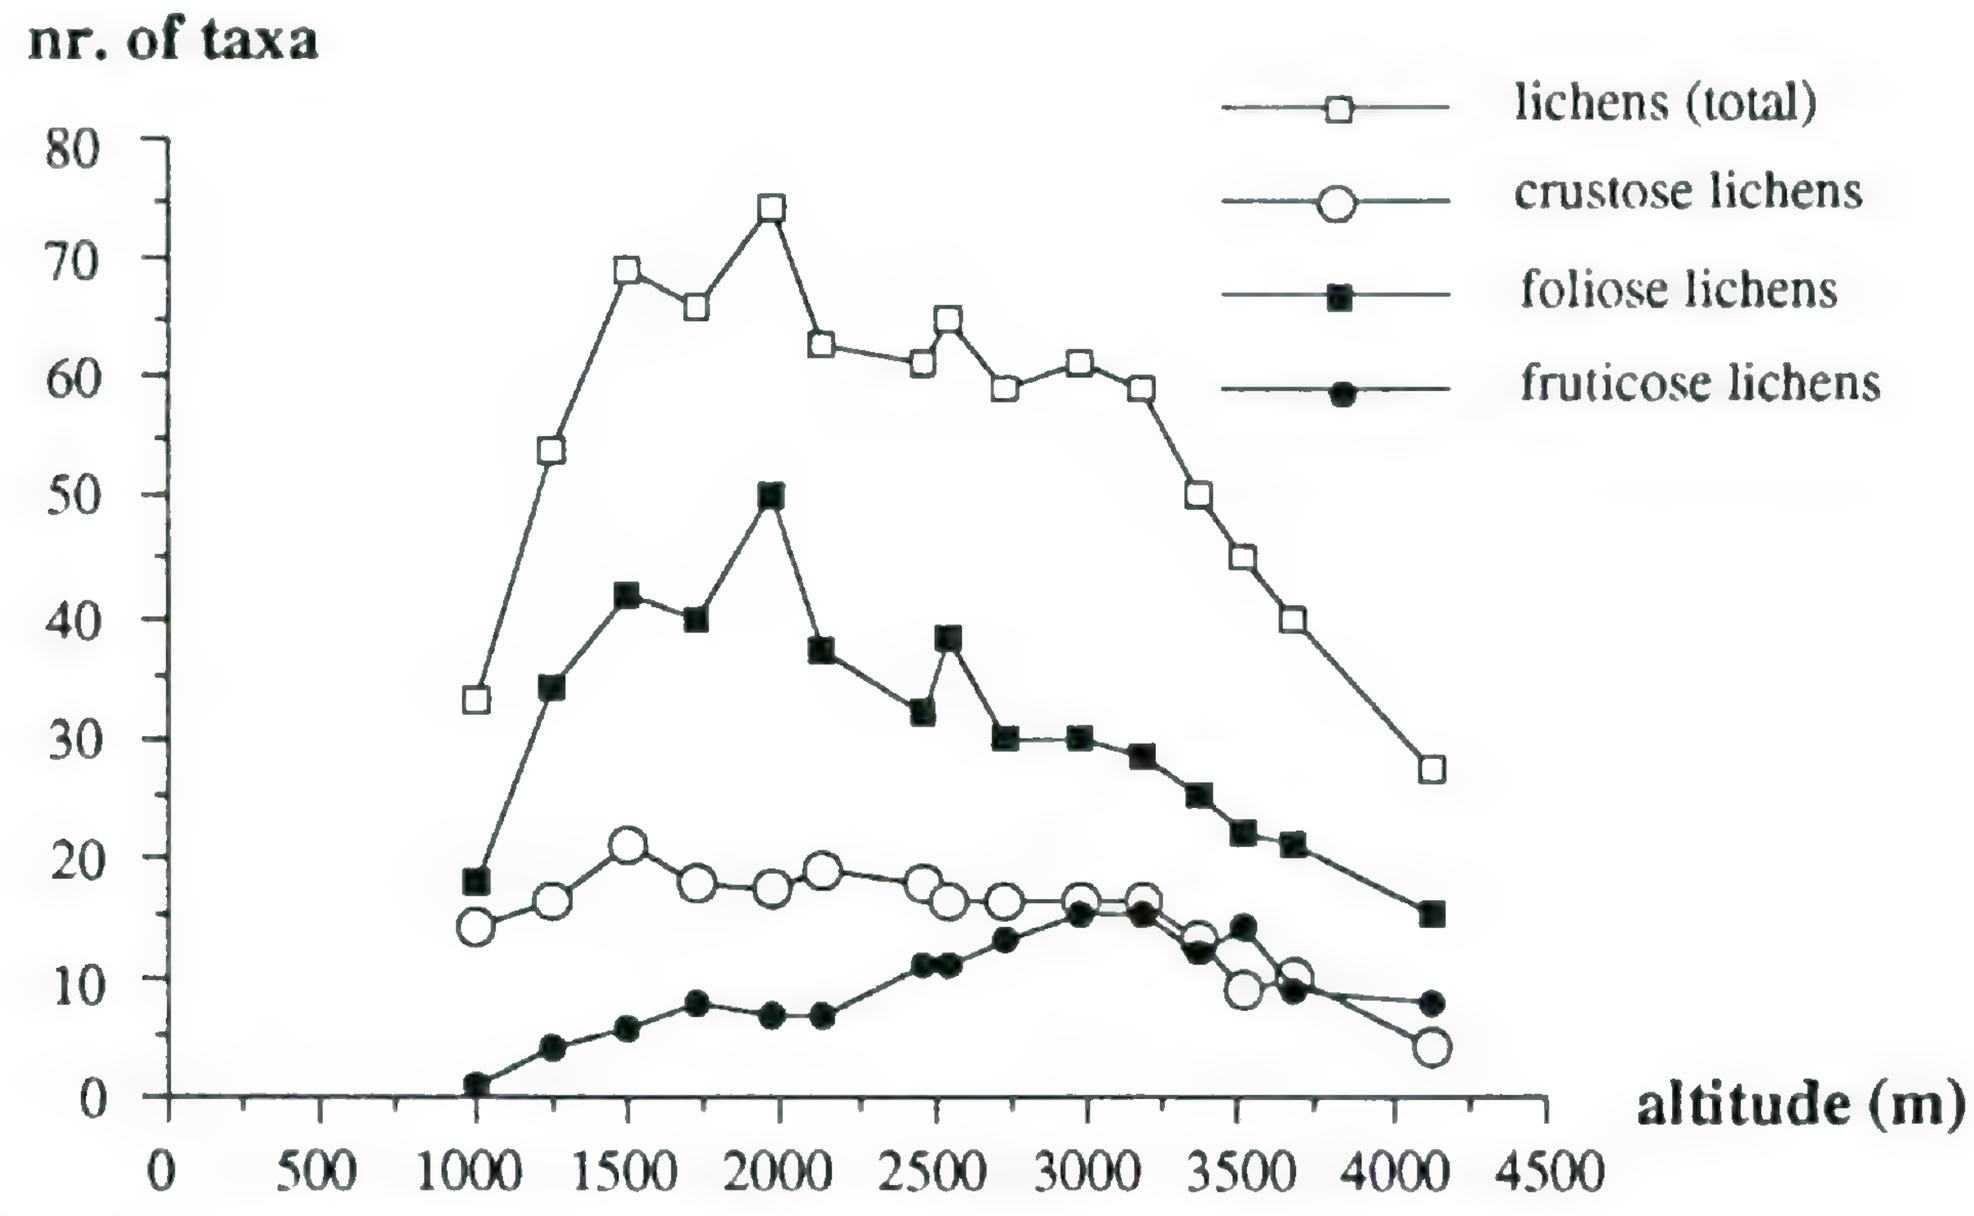

FIGURE 11. Distribution pattern of lichen richness in relation to altitude, as derived from Table 2.

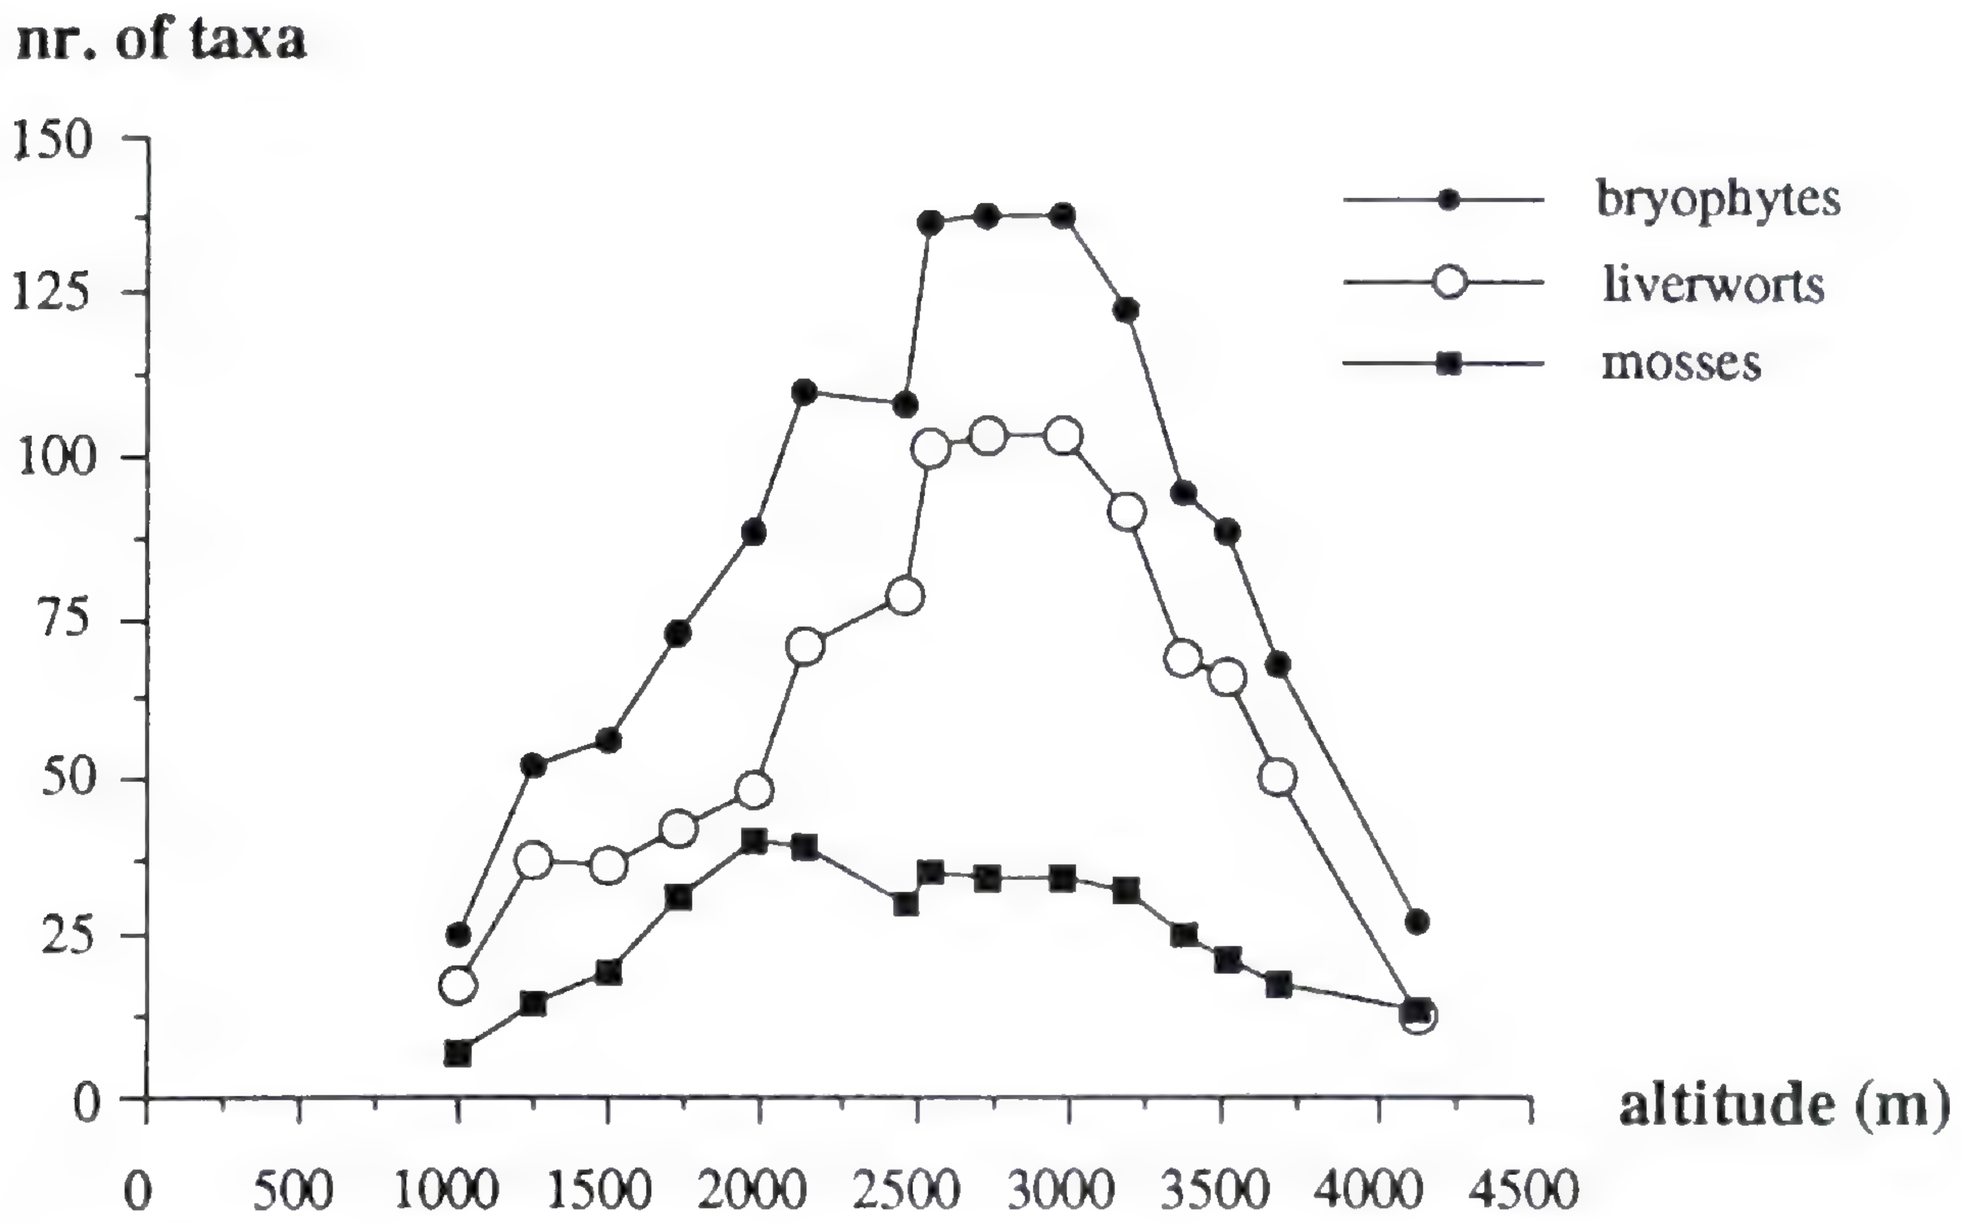

FIGURE 12. Distribution pattern of bryophyte richness in relation to altitude, as derived from Table 2.

of species numbers, of the epiphytic flora, and reach maximum species richness between 2,550 m and 3,190 m (Fig. 12). Shmida & Wilson (1985) proposed two hypotheses, besides niche relations and habitat diversity (e.g., MacArthur, 1965), to explain how species diversity along a macrogradient can be caused and maintained: mass effect and ecological equivalency. Mass effect is the establishment of species in sites where they cannot be self-maintaining, and ecological equivalency is the coexistence of species within the same fundamental niche.

The mass effect hypothesis requires the existence of an adjacent core area from which there is a steady influx of propagules to the site. In practice it is not always easy to establish whether a species will be able to survive at a site.

The mass effect hypothesis is attractive for epi-

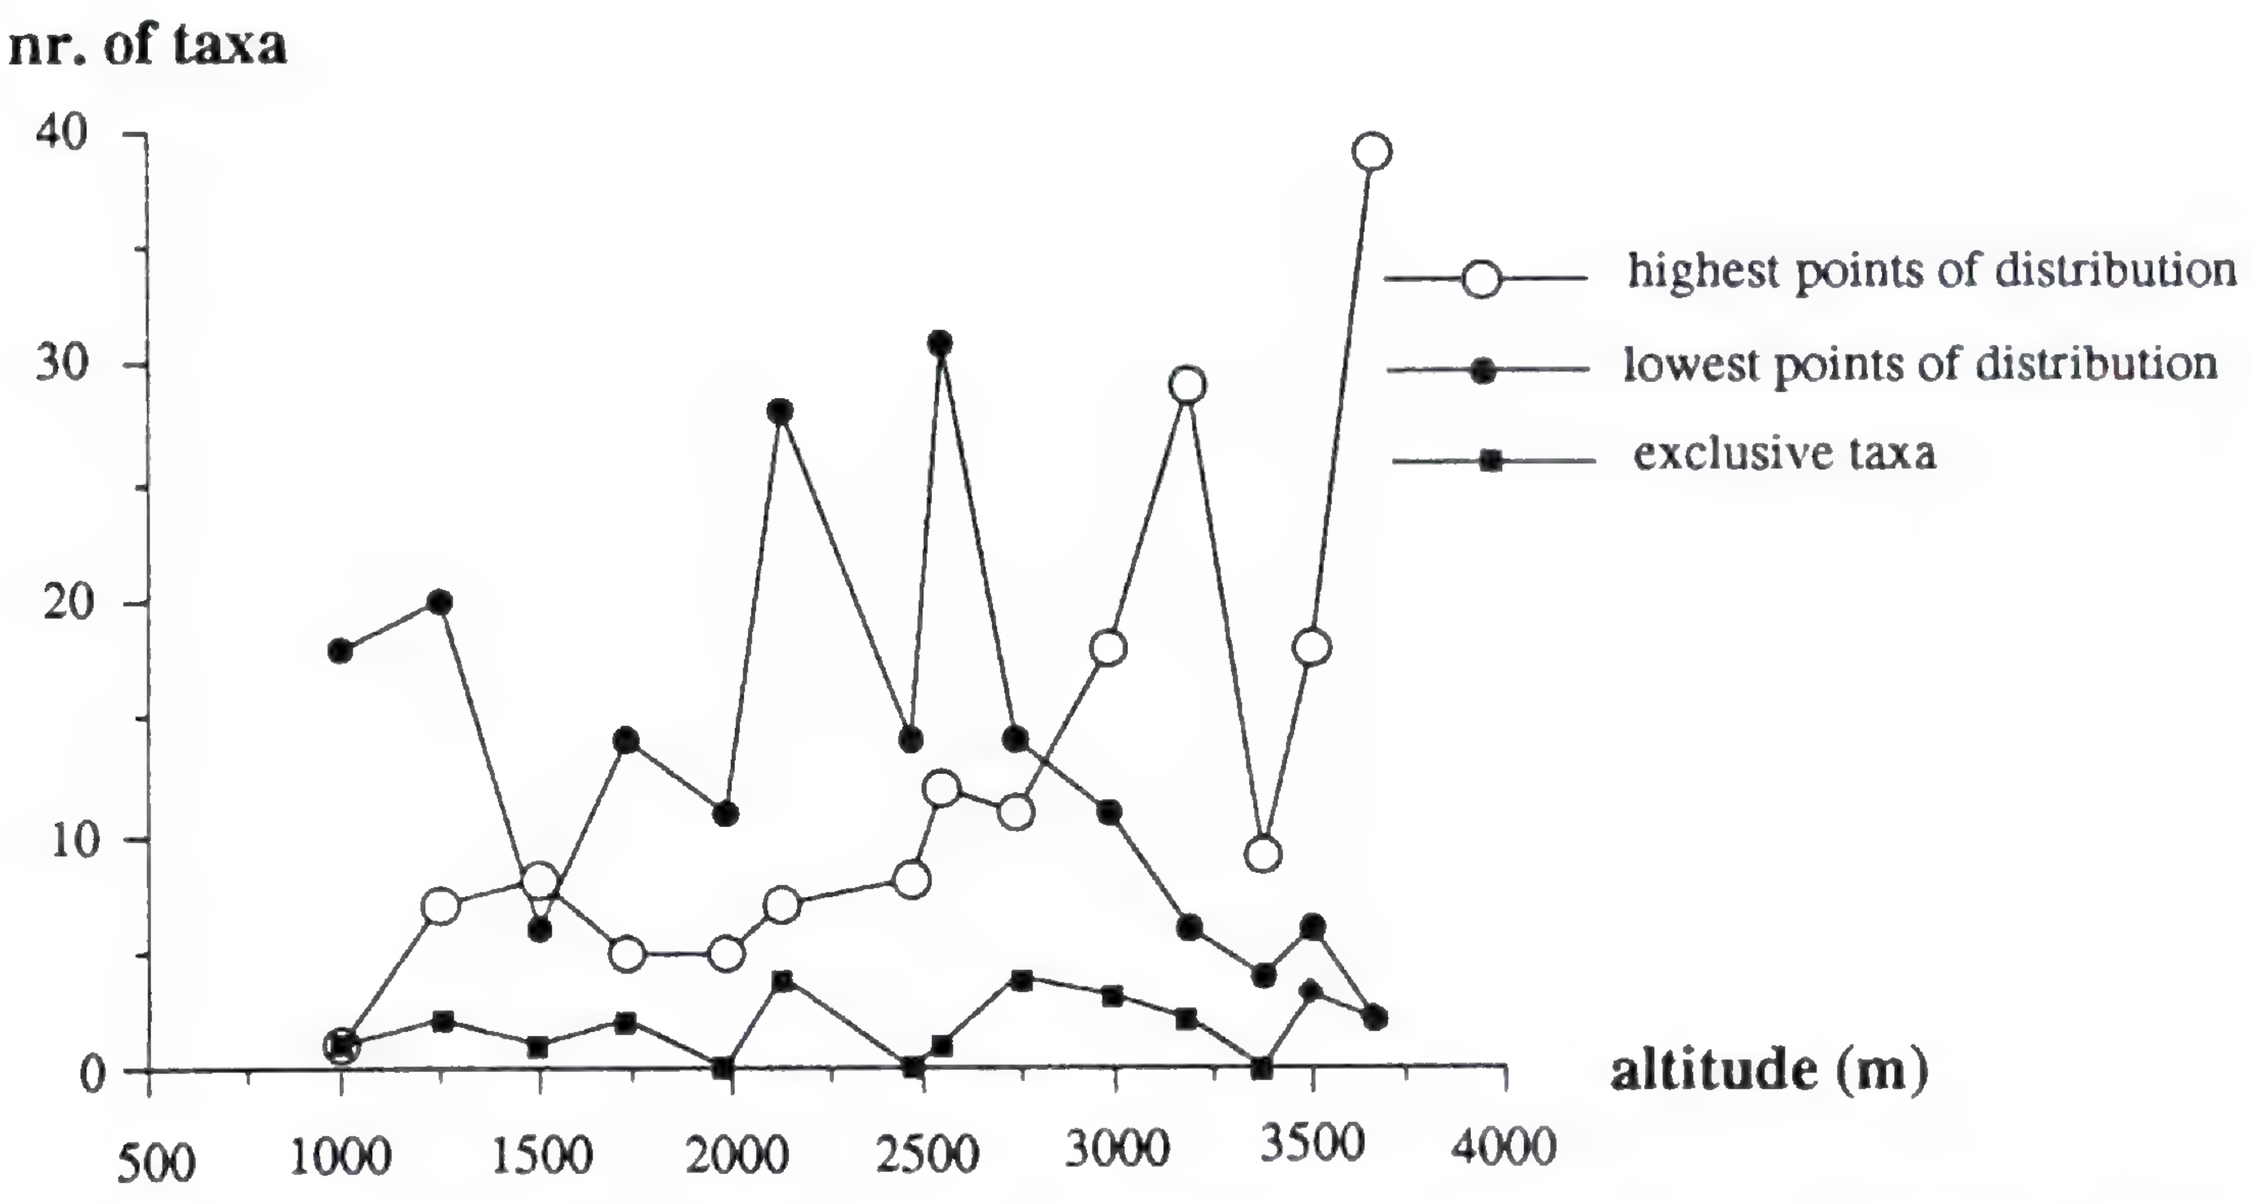

FIGURE 13. Distribution of taxa of liverworts along the altitudinal gradient; number of exclusive taxa for each altitude and number of endpoints of species ranges.

TABLE 3. Average position of sites along the first axis of ordination as generated by Detrended Correspondence Analysis. Scaling of the axis in units of standard deviation (s.d. units) × 100 (Hill, 1979).

| | Site altitude (m) | | | | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1,250 | 1,500 | 1,725 | 1,980 | 2,130 | 2,460 | 2,550 | 2,740 | 2,970 | 3,190 | 3,370 | 3,510 | 3,670 | | | | | | | |
| Eigenvalue axis ½ | | | | | | | | | | | | | | | | | | | | |
| All data | 0.613/0.131 | 386 | 372 | 325 | 283 | 224 | 182 | 133 | 98 | 83 | 58 | 26 | 2 | 0 | | | | | | |
| Macrolichens | 0.630/0.137 | 357 | 360 | 341 | 274 | 204 | 174 | 138 | 101 | 80 | 42 | 18 | 0 | −11 | | | | | | |

| Mosses | 0.730/0.096 | 528 | 478 | 446 | 396 | 345 | 261 | 217 | 158 | 151 | 107 | 44 | 0 | 0 | | | | | | |
| Bryophytes | 0.646/0.089 | 454 | 422 | 351 | 321 | 264 | 212 | 156 | 118 | 106 | 81 | 34 | 8 | 0 | | | | | | |

phytic bryophytes and lichens. First, many lichens and bryophytes often produce spores in abundance (Richards, 1984) and/or have extensive vegetative reproduction; parts of the plants just break off or special structures are formed, like gemmae in mosses and soralia or isidia in lichens. While data on dispersal efficiency of bryophytes and lichens are difficult to obtain, some impression may be obtained by the high speed of colonization of new available sites.

Second, in a frequently disturbed habitat it will be easier for propagules to find a suitable (vacant) site to establish themselves. The epiphytic habitat is likely to have a high rate of disturbance due to the exfoliation of bark fragments, the occurrence of tree or branch fall, and disturbances by animals such as mammals (Perry, 1978b), birds (nesting material, nesting sites, and invertebrate foraging; Nadkarni & Matelson, 1989), and invertebrates (pathways of leaf cutter ants; pers. obs.).

According to Shmida & Wilson (1985), the influence of ecological equivalency on overall richness should be highest in systems in which habitats are patchily distributed (isolated branches) and/or in which competitive interactions are reduced. As to competition, indications are that bryophyte communities are not at competitive equilibrium (Slack, 1977; Watson, 1980), and that competitive interactions between bryophytes are not very intense (During & ter Horst, 1987; During and van Tooren, 1988).

Mass effect and ecological equivalency hypotheses, in combination with overlapping species ranges, predict the highest species diversity at transition zones, where two distinct floras meet (= contact transition). The distribution patterns of individual liverwort taxa along the elevational gradient (Fig. 13) show that at 2,130 m many taxa have their lowest point of distribution, coinciding with a marked decrease of humidity below this altitude (Figs. 5, 6). A second peak in "points of lowest distribution" at 2,550 m indicates the first occurrence of many liverwort species characteristic of the higher (altitudinal) forest, e.g., *Lepicolea pruinosa* (Tayl.) Spruce, *Jamesoniella rubricaulis* (Nees) Grolle, and several *Herbertus* species. At an altitude of 3,190 m many species from lower altitudes reach their upper limit, e.g., *Taxilejeunea pterigonia* (Lehm. & Lindenb.) Schiffn., *Frullania caulisegua* (Nees) Nees (=*F. obcordata*), and *Plagiochila bursata* (Desv.) Lindenb. The difference in maxima between points of lowest and of highest altitudinal distributions demonstrates the presence of a zone of overlap between 2,550 and 3,190 m. This transition zone coincides nicely with the belt

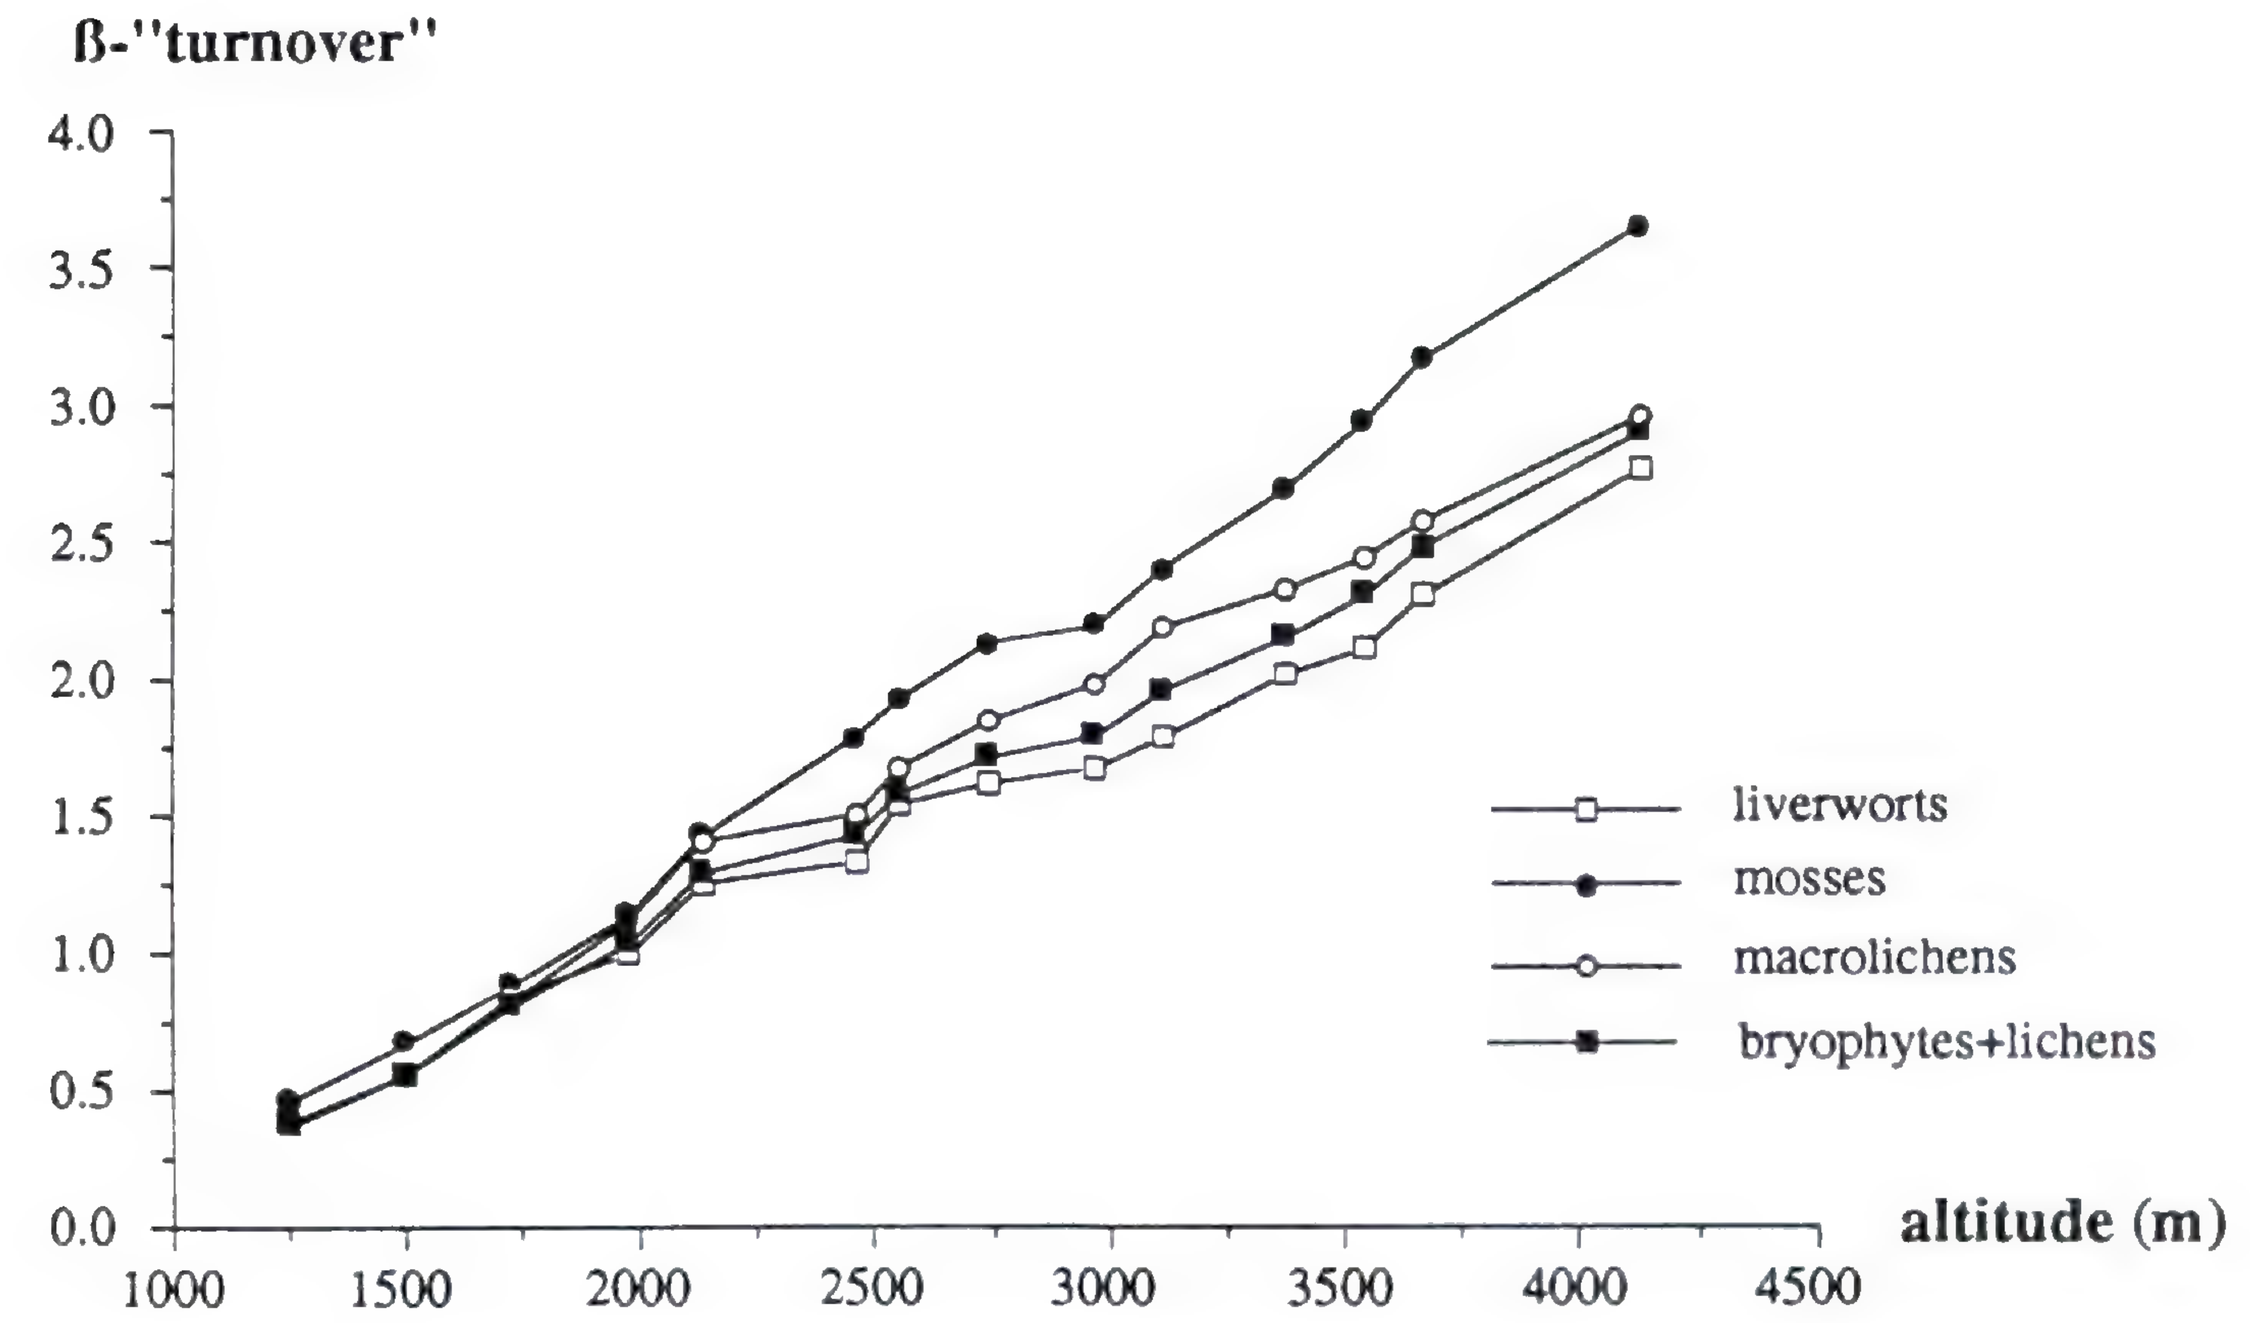

FIGURE 14. Beta diversity along the altitudinal gradient, using the Wilson & Shmida (1984) measure, or "beta turnover," of diversity.

of highest species richness (Fig. 12), as predicted. However, induced floristic transition zones, where a sharp environmental boundary in a gradient is present, have a great variety of species as well, but this type of transition zone is likely to have species centered in it. On the total of 127 taxa of liverworts occurring in the transition zone, there are 101 taxa (ca. 80%) that occur outside this altitudinal range as well and each altitude sampled within this range has only 2–6 (= <10%) exclusive species (Fig. 13). The bryophyte floras from lower and higher elevations in the transect are from a different origin, as demonstrated by Gradstein et al. (1989). They concluded: "It appears that at lower altitudes, below 3,000 m, wide ranging tropical species prevail whereas narrow ranging tropical species and species of temperate origin are more common at higher altitudes."

## BETA DIVERSITY PATTERNS

Relative site position along the first axis of ordination, using DECORANA (Table 3), may be seen as a reliable estimate of species turnover, when the gradient is unidimensional (Økland, 1986), as shown by the much higher eigenvalues of the first axis than of the second axis. For macrolichens, mosses, and liverworts, Spearman's rank coefficients for correlation between ordination rankings of sites along the first axis and altitude are highly significant ($R \geq 0.989$; $P < 0.001$). Altitude, a complex ecological factor, thus explains well the variation in the data for these taxonomic groups.

Macrolichens generally have a greater altitudinal range than liverworts and mosses, indicated by a shorter first axis of ordination of, respectively, 3.68 s.d., 4.30 s.d., and 5.28 s.d. Lichens were shown to have wider amplitudes than bryophytes (mainly mosses) in relation to latitudinal and edaphic (pH, texture, and moisture) gradients in the Canadian subarctic forest tundra as well (Robinson et al., 1989) and along a potential evapotranspiration gradient and a gradient based on Conrad's index of continentality in pine forests in Finland (Oksanen, 1983).

Mosses apparently are more specialistic than liverworts (Table 3), a conclusion also reached by Florschütz-de Waard & Bekker (1987) studying different types of lowland forest in Suriname.

The change in beta diversity on the altitudinal gradient, using Wilson & Shmida's (1984) measure, "beta turnover," reveals that the overall more specialistic behavior of mosses may in particular be attributed to the greater species turnover of mosses at altitudes above 2,130 m (Fig. 14).

Lee & La Roi (1979) compared half change values (Whittaker, 1960) of bryophytes along an altitudinal gradient in Canada with values derived from studies by Slack (1977) in the United States. Half change values along altitudinal coenoclines

TABLE 4. Half changes of elevational coenoclines in temperate and tropical America. (1) From Slack (1977), coenocline: length 970 m, mid-elevation ca. 1,000 m; (2) from Lee & La Roi (1979), coenocline: length 1,250 m, mid-elevation ca. 1,100 m; (3) this study, coenocline: length 1,000 m, mid-elevation 1,750 m (a) and 3,170 m (b).

| | | Bryophytes | Macrolichens | Bryophytes/ macrolichens |
|---|---|---|---|---|
| Adirondack Mountains, New York, U.S.A. | (1) | ca. 1.26 | — | — |
| Jasper National Park, Canada | (2) | 1.1 | — | — |
| Colombia (a) reference stand: 1,250 m | (3) | 1.45 | 0.93 | 1.26 |
| (b) reference stand: 3,670 m | (3) | 1.30 | 0.94 | 1.22 |

are presented in Table 4. Semi log regressions used for the calculation of half changes in Colombia all had $R^2$ values of over 0.92. Contrary to indications given by beta turnover values (Fig. 14), bryophytes and macrolichens do appear to have a different rate of biotic change at lower altitudes, with half changes of 1.45 and 0.93, respectively. A possible explanation may be methodological. Half change values are calculated using similarity values of sites to a reference (first) stand. While for the other sites in the coenocline some correction is possible for outliers by means of the regression used, the composition of the first stand is determinant. Beta turnover as measure does not attach extra weight to one of the stands.

Half change values in the tropical mountains of Colombia are greater, especially for the "1,250 m coenocline," than have been reported for temperate North American mountains, indicating narrower species ranges in the tropics in relation to altitude as predicted by Janzen (1967) and documented for lizards, frogs, and snakes (Huey, 1978). However, present data on bryophytes should be regarded with caution, since the number of substrate types between studies varied. Whereas this study was limited to epiphytes, Slack's (1977) study included bryophytes from a wide range of both epiphytic and terrestrial substrate types, and Lee & La Roi (1979) sampled the three most abundant terrestrial substrates only in each stand. Including bryophytes from more substrate types in the analysis will lead to a higher species turnover, as remarked by Lee & La Roi (1979), not invalidating the general conclusion. Furthermore, actual species turnover in the present study is higher than recorded because of occasional species lumping.

# CHROMOSOME CYTOLOGY OF THE AFRICAN GENUS *LAPEIROUSIA* (IRIDACEAE–IXIOIDEAE)[1]

*Peter Goldblatt*[2] *and Masahiro Takei*[3]

ABSTRACT

Chromosome counts, now available for 33 of the approximately 40 species of *Lapeirousia*, show the genus to be remarkably variable cytologically. Excluding polyploidy, numbers range from $n = 10$ to 9, 8, 7, 6, 5, 4, and 3 in what we believe to be a descending dysploid series. A cycle of polyploidy and secondary descending dysploidy appears to have occurred in the tropical African section *Paniculata*. In *L. erythrantha* of the section there are both diploid populations with $n = 4$ and polyploid populations with $n = 6$, the latter karyotype having about twice as much chromosome material as the $n = 4$ karyotype. Although chromosome numbers vary among the species, the single large chromosome pair and total amount of chromosome material appear to be conserved, indicating the progressive fusion of small chromosomes, from a putatively ancestral bimodal karyotype with one long and nine short chromosome pairs. A phylogeny for section *Paniculata* is proposed based largely on karyotype change. An unusually high frequency of B chromosomes is evident in species with higher chromosome numbers. Not before detected, their irregular presence in populations probably explains past difficulty in determining chromosome numbers in several species of the genus.

Chromosome cytology is an important factor in considerations of the systematics and phylogeny of *Lapeirousia*, a widespread African genus of Iridaceae subfamily Ixioideae. The estimated 40 species of the genus (Goldblatt & Manning, in prep.) are currently divided among two subgenera, subgenus *Lapeirousia* with sections *Lapeirousia* and *Sophronia*, and subgenus *Paniculata* with sections *Paniculata* and *Fastigiata* (Goldblatt & Manning, 1990; Goldblatt, 1990a; Goldblatt & Manning, 1992). That the chromosome cytology of *Lapeirousia* is extremely variable is well known (Goldblatt, 1990b): excluding polyploidy, base numbers range from $x = 10$ to 3. Such variability is remarkable in plants in general, including Iridaceae, most genera of which exhibit little or no variation in basic number (Goldblatt, 1971).

Based on outgroup comparison, ancestral base number in *Lapeirousia* is most likely $x = 10$, but species of *Lapeirousia* with $2n = 20$, 18, 16, and some with $2n = 12$ or 10 are distinctive in having strongly bimodal karyotypes with one long chromosome pair and nine to four smaller pairs less than half as long as the long pair. Only in the predominantly tropical African section *Paniculata* are there departures from this pattern, and most species have karyotypes with chromosomal rearrangements that have resulted in derived base numbers of $x = 6$, 5, 4, and 3. Among these is the widespread and diverse *L. erythrantha*, which until now has been thought to be a hypotetraploid with a secondary base of $n = 6$, derived from ancestors with $n = 4$ (Goldblatt, 1990b). New counts presented here for *L. erythrantha* confirm $2n = 12$ in some Zimbabwean populations, but we have found other populations both in Zimbabwe and Zaire with $2n = 8$. These and several more new counts of both tropical and southern African species shed new light on the cytology of *Lapeirousia* and show an unexpected frequency of B chromosomes in several species. We believe that B chromosomes are responsible for some of the apparent intraspecific chromosomal variability in base number reported in several species of the genus and uncertainty about the correct number in others (Goldblatt, 1972, 1990b). Consequently, we also review cytological patterns throughout the genus.

## MATERIAL AND METHODS

Seeds or corms of wild-collected species (Appendix) were sprouted in the greenhouse, and emer-

[1] Support for this study by grants BSR 8500148 and 8906300 from the U. S. National Science Foundation is gratefully acknowledged. We thank Jane Masterson and Hewson Swift, University of Chicago, for cytophotometric estimations of total DNA per genome in selected species.

gent leaf and root tips were harvested for analysis of mitosis in one of two ways. For rapid determination of chromosome number, root tips were pretreated in saturated aqueous m-bromonapthalene for 4 hours at room temperature, then fixed in 3:1 absolute ethanol-glacial acetic acid for 5 minutes. After hydrolysis in 10% HCl at 60°C for 6 minutes, tips were squashed in FLP orcein (Jackson, 1973). For more critical analysis, leaf and root tips were pretreated in 0.002 M aqueous 8-hydroxyquinoline for 4–5 hours at room temperature, then fixed in modified Carnoy's solution (absolute ethanol-glacial acetic acid-chloroform 6 : 3 : 1) at 8°C for about 24 hours. Both root and leaf tips were stained in Feulgen reagent and squashed in 1% aceto-orcein. Photographed preparations were all made using the latter technique. For purposes of comparison we included one species of *Watsonia*, which belongs to the same tribe Watsonieae as *Lapeirousia*, and *Pillansia templemanni*, only genus of Pillansieae, and outgroup to Watsonieae, in the study.

Comparative genome size (Table 1) was estimated by calculating total chromosome length in metaphase karyotypes of comparably condensed chromosomes, always treated in exactly the same manner. Since chromosomes are not always contracted to exactly the same degree, this method is not completely reliable. It is, however, sufficient to distinguish different ploidy levels. Accurate cytophotometric determinations made by Jane Masterson using *Nicotiana tabaccum* as a standard (Table 2) confirm our hypothesis that the $2n = 12$ cytotype of *Lapeirousia erythrantha* is polyploid, as are the karyotypes of *L. otaviensis* and *L. schimperi*.

## Observations

*Number and size.* Chromosomes of *Pillansia*, *Watsonia*, and *Lapeirousia* are moderate to small in size (Figs. 1–25), with either modest, or, in most species of *Lapeirousia*, with considerable range in number and size (Table 1). Total length variation across *Lapeirousia*, excluding B chromosomes, is 0.9–7.6 μm. In *Pillansia* and *Watsonia coccinea* chromosomes are comparable in size (Figs. 1, 2, 27A, B), but all fairly small, 0.7–4 μm long.

Chromosome number is consistently $2n = 20$ in *Lapeirousia* sect. *Fastigiata* (Table 1; Figs. 3, 4), but in the other section of subgenus *Paniculata*, sect. *Paniculata*, numerical range is extreme, with the highest number $2n = 16$ and the lowest $2n = 6$ (Table 1). In subgenus *Lapeirousia* diploid numbers of $2n = 18$ and 16 occur in section *Sophronia* (Table 1; Figs. 16–23) while all species of section *Lapeirousia* so far counted have $2n = 16$ (Figs. 19, 24, 25). With decrease in number there is an apparent gradual increase in size of one or more chromosome pairs (Table 1).

*Karyotypes.* Bimodal karyotypes characterize *Watsonia* and the majority of species of *Lapeirousia*, including all those of subgenus *Lapeirousia* and subgenus *Paniculata* sect. *Fastigiata*. Although four longer chromosome pairs also stand out in *Pillansia* (Fig. 1, 27A), size differences are too gradual for the karyotype to be characterized as strictly bimodal. In *Watsonia* (Figs. 2, 27B) there are two long chromosome pairs but always just one long pair in bimodal karyotypes in *Lapeirousia*. In *Lapeirousia* these long chromosomes are 4.1–6.5 μm long, and the remainder are generally 1–2 μm long, arbitrarily characterized here as small or medium (Table 1). We are uncertain of the reason for the variation in the length of the long pair among the species, although we believe that this pair is homologous across the genus because of its distinctive prophase morphology (see below). Differential contraction at metaphase due to preparation or enlargement of the chromosomes across the entire karyotype could explain the differences we have observed.

In species with bimodal karyotypes and $2n = 20$ (section *Fastigiata*) all 18 of the smaller chromosomes are small (less than 2 μm long according to our arbitrary criterion for categorizing the chromosomes by size). Bimodal karyotypes with $2n = 18$ (some species of section *Sophronia*) have two of the smaller chromosomes appreciably larger than the remainder, and these fall into our medium category. In bimodal karyotypes with $2n = 16$ (some species of section *Sophronia* and all species of section *Lapeirousia* examined) two pairs fall in our medium group.

In section *Paniculata* the typical bimodal karyotype with one long pair and many smaller ones occurs in *Lapeirousia avasmontana* ($2n = 16$), *L. gracilis* and *L. neglecta* (both $2n = 12$) and *L. sandersonii* ($2n = 10$) (Figs. 6, 7, 9). In *L. gracilis* two of the small chromosome pairs fall in our medium category. Bimodality is less pronounced in *L. setifolia*, *L. abyssinica*, and the $2n = 8$ karyotype of *L. erythrantha* (Figs. 10, 11). The karyotypes of *L. rivularis* and the $2n = 12$ cytotype of *L. erythrantha* show no bimodality (Figs. 12, 13). In *L. schimperi* and *L. otaviensis*, $2n = 10$, there is a secondary development of bimodality with a long metacentric pair 6.9–7.6 μm long, about one-third again as long as the next longest pair (Figs. 14, 15). In *L. schimperi* this

second pair has a prophase staining pattern that suggests homology with the long chromosome pair in the karyotypes of other species (Fig. 26). *Lapeirousia otaviensis* has two karyotypes among the plants we examined. In one, presumably the ancestral type, the chromosomes closely resemble those of *L. schimperi*, except that the second longest pair is metacentric, whereas in *L. schimperi* the shortest pair is submetacentric and second longest pair is acrocentric. Generally, only one satellite is visible, located on one of the two fourth longest chromosomes. The other karyotype in *L. otaviensis* is heterozygous for a translocation involving one of the second longest pair and one other chromosome. There is thus only one member of the second longest pair and only one very short, nearly telocentric chromosome. This karyotype also normally has only one satellite chromosome. Despite these irregularities, the similarity to the karyotype of *L. schimperi* is striking.

*Satellite position.* A pair of small satellites, located on the short arms of the longest pair of small chromosomes, are frequently present in species of *Lapeirousia* with bimodal karyotypes (Figs. 3–10, 16–21). Two pairs of satellites are present in *L. coerulea* ($2n = 8$) and the $2n = 8$ karyotype of *L. erythrantha* (Figs. 8, 11). In *L. dolomitica* subsp. *lewisiana* ($2n = 16$) one of the two pairs of satellites are very large (about as long as the long chromosome arms) and the short arms are minute; the second pair of satellites are also unusually large and slightly exceed the short chromosome arms in length (Fig. 25). In *L. azurea* ($2n = 20$), *L. silenoides* ($2n = 18$), *L. littoralis*, and *L. oreogena* (both $2n = 16$), all of which also have two pairs of satellites, both satellite chromosome pairs have short arms shorter than the satellites. The situation in *L. gracilis* is puzzling: two cytotypes (Figs. 5, 6) differing in satellite number and morphology are present in the same pop-

TABLE 1. Chromosome numbers, total chromosome length (diploid), and karyotype features in *Lapeirousia*. Counts obtained here (Appendix 1) are combined with those previously published (Goldblatt, 1971, 1972, 1990a). Species are arranged within sections according to karyotypic similarity. Abbreviations: L = Large (>4 μm), M = medium (2–4 μm), S = small (<2 μm), m = metacentric, sm = submetacentric, a = acrocentric, – = data not available. Total chromosome length was determined by linear measurement of photographed karyotypes, prepared in exactly the same manner. Data are not directly comparable with the measurements of Goldblatt (1990b) for the same species due to the different method of preparation. B chromosomes are not included in the measurements of total chromosome length or descriptive statistics.

[1] Reported as $2n = 20$ (Goldblatt, 1971, 1990a) but almost certainly $2n = 18 + 2B$—two very small chromosomes are probably B chromosomes.
[2] In light of two counts here of $2n = 18 + 0 - 2B$ for the species, we think the earlier report of $2n = 20$ (Goldblatt, 1990a) should correctly be $2n = 18 + 2B$.
[3] Earlier counts included $2n = 18$, ca. 20 and 18(–20)—these should probably correctly be $2n = 18 + 0 - 2B$.
[4] Two populations reported as having $2n = 18$ probably had $2n = 16 + 2B$.
[5] Earlier counts of $2n$ = ca. 18, 16–18 (Goldblatt, 1971, 1972) probably reflected uncertainty due to the irregular presence of B chromosomes; individuals counted here are from the same extended population as examined before.
[6] Originally reported as $2n$ = ca. 20 and $2n = 20$ (Goldblatt, 1971, 1990a), but we think probably correctly $2n = 16 + 0 - 6B$. Original counts included cells with as few as 16 and as many as 22 chromosomes.

TABLE 2. Genome sizes estimated for selected species of *Lapeirousia* following the classification of Goldblatt (1990). All C-values have been reduced to the 1C level. Measurements were made cytophotometrically by Jane Masterson with *Nicotiana tabaccum* as a standard; values represent the means of 10 measurements.

| Taxon | Mean 2C-value pg | Chromosome number $2n$ | Mean 1C-value pg |
|---|---|---|---|
| *L. erythrantha* | 2.7 | 8 | 1.35 |
| | 5.8 | 12 | 1.45 |
| *L. gracilis* | 2.4 | 12 | 1.20 |
| *L. otaviensis* | 5.09 | 10 | 1.27 |
| *L. schimperi* | 5.08 | 10 | 1.27 |

ulation. Some individuals have four satellites: one pair, on the second longest chromosome pair, are comparatively long, slightly exceeding the short arms in length; a third satellite on chromosome 3 is also fairly large; and a fourth satellite, extremely large, is located on one of the shortest chromosomes, the short arm of which is minute. Other individuals have small satellites on the second chromosome pair (the most common and presumably the basic condition in the genus).

*Prophase morphology.* In all karyotypes one long acrocentric chromosome pair, often the only long pair in the entire complement, has a distinctive prometaphase structure (Fig. 26). Largely heterochromatic and darkly stained, a small subterminal portion of the long arm is euchromatic. So distinctive is its appearance that we assume that this long chromosome pair is homologous across all the species so far examined and that it is maintained intact, whereas some (or possibly all) of the other chromosomes have been involved in structural rearrangements. The small chromosomes, found in the majority of species, are largely heterochromatic except for the distal ends of the longer arms, which are euchromatic and lightly stained until metaphase (Fig. 26). In *Lapeirousia schimperi* and *L. otaviensis* profound structural rearrangement of the karyotype makes identification of the conserved long chromosome pair of most other species difficult, but, at least in *L. schimperi*, the second longest pair seems homologous with the conserved long pair of most other species (Fig. 26F).

*Total chromosome length.* Irrespective of chromosome number, the majority of species of *Lapeirousia* examined have a total chromosome length in the 24–29 μm range (Table 1), which we assume is the diploid level for the genus. Total chromosome length is close to twice this amount in the $2n = 12$ cytotype of *L. erythrantha* (54.1 μm), but not in the $2n = 8$ cytotype of the species (24.5 μm) (Table 2). This doubling is also found in *L. rivularis* (47.2 μm), *L. schimperi* (47.1 μm), and *L. otaviensis* (47.8 μm). We assume this represents cryptic polyploidy (i.e., polyploidization either followed or preceded by descending dysploidy). Absolute DNA amount per genome (Table 2) is available for the two cytotypes of *L. erythrantha* and for *L. gracilis*, *L. otaviensis*, and *L. schimperi*. These determinations confirm the estimates based on total chromosome length. *Lapeirousia otaviensis*, *L. schimperi*, and $2n = 12$ *L. erythrantha* have 5.1–5.8 pg DNA per genome, whereas *L. gracilis* and $2n = 8$ *L. erythrantha* have 2.7–2.8 pg per genome.

Total chromosome length falls some 20–40% above the expected diploid level (Table 1) in a few species (*L. corymbosa*, *L. azurea*, *L. littoralis*, *L. dolomitica*), but we doubt that these species are polyploid because they have karyotypes nearly identical with obviously diploid species. Some other phenomenon must be involved in the increase in total chromosome length in these examples, which seems beyond what might be considered experimental error. *Pillansia templemanii* is obviously tetraploid. Our counts confirm tetraploidy already reported in two other populations (Goldblatt, 1971, 1977) of this fairly narrowly distributed species.

*B chromosomes.* A significant part of the karyotypes of some species, B chromosomes are identified in *Lapeirousia* by precocious and uniform dark staining at prophase. They vary considerably in size, being nearly as long as the long chromosomes in *L. oreogena* (Fig. 22), but more commonly they are about as long as the small chromosomes. All three populations of *L. silenoides* now known cytologically appear to have B chromosomes (Fig. 17), which are also fairly common in the $2n = 12$ cytotype of *L. erythrantha*. We detect no particular geographic or ecological pattern to the distribution of B chromosomes in the genus but note that B chromosomes have so far been identified only in species with higher diploid numbers. Because of their frequency, we have concluded that some past counts in the genus, inconsistent with our current findings, are due to the unrecognized presence of B chromosomes. The presumed correct chromosome numbers are included in Table 1 with footnotes explaining our reasons for assuming past errors.

## DISCUSSION

Based both on outgroup comparison, and on the more common trends in numerical change in chromosome number of plants (Jones, 1974, 1977) we infer that the ancestral base number in *Lapeirousia* is most likely $x = 10$. *Lapeirousia* is currently regarded as a member of tribe Watsonieae (subfamily Ixioideae) (Goldblatt, 1989, 1990c, 1991) in which other base numbers are $2n = 20$ (*Thereianthus*, *Micranthus*), 18 (*Watsonia*), and 16 (*Savannosiphon*) (Goldblatt & Marais, 1979; Goldblatt, 1989). *Pillansia*, only genus of Pillansieae, most primitive of the three tribes of Ixioideae, also has $x = 10$ ($2n = 40$) (Goldblatt, 1977), an observation confirmed here for two additional populations of the species. Moderately bimodal karyotypes characterize both *Micranthus* and *Watsonia* (Goldblatt, 1971). The karyotype of *Lapeirousia* differs from that of *Micranthus* largely in its more pronounced bimodality, but the patterns seem comparable. In *Watsonia*, with $2n = 18$, there are two long and seven short chromosome pairs.

Within *Lapeirousia* differences in number and karyotype seem best explained by reduction in number, accomplished by fusion and elimination of redundant centromeres (i.e., unequal reciprocal or Robertsonian translocation, see Jones, 1974,

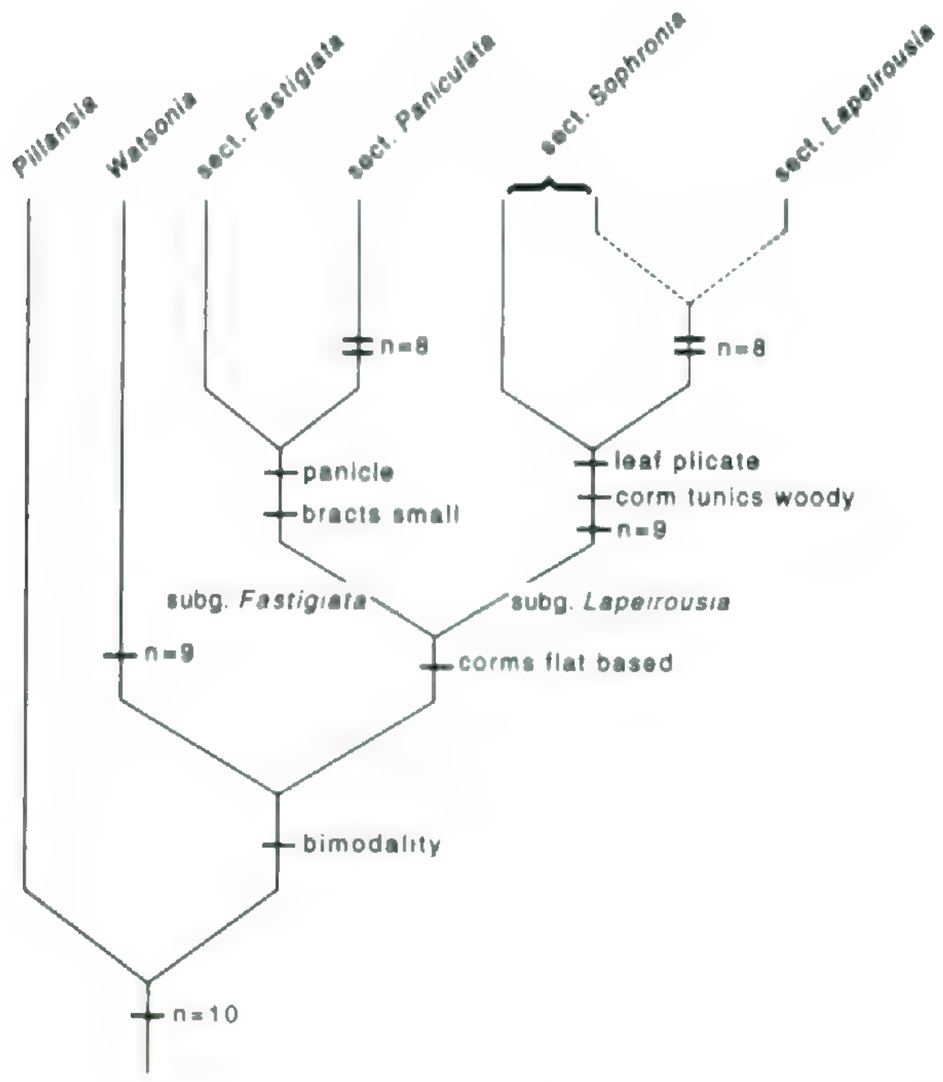

FIGURE 28. Diagram of relationships of *Lapeirousia* and its subgenera and sections, including outgroups *Watsonia* and *Pillansia*, with chromosomal data superimposed on a topology established by Goldblatt and Manning (1990). Although both *Watsonia* and *Lapeirousia* sect. *Lapeirousia* have $n = 9$, they are not homologous characters: the karyotypes indicate independent derivation in each lineage.

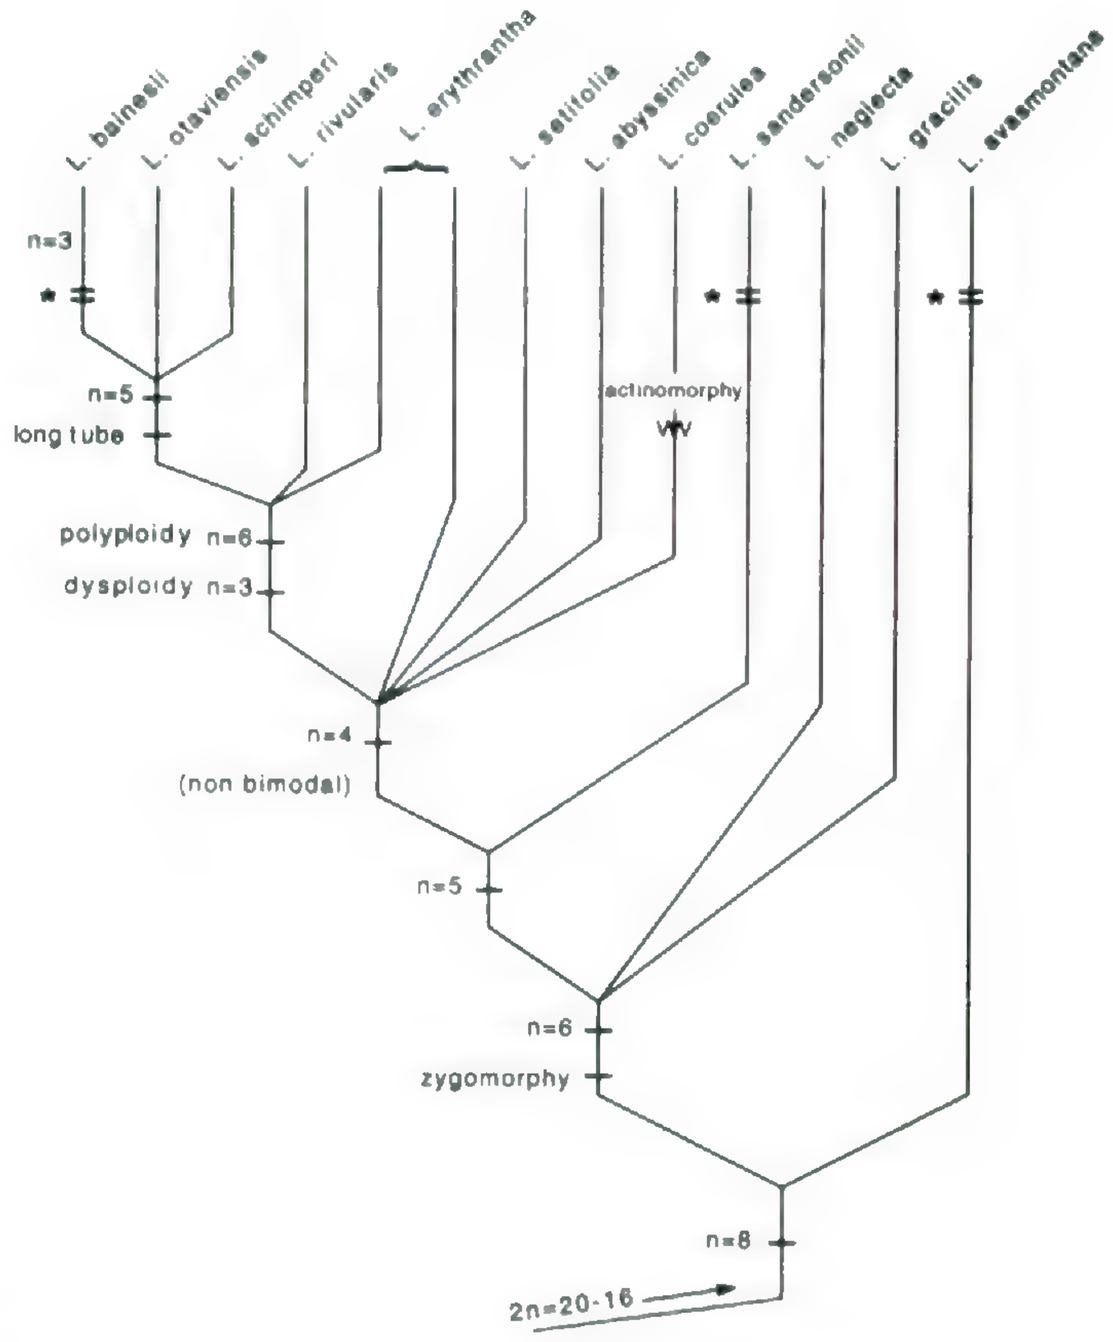

FIGURE 29. Diagram of inferred relationships in *Lapeirousia* sect. *Paniculata*. The tree is based largely on chromosomal characters, but includes apomorphic morphological characters established by Goldblatt (1990a).

1977). This hypothesis is also supported by the observed increase in size of one chromosome pair as number decreases (Table 1).

The infrageneric phylogeny established by Goldblatt and Manning (1990) for *Lapeirousia* makes it clear that decrease in number has occurred in subgenera *Paniculata* and *Lapeirousia* independently (Fig. 28). All species of subgenus *Lapeirousia* have numbers based on $x = 9$ or 8, and the only counts so far obtained for section *Lapeirousia*, excluding B chromosomes, are $2n = 16$, a number also present in some species of section *Sophronia*. It is uncertain at present whether $n = 8$ was achieved more than once in subgenus *Lapeirousia*. Chromosomal data suggest that section *Sophronia* may be paraphyletic with section *Lapeirousia* nested within it. This question awaits further investigation.

In subgenus *Fastigiata*, section *Fastigiata* consistently has $2n = 20$, but the lowest number in section *Paniculata* is $2n = 16$, in *L. avasmontana*, one of two species in the section with actinomorphic flowers (Fig. 29). Among the remaining species of the section relationships are obscure except for a small clade of species with pale-colored flowers with long perianth tubes (*L. schimperi*, *L. otaviensis*, and *L. bainesii*). Phylogeny of the section must therefore be largely inferred from the karyology. Decrease in number appears to have proceeded stepwise with one or more species at each step (Fig. 29), with a plateau at $2n = 8$, where the central species is *L. erythrantha* (previously thought to have exclusively $2n = 12$). *Lapeirousia coerulea*, which also has $2n = 8$, has actinomorphic flowers, almost certainly a reversal, given its nested position within a clade of largely zygomorphic-flowered species.

The situation in *Lapeirousia erythrantha*, with populations having either $2n = 8$ or 12, is particularly interesting. Past counts for the species have consistently been $2n = 12$ (Goldblatt, 1990b), and we have confirmed this count in two additional populations. The $2n = 12$ cytotype is the more widespread, occurring exclusively in Malawi and Zambia, and also in some Zimbabwean populations, but populations with $2n = 8$ are scattered across Zimbabwe and Zaire (Fig. 30). On the basis of total chromosome length, *L. erythrantha*, then only known from its $2n = 12$ cytotype, was assumed to be polyploid, as was *L. rivularis*. We now modify this assumption. Ancestral base number in *L. erythrantha* is most likely $x = 4$, the base number also in the morphologically similar, and presumably closely related, *L. setifolia* and *L. abyssinica* (Goldblatt, 1990b). The $2n = 8$ karyotype of *L. erythrantha* has been confirmed to be diploid, and

the $2n = 12$ karyotype tetraploid by measurement of total DNA genome.

The diploid number of $2n = 12$ may have been achieved by one of two possible paths. Dysploid reduction from $n = 4$ to 3 by Robertsonian translocation followed by tetraploidization to $n = 6$ is one scenario. Alternatively, a polyploid event resulting in tetraploidy, $2n\,(4x) = 16$, and subsequent dysploid reduction to $2n\ (4x) = 12$, may have occurred. We favor the former hypothesis because it involves only two major chromosomal mutations, whereas the second involves three. In *L. erythrantha* polyploidy and subsequent dispersal of the $2n = 12$ cytotype through Zambia, Malawi, and northern Zimbabwe is our best explanation for the cytological pattern now evident in *L. erythrantha*. There seems to be no doubt that the two cytotypes of *L. erythrantha* are conspecific. Except for a slightly more slender growth habit in some of the $2n = 8$ cytotypes, there is nothing we can detect in their morphology to distinguish the cytotype in this common and widespread species.

In *Lapeirousia rivularis*, a similar karyotype, although not identical to the $2n = 12$ cytotype of *L. erythrantha*, is also evidently cryptically polyploid. The origin of this karyotype is uncertain, but it seems to us more parsimonious to assume a derivation from the $2n = 12$ karyotype of *L. erythrantha*. This presumes also the derivation of a species, *L. rivularis*, from a cytotype of *L. erythrantha*. Alternatively, *L. rivularis* may have arisen from other ancestors presumably with $x = 4$ (or 3), with subsequent polyploidization so that the karyotype now resembles that of the $2n = 12$ cytotype of *L. erythrantha*.

Our results indicate that *Lapeirousia schimperi*, *L. otaviensis*, and presumably the related *L. bainesii*, which form a clade (Goldblatt, 1990a) distinguished by their long- to very long-tubed flowers, are also polyploid (Tables 1, 2). We cannot say whether they are more likely to be derived from *L. erythrantha* or to have another ancestry, but parsimony is followed in Figure 29, in the tree generated by combining cytology and morphology of the lineage.

Continuing studies will eventually yield more light on the question of phylogeny of *Lapeirousia*. It is, however, clear that the karyological history of the genus is remarkably complex and has probably involved primary dysploidy in at least two lineages, from $x = 10$ to 8 in subgenus *Lapeirousia*, and from $x = 10$ to 4 in section *Paniculata*. A secondary burst of polyploidy is evident in section *Paniculata*, and secondary descending dysploidy appears to have occurred in *L. erythrantha* (and its close ally *L. rivularis*) and perhaps independently in the clade that includes *L. schimperi*, *L. otaveinsis*, and *L. bainesii*, the latter having populations with $n = 6$.

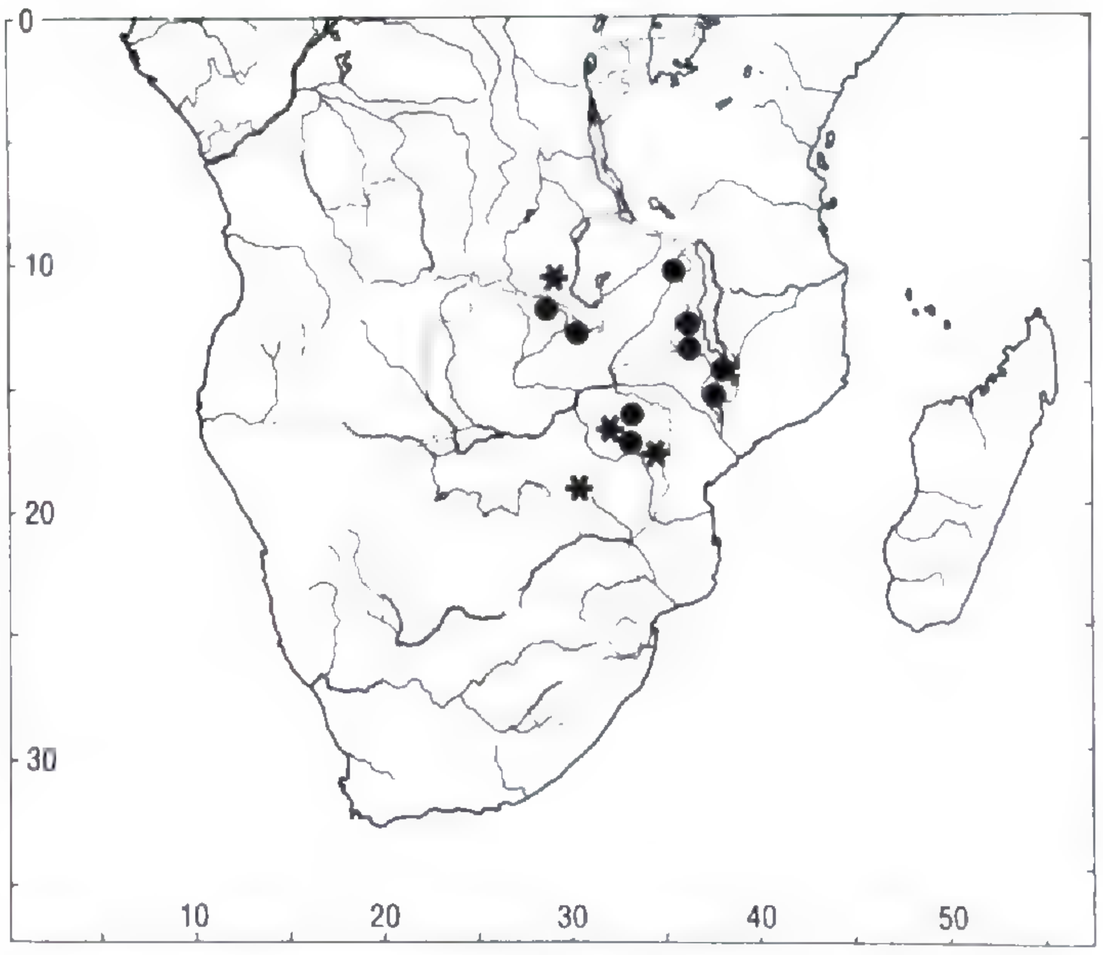

FIGURE 30. Cytogeography of *Lapeirousia erythrantha*. Populations with $2n = 8$ represented by stars; populations with $2n = 12$ by solid circles.

# CHROMOSOME NUMBERS OF NEOTROPICAL *CASTILLEJA* (SCROPHULARIACEAE: TRIBE PEDICULAREAE) AND THEIR TAXONOMIC IMPLICATIONS[1]

*T. I. Chuang*[2] *and L. R. Heckard*†[3]

## ABSTRACT

Meiotic chromosome numbers in *Castilleja* are reported for 105 collections representing 34 species, mostly from Mexico, with a few from Central America and South America. Chromosome numbers of the following 19 species are reported here for the first time: *C. bryantii*, *C. ecuadorensis*, *C. fissifolia*, *C. fruticosa*, *C. gracilis*, *C. hirsuta*, *C. integrifolia*, *C. irazuensis*, *C. linifolia*, *C. nubigena*, *C. ornata*, *C. ortegae*, *C. purpusii*, *C. roei*, *C. scorzonerifolia*, *C. stenophylla*, *C. talamancensis*, *C. tenuifolia*, and *C. virgata*. Of the 34 species, 24 are exclusively diploid ($n$ = 12); five are tetraploid ($n$ = 24) only; two are octoploid ($n$ = 48) only; three have two or more levels of ploidy ($n$ = 12, 24, and 72). These polyploid species (including *C. aspera*, *C. integrifolia*, and *C. tenuiflora*) are the most troublesome taxonomically and substantiate our contention that polyploidy and hybridization are largely responsible for the complex morphological variation found in *Castilleja*. It is estimated that only 25% of Mexican elements of *Castilleja* (excluding *C. affinis* and *C. subinclusa*) exhibit polyploidy, in contrast to more than 50% polyploidy in western North American representatives. The unusual chromosome number of $n$ = 10 in the closely related *C. gracilis* and *C. tenuifolia* is postulated to be an aneuploid reduction from an $n$ = 12 progenitor. The role of chromosome number, especially polyploidy, in the evolution of *Castilleja* and its taxonomic significance is indicated for individual species.

This paper represents the fourth in a series of reports on chromosome numbers in *Castilleja* (Scrophulariaceae) and is part of our continuing effort to furnish evidence of the significance of polyploidy and accompanying hybridization in forming the complex patterns of variation that characterize the genus. It is also our intention to clarify taxonomic and evolutionary relationships among its members. Our emphasis in this report is on those species occurring in Mexico, Central America, and South America.

*Castilleja* (Indian Paintbrush) comprises over 200 perennial and annual hemiparasitic species. They are almost all American with their heaviest concentration in western North America, where they have been a continual source of extreme taxonomic difficulty, perhaps due partly to the prevalence of weak barriers to natural hybridization and associated polyploidy. Asa Gray's (1862) comment remains discouragingly prophetic: "The species of this genus are most troublesome and unsatisfactory, not only on account of the difficulty of investigating the dried specimens, but also from the variability of the characters which have been relied upon in arranging them, and especially of the calyx."

Heckard (1968) reported chromosome numbers of 54 taxa in *Castilleja*, largely of the Pacific Coast states and Mexico. Heckard & Chuang (1977) reported chromosome numbers of 35 taxa from the Great Basin and Rocky Mountains, and Chuang & Heckard (1982) reported 13 taxa of annual *Orthocarpus* (sects. *Castillejoides* and *Cordylanthoides*) mainly from California, which have recently been merged into *Castilleja* subg. *Colacus* sect. *Oncorhynchus* (Chuang & Heckard, 1991). Our continuing survey of chromosome numbers in the genus in western North America (Heckard,

[1] We are deeply grateful to Robert W. Cruden in particular, and Dennis E. Breedlove, Robert Bye, Annetta Carter, Lauramay T. Dempster, Noel H. Holmgren, and Reid Moran, who kindly collected cytological material for this investigation. We also express our sincere appreciation to Lincoln Constance and Paul Silva for critical reading of the manuscript and helpful suggestions, to Fei Mei Chuang for skillful technical assistance, and to Guy L. Nesom for a loan of 21 specimens of Mexican *Castilleja* (TX).

[2] Department of Biological Sciences, Illinois State University, Normal, Illinois 61761, U.S.A.

[3] Jepson Herbarium, University of California, Berkeley, California 94720, U.S.A.

1968; Heckard & Chuang, 1977; Chuang & Heckard, 1982; Chuang & Heckard, unpublished data) has shown that more than half of the 100 species counted are polyploid or have a diploid level plus one or more polyploid levels. For example, one species complex, *Castilleja affinis-litoralis*, has a diploid plus five levels of polyploidy from 4*x* to 12*x*. The widespread *C. miniata* of the western United States and Canada has a diploid and four additional levels of polyploidy from 4*x* to 10*x*.

*Castilleja* is represented in Mexico by approximately 55 species, Central America by 9 species, and South America by 12 species, mostly in the Andes. Judging from its richness in species, mainland Mexico, especially the Sierra Madre Occidental, is one of the major centers of diversity for the genus, second only to the western United States. Mexican and Central American *Castilleja* was last treated monographically by Eastwood (1909), who recognized 54 species, 17 of which were described as new. Although her classification is used as a basis for our review and presentation of chromosome numbers, it is evident that there is need for an updated treatment of Mexican *Castilleja* based on the abundant recent collections in the major herbaria in Mexico and the United States, field observation, cytological investigation, and SEM studies of seeds and trichomes. Subsequently, many new species of Mexican, Central American, and South American *Castilleja* were proposed by various authors. Brandegee (1914) described one from Chiapas, Mexico; Standley, three from mainland Mexico (1936, 1940), one from Costa Rica (1938); Standley & Steyermark (1944), one from Guatemala; Pennell, four from Panama (1940), three from Venezuela (1953); Edwin (1970), four from Peru; Crosswhite (1970) and Rzedowski (1975), one each from mainland Mexico; Holmgren, four from Mexico (1976), four from Costa Rica and Panama (1978), and one from Ecuador (Holmgren & Molau, 1984); Moran (1969, Levin & Moran, 1989), two from islands off Baja California; Breedlove & Heckard (1970), one from Sinaloa, Mexico, originally described as the monotypic genus *Gentrya*, which has recently been relegated to subgeneric status in *Castilleja* (Chuang & Heckard, 1991). Most recently, an additional four species were described from mainland Mexico by Nesom (1992b) and another four from Peru by Chuang & Heckard (1992a), the latter included in our newly proposed bee-pollinated subgenus *Colacus*.

There are only a few reports of chromosome numbers of Mexican *Castilleja*, consisting of scattered data on individual species (Beaman et al., 1962; Ward, 1983, 1984; Ward & Spellenberg, 1986) and four of our unpublished counts indicated on herbarium labels, which were listed in Holmgren's (1976, 1978) and Holmgren & Molau's (1984) publications.

## Materials and Methods

Cytological materials were obtained from the wild by various collectors (see Table 1), and fixed in Farmer's solution (3 anhydrous ethanol: 1 glacial acetic acid, v/v). Fixed flower buds were immediately cooled on ice in the field and stored under refrigeration in the laboratory. All counts were made from aceto-carmine squashes of pollen mother cells and observed with a Zeiss phase contrast microscope. Chromosome drawings were made by camera lucida at magnifications of ×2100 and ×2600.

## Results and Discussion

In this contribution we present meiotic chromosome counts of 105 collections, representing 34 species in *Castilleja* from Mexico, Central America, and South America of which 19 species are reported here for the first time. Among the 34 species represented, 24 are exclusively diploid ($n = 12$) and the remaining ten exhibit polyploidy: five (*C. affinis*, *C. integra*, *C. lithospermoides*, *C. ornata*, and *C. subinclusa*) are tetraploid ($n = 24$) only; two (*C. linifolia* and *C. purpusii*) are octoploid ($n = 48$) only; and three (*C. aspera*, *C. integrifolia*, and *C. tenuiflora*) have two or more levels of ploidy ($n = 12$, 24, and 72). The last three polyploid species are the most troublesome taxonomically and substantiate our contention that polyploidy and hybridization are largely responsible for the complex morphological variation found in *Castilleja*. It is estimated that only 25% of Mexican elements of the genus (excluding *C. affinis* and *C. subinclusa*, which are undoubtedly Californian elements) are polyploid, in contrast to more than 50% of western North American representatives. Many more complex species are found in the western United States, where the genus appears to be undergoing an accelerated phase of evolution.

The chromosome number of $n = 10$ is found in two closely related Mexican species, *C. gracilis* and *C. tenuifolia*, in sect. *Epichroma* Benth. (subg. *Castilleja*), although the same number was reported in *C. lineariloba* (Benth.) Chuang & Heckard (Chuang & Heckard, 1982, published as *Orthocarpus linearilobus* Benth.), which has recently been included in subgenus *Colacus* sect. *Oncorhynchus* (Chuang & Heckard, 1991). It is pos-

TABLE 1. Chromosome numbers of neotropical *Castilleja*. Voucher specimens are deposited in the Jepson Herbarium (JEPS) and the University of California Herbarium (UC), both at Berkeley, except where otherwise indicated. First reports for species are in boldface.

tulated that $n = 10$ may be derived from an aneuploid reduction from $n = 12$ progenitors, and is apparently of independent origin in these two subgenera.

Knowledge of basic chromosome number and range of polyploidy has helped in understanding the causes of taxonomic complexity in this genus. Nonetheless, this information alone does not provide sufficient evidence for making taxonomic judgments at the subgeneric, sectional, and specific levels, because of chromosomal constancy at the

diploid level (except $n = 10$ in the three species mentioned above) and abundant intraspecific polyploidy. We believe that extensive field observation of variation patterns and additional SEM studies of seeds and trichomes remain the best source of evidence for such taxonomic decisions. Overemphasis of minor morphological variation, especially in complex polyploid species, may lead to unwieldy and impractical classification in *Castilleja*.

The annotated list of chromosome numbers including locality and voucher citation is shown in Table 1. When pertinent, we comment on the relationship of chromosome number and hybridization to the evolution and systematics of the genus.

**Castilleja affinis** Hook. & Arn.

*Castilleja affinis* is a widespread polymorphic species, ranging from coastal northern Oregon south to northern Baja California. This is a highly unwieldy complex with six ploidy levels, $n = 12$ to 72 (Heckard, 1968; Chuang & Heckard, unpublished data). This species has been treated recently by Chuang & Heckard (1992b) as comprising three subspecies, namely, subsp. *affinis*, subsp. *neglecta*, and subsp. *litoralis*. Some populations appear to intergrade to such an extent with abutting *C. applegatei* subsp. *pinetorum*, *C. mollis*, *C. subinclusa*, and *C. wightii* that it is difficult to separate them taxonomically. All three counts from Baja California are tetraploid ($n = 24$); this same number is also fairly widely distributed northward to coastal and Sierra Nevada foothill areas of central California (Heckard, 1968; Chuang & Heckard, unpublished data). Undoubtedly, hybridization and polyploidy have played important roles in creating taxonomic perplexity in this species complex. We suspect that the varying combinations of ploidy levels have evolved to ensure that sympatric populations will have different chromosome numbers and thus be able to coexist without freely hybridizing.

**Castilleja arvensis** Schltdl. & Cham.

This annual *Castilleja* is the most widespread species in the genus, extending from central and northeastern Mexico, south to Central America, and nearly through South America. Our count of $n = 12$ agrees with previous reports (Heckard, 1968; Spellenberg, 1986).

**Castilleja aspera** Eastwood

This species of Chihuahua and Durango is variable with regard to herbage and galea indumentum and leaf shape, but is generally recognizable by the shallowly cleft lateral calyx lobes with acute segments. The chromosome numbers of $n = 12$ and 24 have been reported from Durango (Heckard, 1968). We report two additional counts of $n = 12$ from Chihuahua and Durango. Nesom (1992b) described *C. durangensis* based on Cruden's collection (*Cruden 1160*, holotype, TEX; isotypes, GH, UC; reported as *C. aspera*, $n = 12$ by Heckard, 1968) from about 5 km northeast of El Salto, Durango. We regard these as minor morphological differences of little taxonomic significance at the specific level. The plants may be forms intermediate between *C. aspera* and *C. scorzonerifolia*; nevertheless, this morphological variation deserves further critical study in the field.

**Castilleja bryantii** Brandegee

This species, endemic to Baja California and extending from the vicinity of San Ignacio to the Cape Region, is reported here for the first time as $n = 12$. *Castilleja socorrensis*, a species closely related to *C. bryantii* and endemic to Isla Socorro, was recently proposed by Moran (Levin & Moran, 1989) and was said to differ from the latter mainly by its smaller flowers. Whether these two should be regarded as separate species must await further study.

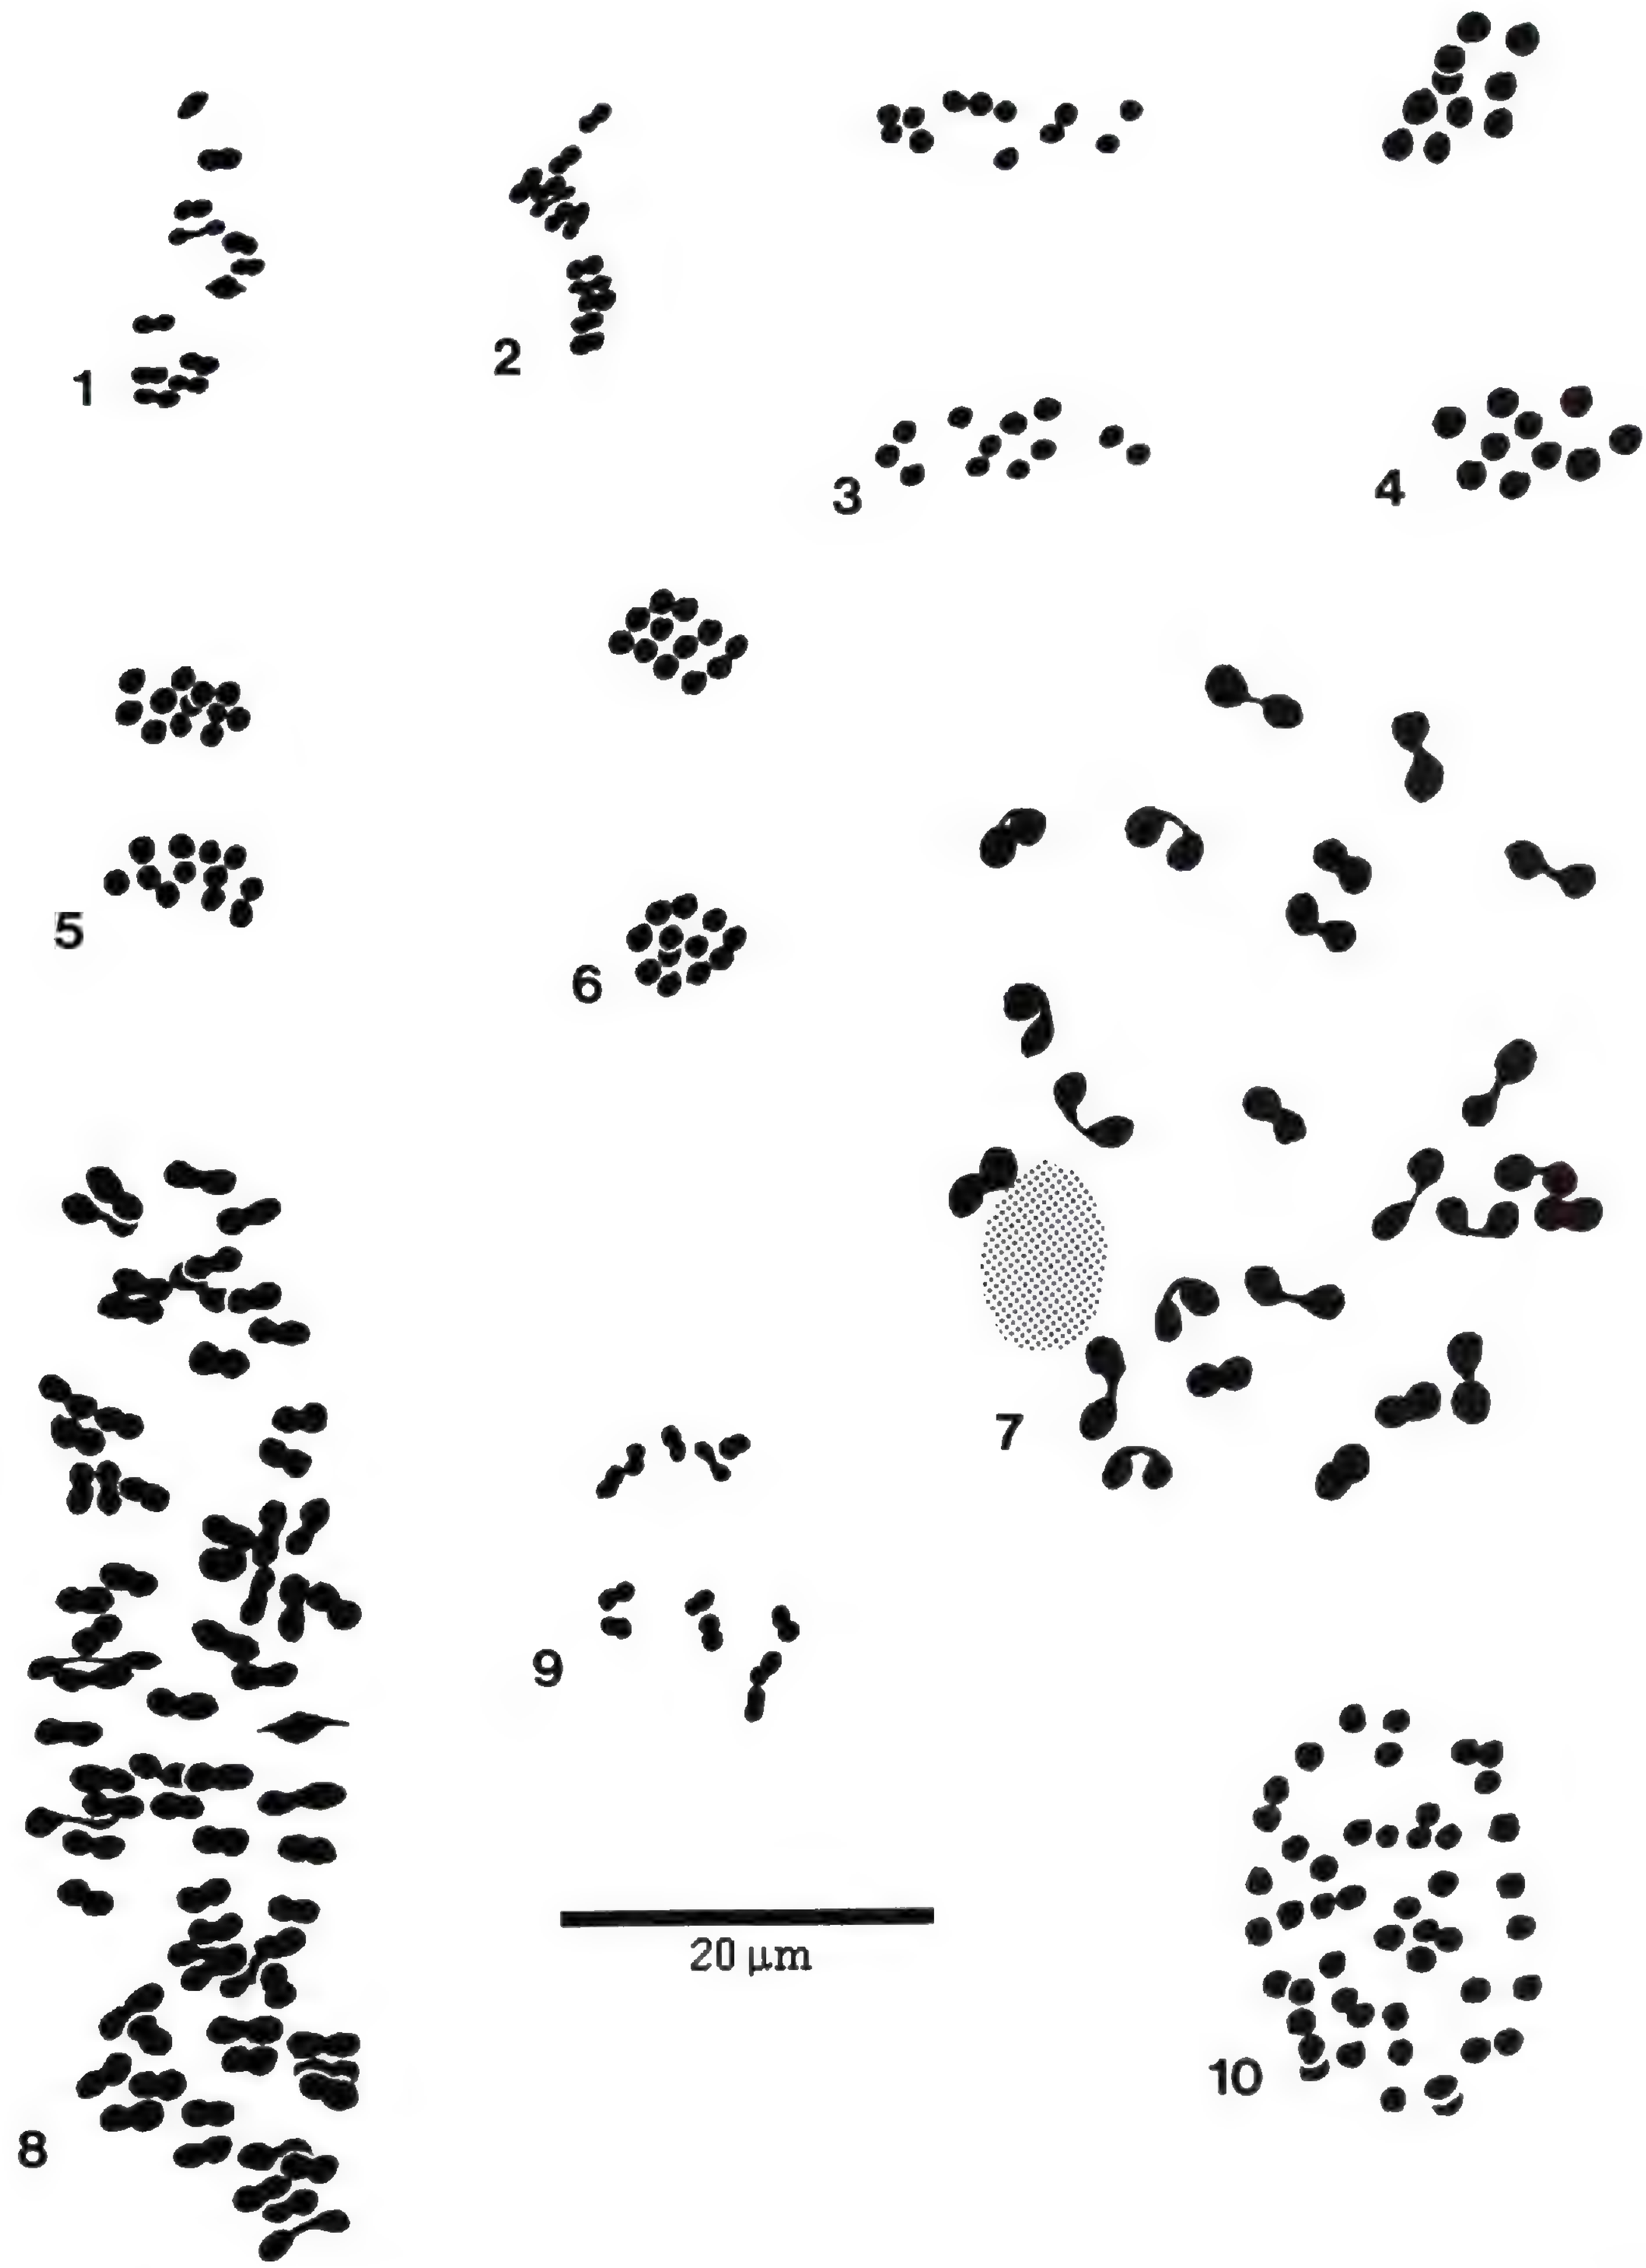
**Castilleja ecuadorensis** N. Holmgren

This species, endemic to Ecuador, is perhaps a close relative of the highly variable *C. fissifolia*. The count of $n = 12$ represents the first report for this species.

**Castilleja fissifolia** L. f.

*Castilleja fissifolia*, the lectotype species of the genus, appears to be an exceptionally polymorphic species with regard to habit and leaf division, and many forms have been accorded separate specific rank. Based on his own observations, Weddell (1857) concluded that intergradations occur between different growth forms, as well as different developmental forms of calyx, corolla, and leaves, and treated these as varieties of a single species, including even *C. integrifolia*. Melchior (1931) followed this disposition, but raised Weddell's varieties of *C. fissifolia* to subspecific level. This species complex awaits a comprehensive investigation over its entire range of distribution to determine whether these morphological forms deserve taxonomic recognition and at what rank.

Our count of $n = 12$ from Ecuador (three populations) represents the first number reported for



FIGURES 1–10. Meiotic chromosome figures of first counts of Mexican, Central American *Castilleja*. The stage of meiosis for each phase is indicated as: Diak., diakinesis; MI, metaphase I; TI, telophase I; TII, telophase II. —1. *C. bryantii*, $n = 12$, MI (*Heckard 3250*). 2. *C. ecuadorensis*, $n = 12$, MI (*Holmgren 10170*).—3. *C. fissifolia*, $n = 12$, TI (*Holmgren 10105*).—4. *C. gracilis*, $n = 10$, TI (*Cruden 1973*). —5. *C. hirsuta*, $n = 12$, TI (*Cruden 1709*).—6. *C. integrifolia*, $n = 12$, 1/2 portion of TII (*Cruden 1552*).—7. *C. integrifolia*, $n = 24$, Diak. (*Cruden 1352*).—8. *C. integrifolia*, $n = 72$, MI (*Cruden 1635*).—9. *C. irazuensis*, $n = 12$, Diak. (*Heckard 6219*).—10. *C. linifolia*, $n = 48$, 1/2 portion of TI (*Breedlove 18747*).

this species, although our unpublished number was listed in Holmgren & Molau's (1984) treatment of Ecuadorian Scrophulariaceae.

**Castilleja foliolosa** Hook. & Arn.

This species, one of the most distinct in cismontane California and northern Baja California, is easily separable by its herbage densely covered with white-woolly branched hairs, undivided lateral calyx lobes, and tight-fitting seed coat. This count of $n = 12$ from northern Baja California agrees with a previous report (Heckard, 1968). The total of seven populations sampled thus far has given only diploid counts.

**Castilleja fruticosa** Moran

*Castilleja fruticosa* is endemic to the southern end of Guadalupe Island, Mexico, and is a close relative of the little known *C. guadalupensis* Brandegee, another endemic to Guadalupe Island, but occurring in a different habitat on the higher and much moister northern part of the island. Moran (1969) pointed out, "It (*C. guadalupensis*) has not been collected since 1898 and evidently is now very rare if not extinct." This species is distinguished from *C. guadalupensis* by its herbage and bracts covered with glandular hairs intermixed with pilose, longer nonglandular hairs, in contrast to the densely and closely tomentose dendritic hairs of the latter. Our count of $n = 12$ is the first number reported for this species.

**Castilleja gracilis** Benth.

The count of $n = 10$ represents the first report for this species, although Holmgren (1976) indicated our unpublished count on the herbarium label. This species is closely related to *C. tenuifolia*, which has the same chromosome number of $n = 10$, but has a larger stature, a longer corolla, and a much more colorful calyx. *Castilleja venusta* Rzedowski (1975), described from Cerro Teotepec, Guerrero, Mexico, resembles *C. gracilis* in vegetative morphology. However, a careful study of an isotype of *C. venusta* (*Rzedowski 18150*, MICH) reveals that it has distinct floral features in its well developed 3-lobed lower corolla lip and truncate calyx lobes. It would be interesting to see whether *C. venusta* also has the same chromosome number of $n = 10$ as found in *C. gracilis* and *C. tenuifolia*.

**Castilleja hirsuta** Martens & Galeotti

Chromosome counts of $n = 12$ were determined from two populations, both from Veracruz, and represent the first reports for this species. This species occurs in Morelos, Hidalgo, and Veracruz and is distinguishable by its entire calyx lobes, which are dilated distally and colored deep-red down to a near-ovary position. Bentham (1846) treated this species in sect. *Epichroma* Benth. on the basis of the somewhat enlarged calyx-limb. We would agree with Eastwood (1909) in including it in sect. *Euchroma* (Nutt.) Benth. because of the spicate inflorescence, entire and nearly orbicular to oblong-lanceolate leaves, and a calyx subequally cleft in front and in back. It is perhaps related to *C. scorzonerifolia*, but this possibility needs further study.

**Castilleja integra** A. Gray

This fairly well defined species is widespread from northern Mexico (Nuevo León, Coahuila, Durango, Chihuahua, and Sonora) north to the southeastern and southwestern United States. It is one of the Mexican elements of *Castilleja* that extends north to the adjacent regions in the United States. This species is closely related to *C. purpurea* and the newly described *C. genevievana* (Nesom, 1992a), but is distinguished by its entire leaves and mostly orange-red to scarlet inflorescence. Because of its intermediate morphology and range of distribution between *C. integra* and *C. purpurea*, *C. genevievana* may represent a form intermediate between the two.

Two chromosome levels ($n = 12$ and 24) were previously reported for 15 populations from our samples (Heckard, 1968; Heckard & Chuang, 1977) and two collections by Ward (1983, 1984). No cytogeographic pattern is apparent in the distribution of the two cytotypes in the United States. The count of $n = 24$ here represents the first count for this species from Mexico. More sampling throughout the range of the species, particularly from Mexico, is needed to establish its cytogeographic patterns.

**Castilleja integrifolia** L. f.

This species is characterized by its racemose inflorescence, entire leaves, entire floral bracts, and conspicuously falcately spreading flowers, which turn black in drying. It is one of the most widely ranging species in the genus, extending from Colombia north to Central America and southern Mexico. It is highly variable with respect to habit, indumentum, leaf shape and size, and color of bracts and flowers; a few morphological variants have been accorded rank as separate species. It

was relegated to infraspecific rank under *C. fissifolia* by Weddell (1857) and Melchior (1931).

This is one of the few polyploid complexes heretofore found in Mexico, as evident in the newly reported counts of $n = 12$, 24, and 72 for this species. Among the nine chromosome counts obtained thus far, the number $n = 12$ is found in three populations from Chiapas, Mexico; $n = 72$ from two populations in Guerrero, Mexico; and $n = 24$ from four populations in Guatemala. Many more population samplings are needed to establish its cytogeographic patterns. The presence of four levels of chromosome number ($n = 12$, 24, and 72, including $n = 48$ for *C. linifolia*), as well as possible hybridization with the related *C. tenuiflora* and others, are responsible for a large part of the complexity of this species.

The diploid Breedlove collection from a marshy area at the southern end of the valley of San Cristóbal in Chiapas deserves comment. It appears to be an extreme form of *C. integrifolia* in having sparsely puberulent herbage, linear leaves, and narrow flowers. It is also very similar to *C. linifolia* in sharing such features as a racemose inflorescence and linear leaves.

**Castilleja irazuensis** Oersted

This species is narrowly endemic to the summits of the two high volcanoes, Volcán Irazú and Volcán Turrialba, Costa Rica. According to Holmgren (1978), *C. irazuensis* is closely related to *C. talamancensis*, which is endemic to the Cordillera de Talamanca in southern Costa Rica. This report of $n = 12$ represents the first count for this species.

**Castilleja jiquilpana** Nesom

This newly described species (Nesom, 1992b) is endemic to the vicinity of Jiquilpan, and is undoubtedly a close relative of the highly polymorphic *C. scorzonerifolia*. It may be distinguished with some difficulty by its deeply divided leaves with linear lobes and smaller (1 mm long), ovoid-deltoid seeds with a fairly deep-netted seed coat.

This count of $n = 12$ agrees with a previous count from a collection made by Cruden (*Cruden 1149*, ca. 22 km W of Jiquilpan, UC) and published as *C. glandulosa* (Heckard, 1968).

**Castilleja lanata** A. Gray

The count of $n = 12$ from three collections agrees with the one previously reported for this species from New Mexico (Ward, 1983). This species is widespread from northern Mexico (including northern Baja California) and western Texas to southern Arizona, and the northern Channel Islands of California. This is one of the Mexican elements of *Castilleja*, extending north to the southern United States. *Castilleja lanata*, *C. hololeuca* (relegated to subspecific status, Chuang & Heckard, 1992b), together with *C. foliosa* and *C. grisea*, have been included in sect. *Lanatae* (Pennell, 1951) because of their grayish or white-tomentose herbage, branched hairs, and calyx lobes that are rounded or wholly united laterally. This species differs from the closely related *C. foliolosa* and *C. grisea* by its white-woolly felt of long interwoven, slightly branched hairs and entire leaves.

**Castilleja linifolia** N. Holmgren

The count of $n = 48$ (octoploid) from three collections represents the first chromosome number reported for this species, although Holmgren (1976) included this number (in *Cruden 2000* and *Breedlove 18747*) in his original description from our unpublished counts on the herbarium labels. This species is known only from southern Durango and adjacent Sinaloa, and appears to be related to a highly variable polyploid species, *C. integrifolia*, except that the former has glabrous to sparsely pilose herbage, and entire, linear-filiform leaves. It is probable that this octoploid ($n = 48$) is a part of the *C. integrifolia* complex, of which three chromosome levels ($n = 12$, 24, and 72) have thus far been revealed.

**Castilleja lithospermoides** Kunth

The count of $n = 24$ from three populations reported here agrees with a previous report (Heckard, 1968). The identification of these collections appears questionable. Nevertheless, all of them match well a specimen cited by Eastwood (1909) as *C. lithospermoides* (*Pringle 2565*, near Guadalajara, Jalisco, Mexico, UC), in having herbage covered with hispid-pilose nonglandular hairs intermixed with short glandular hairs, and seeds 1.8–2 mm long, linear-oblong, with a shallowly reticulate seed-coat with the membranaceous inner tangential walls of seed-coat cells retained at maturity.

Nesom (1992b) reduced this species to synonymy under *C. scorzonerifolia*, based upon study of microfiche of the types (P). We agree with Nesom that the original illustrations (Kunth, 1817) of *C. lithospermoides* (pl. CLXIV) and *C. scorzonerifolia* (pl. CLXV) are almost identical. Based on specimens at hand, we are able to distinguish four different seed forms among the plants, which we tentatively identify as *C. lithospermoides* and

its close relatives *C. scorzonerifolia*, *C. glandulosa*, and *C. jiquilpana*. We herein designate these four species as the *C. scorzonerifolia* complex, which merits further investigation, especially a careful study of the type specimens as well as field investigation of natural populations over their range of distribution.

**Castilleja mexicana** (Hemsl.) A. Gray

This report of $n = 12$ from three collections agrees with the one previously reported count (Ward, 1984). This species was originally described as *Orthocarpus mexicanus* (Hemsley, 1882: 463) and was meticulously and beautifully illustrated (pl. LXIII. A. figs. 1–6). In his original description, Hemsley commented that, "Although this is very closely allied to *Castilleja sessiliflora*, we have preferred placing it in *Orthocarpus*, because it certainly ought to go into the same genus as *Orthocarpus australis* [= *Castilleja laciniata* Hook. & Arn. from Peru; see Chuang & Heckard, 1991: 657], and because it differs from nearly all the species referred to *Castilleja* in the bifid lobes of the calyx, and in the long exserted corolla with nearly equal lips." This observation substantiates our recent realignment (Chuang & Heckard, 1991) to include Keck's (1927) *Orthocarpus* sects. *Castillejoides* and *Cordylanthoides* in genus *Castilleja* (subg. *Colacus* sect. *Oncorhynchus*).

Eastwood (1909: 583) observed that, "*Castilleja sessiliflora* Pursh is excluded as all specimens seen appear to be *C. mexicana*. The two are very closely related." Nesom (1992a) reduced *C. tortifolia* Pennell to synonymy under *C. mexicana*, but maintained *C. mexicana* and *C. sessiliflora* as distinct species, based on such minor differences as color of bracts and indumentum of stems.

*Castilleja mexicana* and *C. sessiliflora* can easily be distinguished from other Mexican species by their dwarf stature, falcate yellow or purplish corolla long-exserted from the calyx, and well developed lower corolla lip with three thin petaloid lobes nearly equaling the upper lip. These two were included in section *Callichroma* [type: *C. purpurea* (Nutt.) Don] by Bentham (1846); later, Pennell (1935) proposed section *Anthochroma* to include *C. sessiliflora* and its relatives.

**Castilleja nubigena** Kunth

The count of $n = 12$ from two populations is reported here for the first time for this endemic of the high mountains of Ecuador. This species is closely related to *C. pumila* (Benth.) Weddell ex Herrera, and both are perhaps part of the *C. fissifolia* complex. As indicated earlier, Melchior (1931) followed Weddell (1857) in treating most South American species of *Castilleja* as infraspecific taxa under *C. fissifolia*, including this one as *C. fissifolia* subsp. *nubigena* (Kunth) Melchior.

**Castilleja ornata** Eastwood

This count of $n = 24$ is the first report for this species. According to Eastwood (1909), this species is related to *C. glandulosa* (= *C. scorzonerifolia*) in the trisaccate lower lip with the divisions separated by the folds forming the three sacs below, and has different pubescence and generally obtuse leaves.

**Castilleja ortegae** Standley

The count of $n = 12$ from four collections represents the first reported chromosome number for this species. It is distinguished by its narrow, entire, often reflexed leaves, secund racemose inflorescence, distally dilated calyx lobes, and shorter upper corolla lip (beak). Holmgren (1976) created the *Ortegae* group to include this species and *C. pterocaulon* N. Holmgren. Undoubtedly they are closely related to *C. gracilis*, *C. roei*, and *C. tenuifolia* in sect. *Epichroma* Benth., except that the latter three species all have filiform, pinnately dissected leaves. Further study may suggest that *C. ortegae* and *C. pterocaulon* should also be included in this section. *Castilleja ortegae* is found from northern Sonora and southwestern Chihuahua to Sinaloa and adjacent Durango.

**Castilleja patriotica** Fernald

This report of $n = 12$ from five collections in Chihuahua, Mexico, is consistent with previously reported counts from Arizona (Heckard & Chuang, 1977; Ward & Spellenberg, 1986). *Castilleja patriotica* is characterized by its pinnately 3–5-lobed leaves, racemose not secund inflorescence, longer upper corolla lip, and calyx cleft to almost ⅔ in front. It is a member of sect. *Castilleja* (= sect. *Hemichroma* Benth.), which contains *C. fissifolia* (the type of the genus) and *C. integrifolia* of South America, and *C. linariifolia* and *C. subinclusa* (including *C. franciscana*) of the western United States. Holmgren (1976) proposed the designation *Tenuiflorae* group to include *C. patriotica*, *C. tenuiflora*, *C. linifolia*, and *C. mcvaughii* N. Holmgren, based on such features as the narrow, entire, often reflexed leaves, and a long galea equaling or exceeding the tube in length.

FIGURES 11–21. Meiotic chromosome figures of first counts (except *C. tapeinoclada*) of Mexican, Central American, and South American *Castilleja*. The stage of meiosis for each phase is indicated as: Diak., diakinesis; MI, metaphase I; TI, telophase I; TII, telophase II.—11. *C. nubigena*, $n = 12$, TI (*Holmgren 10101*).—12. *C. ornata*, $n = 24$, TI (*Holmgren 8044*).—13. *C. ortegae*, $n = 12$, 1/2 portion of TII (*Breedlove 19192*).—14. *C. roei*, $n = 12$, Diak. (*Cruden 1312*).—15. *C. scorzonerifolia*, $n = 12$, TI (*Holmgren 8059*).—16. *C. stenophylla*, $n = 12$, Diak. (*Holmgren 8017*).—17. *C. talamancensis*, $n = 12$, TI (*Heckard 6219A*).—18. *C. tapeinoclada*, $n = 12$, 1/2 portion of TII (*Cruden 1584*).—19. *C. tenuiflora*, $n = 12$, TI (*Breedlove 18723*).—20. *C. tenuifolia*, $n = 10$, TI (*Cruden 1977*).—21. *C. virgata*, $n = 12$, TI (*Holmgren 10142*).

**Castilleja purpusii** Brandegee

This report of $n = 48+$ is one of the few high polyploid species counted for Mexican *Castilleja* and represents the first estimated number for this species. Although no meiotic irregularity was found, it was impossible to make an accurate count because of the large number of small, clumped chromosomes during metaphase I and II. Although it was estimated to have over 48-bivalent chromosomes, it may very well be $n = 60$; additional material is needed. This species is closely related to *C. pectinata* Matens & Galeotti, differing only in having leaves that are entire to 3-lobed rather than usually pinnately 5–7-lobed.

**Castilleja roei** Crosswhite

The count of $n = 12$ from four collections represents the first report for this species, although Holmgren (1976) indicated our unpublished count from the herbarium labels. *Castilleja roei* is undoubtedly related to *C. tenuifolia* in section *Epichroma* Benth. This is a beautiful species, easily recognizable by its habitat of dripping wet cliffs, perennial habit, filiform leaf segments, and especially its calyx coloration. Holmgren (1976) remarked that this is the only species of *Castilleja* in which the calyx is yellow distally and red proximally.

**Castilleja saltensis** Eastwood

The count of $n = 12$ from two populations collected in Durango agrees with one previously reported, also from Durango (Heckard, 1968). This species is perhaps related to *C. shaffneri* in such features as a dwarf, caespitose habit and a dense, compact floral spike, but is easily identified by its distally dilated, obtuse or rounded lobes of the floral bracts.

**Castilleja schaffneri** Hemsley

Chromosome counts of $n = 12$ were determined from three populations and are in agreement with one previously reported (Beaman et al., 1962). This species is easily distinguished by its dwarf, caespitose habit with many slender decumbent pilose stems from the base and dense spikes with large (mostly 3–4 cm long) red flowers and densely pilose calyx with shallowly cleft lateral lobes. It is distributed in the states of Hidalgo, México, Morelos, Puebla, and Veracruz, at elevations from 2,400 to about 4,000 m. It was meticulously illustrated by Hemsley (1882: 662, pl. LXII. B. figs. 7–13). Nesom (1992b) placed *C. schaffneri* and *C. pringlei* Fernald in synonymy with *C. moranensis* Kunth. However, this suggestion needs further investigation, especially careful study of the type specimen of *C. moranensis*. Eastwood (1909) treated these three species in sect. *Euchroma* (Nutt.) Benth.

**Castilleja scorzonerifolia** Kunth

The report of $n = 12$ from seven populations represents the first count for this species. *Castilleja scorzonerifolia* is a widely distributed species complex, ranging from northeastern to south-central Mexico. Nesom (1992b) reduced *C. lithospermoides* and *C. glandulosa* to synonymy under *C. scorzonerifolia* and pointed out, "It is somewhat variable in features of vestiture, calyx morphology, and degree of corolla exsertion, but for the most part, identifications of this species are relatively constant." The entire complex needs further study.

As indicated earlier, the discovery of at least four seed forms in this complex (including *C. lithospermoides* and *C. jiquilpana*) by our cursory investigation of specimens at hand suggests that detailed SEM study of seeds may help to unravel some of the taxonomic problems in this species group.

**Castilleja stenophylla** M. E. Jones

The chromosome count of $n = 12$ from six populations, all from Chihuahua, represents the first report for this species. This species is perhaps related to *C. integra*, but is distinguished by its entire linear leaves and smaller flowers. Eastwood (1909) placed it in sect. *Hemichroma* Benth., but we prefer to include it in sect. *Euchroma* (Nutt.) Benth. on account of its subequally cleft calyx, floral bracts that are broader than cauline leaves, and densely spicate inflorescence.

**Castilleja subinclusa** Greene
subsp. **subinclusa**

We have recently treated *C. subinclusa* as a highly variable species consisting of two subspecies, subsp. *subinclusa* (including *C. jepsonii*) and subsp. *franciscana*, distributed in cismontane California and northern Baja California (Chuang & Heckard, 1992b). This polyploid complex, one of many in the western United States, has four ploidy levels, $n = 12$ to 48, based on an exhaustive chromosome survey (Heckard, 1968; Chuang & Heckard, unpublished data). It is closely related to the wide-

ranging *C. linariifolia* Benth.; both species were included in sect. *Hemichroma* (= sect. *Castilleja*) by Bentham (1846). Pennell (1951) proposed section *Linariaefolia* to accommodate these two species because they share such features as an unevenly cleft calyx with a much deeper cut in front, and a corolla generally curved forward through a calyx sinus.

All three counts from northern Baja California are tetraploid ($n = 24$); the tetraploid populations of this species are also found randomly distributed north to the northern coastal counties of the San Francisco Bay area.

**Castilleja talamancensis** N. Holmgren

The count of $n = 12$ represents the first report for this species. This species, endemic to the Cordillera de Talamanca, Costa Rica, is similar to *C. irazuensis*.

**Castilleja tapeinoclada** Loesener

This count of $n = 12$ agrees with a previous report (Beaman et al., 1962) for this high-mountain (2,700–4,000 m) species, which is endemic to Guatemala. It is easily identified by its low (less than 10 cm high ) and spreading stature, and inflorescence with few (1–4), large flowers.

**Castilleja tenuiflora** Benth.

This, the most widely sampled species (17 populations) in our study, reveals two ploidy levels ($n = 12, 24$). This extensive survey does not show any specific cytogeographic distinctions between the diploid and tetraploid populations. The counts of $n = 12$ represent the first reported diploid, whereas the counts of $n = 24$ confirm a previous report (Heckard, 1968) for this most common, most widespread (extending from Guererro and Oaxaca, northward through most of Mexico to southeastern Arizona), and one of the most complex Mexican species. It is likely that some of the geographic variants such as a linear-leaved form, some color forms, and a form with a secund inflorescence and longer pedicels, represent populations intermediate between this and the closely related *C. integrifolia*, and perhaps even *C. tenuifolia*. Holmgren (1976) treated the following as conspecific with *C. tenuiflora*: *C. canescens* Benth., *C. laxa* A. Gray, *C. retrorsa* Standley, *C. xylorrhiza* Eastwood, *C. scabridula* Eastwood, and *C. setosa* Pennell.

**Castilleja tenuifolia** Marens & Galeotti

The count of $n = 10$ from five collections is actually the first report for this species, although Heckard (1968) pointed out an uncertain count of $n = 10$; that count was not reported in the list and no voucher specimen was cited. This species was included in the small sect. *Epichroma* by Bentham (1846). Eastwood (1909) stated, "*Epichroma* is probably the most individual subdivision and has, perhaps, the best claim to generic rank . . . ." The same number of $n = 10$ is found also in the closely related *C. gracilis* and distantly related *C. lineariloba* (subg. *Colacus* sect. *Onchorhynchus*). All the other *Castilleja* species counted have a chromosome number of $n = 12$ or multiples of the basic number; the number $n = 10$ is postulated to be an aneuploid reduction from an $n = 12$ progenitor.

The species is easily distinguishable by its annual habit, filiform leaf divisions, secund-racemose inflorescence, and funnelform and colorful calyces. It is distributed in Jalisco, Michoacán, México, Guererro, and Oaxaca.

**Castilleja virgata** (Wedd.) Edwin

This count of $n = 12$ represents the first report for this species. It is very similar to the highly variable *C. fissifolia*. The entire *C. fissifolia* complex is in urgent need of further critical study.

# PHYLOGENETIC RELATIONSHIPS OF THE BROMELIIFLORAE–COMMELINIFLORAE–ZINGIBERIFLORAE COMPLEX OF MONOCOTS BASED ON *rbc*L SEQUENCE COMPARISONS[1]

*W. Dennis Clark,[2] Brandon S. Gaut,[3] Melvin R. Duvall,[3] and Michael T. Clegg[3]*

## Abstract

Four cladistic hypotheses were constructed for Dahlgren's Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex, primarily from suggestions of affinities according to morphology-based treatments: (i) Dahlgren's treatment of the families is correct; (ii) the Bromeliaceae and Zingiberales are sister groups; (iii) the complex is monophyletic, with the Arecaceae as the closest outgroup; and (iv) a clade that contains the Bromeliaceae and Commelinaceae is monophyletic. These four hypotheses were evaluated using sequence data from the chloroplast gene, *rbc*L, that codes for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase. Results were compared between a broad analysis of 499 *rbc*L sequences and a smaller data set that included only families of the complex plus the Arecaceae (52 taxa). The larger data analysis supported hypothesis (iii), minus the Velloziaceae. However, hypotheses (i) and (ii) were not supported, and support for hypothesis (iv) was equivocal. Three decisions on classification can be made based on the results of this study: (i) submerge the Bromeliiflorae into the Commeliniflorae; (ii) remove the Velloziaceae from the complex; and (iii) remove the Cyclanthaceae and Pandanaceae from the Areciflorae.

Studies on the phylogeny and classification of the monocots (Liliopsida) have received considerable emphasis recently among plant systematists. One of the major difficulties, however, has been the relative dearth of morphological characters (compared with the dicots) that are consistently useful for phylogenetic inference. This is probably due both to a general uniformity in floral morphology of monocots (the trimerous "Lilioid" flower) and the occurrence of extremely reduced or specialized floral structures that obscure evolutionary relationships of several key groups. Accordingly, major classifications show significant differences in the treatments of monocots (Cronquist, 1988; Dahlgren et al., 1985; Takhtajan, 1980; Thorne, 1992).

The group of focus in this study is a three-superorder complex, as outlined by Dahlgren et al. (1985), that includes the Bromeliiflorae (six orders), the Commeliniflorae (four orders), and the Zingiberiflorae (one order). Within this group, the family of interest for this project is the Bromeliaceae, a well-defined family that is widely recognized as monophyletic based on several synapomorphies (Gilmartin & Brown, 1987). However, its relationships to other families and its taxonomic position within the monocots are in dispute. Therefore, we constructed four cladistic hypotheses to

[1] This work was supported by grants from the National Science Foundation (BSR-8904637 to WDC and BSR-9002321 to MRD) and the National Institutes of Health (GM45344 to MTC). We gratefully acknowledge Harold G. Hills for contributing several *rbc*L sequences for comparison with our data, Victor A. Albert (University of North Carolina/University of Uppsala) for doing the computer analyses presented in this paper, and Gerald H. Learn, Jr. (University of California, Riverside) for general advice on manipulating DNA sequence data. We also thank Spencer Barrett (University of Toronto) for providing genomic DNA from *Pontederia* and the following for providing fresh plant material: Gregory K. Brown (University of Wyoming), Steve Morgan and Andy Sanders (Botanical Garden and Herbarium, respectively, University of California, Riverside), Harry Luther (Marie Selby Botanical Garden), Michael G. Simpson (San Diego State University), and Robert F. Thorne (Rancho Santa Ana Botanic Garden). Valuable comments were provided on earlier drafts of the manuscript by Victor A. Albert, Mark W. Chase (Royal Botanic Gardens, Kew), Leslie R. Landrum (Arizona State University), and Michael G. Simpson.

[2] Department of Botany, Arizona State University, Tempe, Arizona 85287, U.S.A.

[3] Department of Botany and Plant Sciences, University of California, Riverside, California 92521, U.S.A.

explain the relationships of the Bromeliaceae and related monocots, as follows: (i) Dahlgren's treatment (Dahlgren & Bremer, 1985) of the families, modified with more recent data (Gilmartin & Brown, 1987; Simpson, 1987, 1990), is correct (Fig. 1); (ii) the Bromeliaceae and Zingiberales are sister groups (Fig. 2); (iii) the complex is monophyletic, with the Arecaceae as the closest outgroup (Fig. 3); and (iv) a clade that contains the Bromeliaceae, Commelinaceae, and other commelinoids is monophyletic (Fig. 4). These hypotheses were evaluated by comparison with results from parsimony analyses of DNA sequences from the chloroplast gene *rbc*L.

## Classification

Traditional classifications of plants have necessarily served as the starting point for defining the scope of taxa to be used in modern phylogenetic analyses. However, past and current classifications of some families, such as the Bromeliaceae, are so diverse as to render this process difficult. Major taxonomic treatments put the Bromeliaceae in a variety of higher categories. Takhtajan (1980) considered the Bromeliaceae to be a member of his superorder Lilianae. Other authors have included the commelinoid monocots with the bromeliads (Hutchinson, 1973; Thorne, 1992). However, Cronquist (1978) found the Bromeliaceae to be highly discordant in the subclass Commelinidae; he instead placed them in his Zingiberidae, along with the Zingiberales (formerly in the Liliidae). This change was prompted, at least in part, by a desire to sharpen the definition of the Commelinidae and the Liliidae. Finally, the most divergent view of bromeliad classification among major treatments may be that of Dahlgren et al. (1985), who placed the Bromeliaceae in the superorder Bromeliiflorae, along with four other single-family orders and the two-family order Typhales.

## Phylogenetic Relationships

Identification of shared derived character states using phylogenetic systematics provides a rigorous methodology for inferring evolutionary relationships and for evaluating previous notions of classification. However, many character states that have been used to define taxa are unknown with respect to polarity and may represent primitive retentions. For example, Cronquist (1978) suggested a relationship between Bromeliales and Zingiberales based on their large, showy bracts. Williams & Harborne (1977) made the same suggestion based on the myricetin and quercetin glycosides that occur in both groups. Takhtajan (1980) proposed a relationship between bromeliads and lilialean families, especially Agavaceae, based on numerous similarities: raphides, steroidal sapogenins, flavonoids, scalariform perforations in root vessels, septal nectaries, helobial endosperm, and ". . . definite similarities between pollen grains" (p. 314). The literature is replete with such suggestions. Nonetheless, these suggestions do not tell us which characters are indicators of common ancestry (synapomorphic). The most thorough and perhaps strongest suggestions for the phylogenetic relationships of the bromeliads come from the work of Dahlgren and his associates (Dahlgren & Rasmussen, 1983; Dahlgren & Bremer, 1985; Dahlgren et al., 1985). Although their character polarities were offered as provisional, the monophyly of the Bromeliaceae is apparently supported by three consistent synapomorphies. These are: (i) stellate and scalelike multicellular hairs; (ii) large, solitary silica bodies; and (iii) a conspicuously sepaloid and petaloid perianth. However, only the stellate or scalelike multicellular hairs are unique to the Bromeliaceae; other traits are homoplastic. Additional synapomorphies for the Bromeliaceae might include conduplicate-spiral stigmas (Brown & Gilmartin, 1989a) and a base chromosome number of $x = 25$ (Brown & Gilmartin, 1989b). But the consistency of these characters across the family awaits a more complete evaluation.

The greatest number of ideas about the phylogenetic relationships of the Bromeliaceae involve interfamilial and interordinal levels because these present the greatest difficulty. Cronquist (1988) suggested that the Bromeliales shared a common ancestor with the Zingiberales that ". . . might have been much like some of the more archaic, terrestrial Bromeliaceae, but less xerophytic" (p. 487). The monocot "phylogeny" of Walker (1986) shows the Bromeliidae and the Commelinidae arising together from the Liliidae. Dahlgren & Rasmussen (1983) included the Bromeliaceae with the Velloziaceae, Philydraceae, Haemodoraceae, Pontederiaceae, Typhaceae, and Sparganiaceae in the superorder Bromeliiflorae. However, the sister status of the Bromeliaceae in Dahlgren's system is shown as a polytomy that consists of the bromeliads, the Velloziales, and collectively all of the remaining orders of the Bromeliiflorae.

Sister status of Bromeliaceae and Velloziaceae was more firmly suggested in a cladistic study by Gilmartin & Brown (1987). This suggestion was derived from sequential analyses of likely sister groups, a methodology that was criticized by Simpson (1988) but defended by Gilmartin & Brown

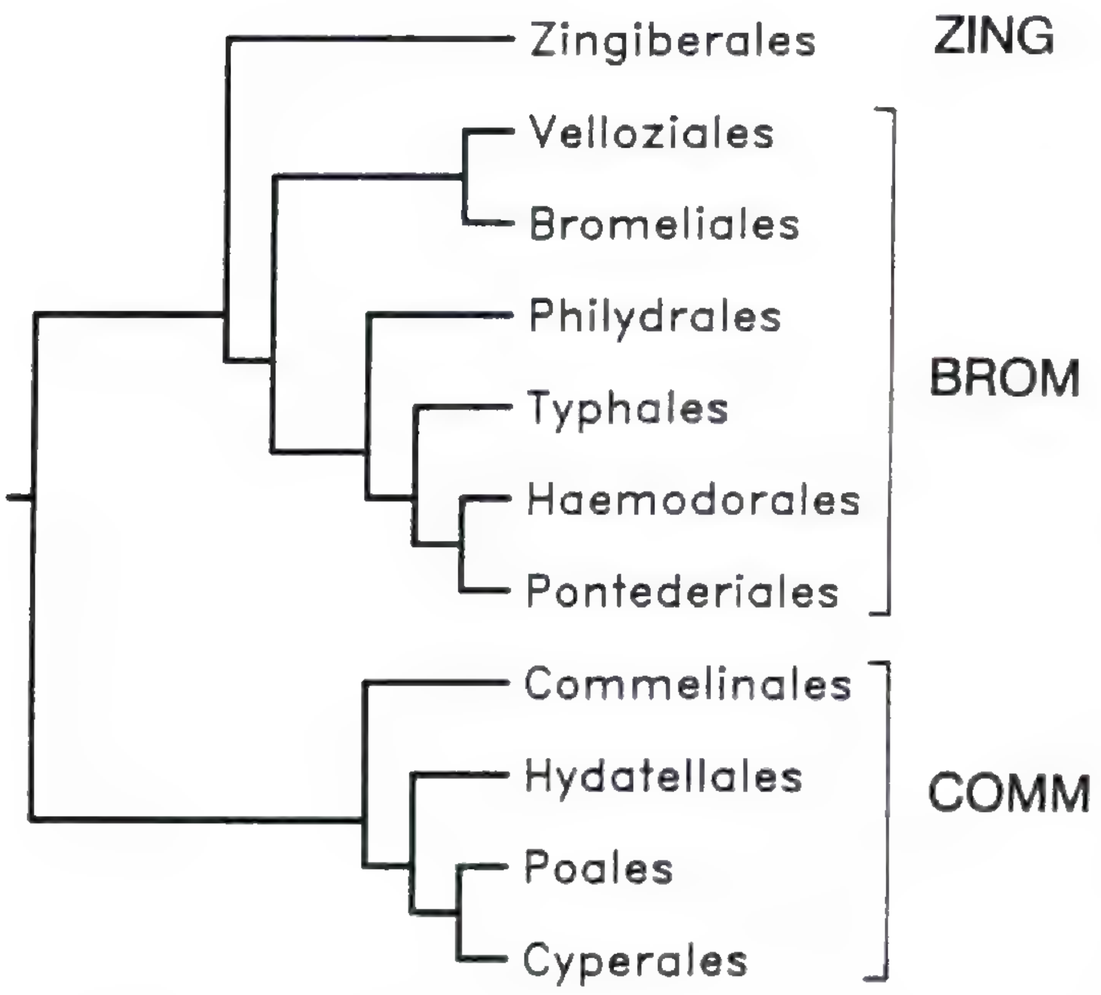

FIGURE 1. Hypothesis 1: Relationships within the three- superorder complex. ZING = Zingiberiflorae, BROM = Bromeliiflorae, COMM = Commeliniflorae.

(1988). Regardless, no synapomorphies were identified that distinguished a Bromeliaceae–Velloziaceae clade from the other families examined.

At a more inclusive taxonomic level, monophyly of the Bromeliiflorae is supported in the Dahlgren scheme by an apomorphic subtype of helobial endosperm. Furthermore, this scheme shows that the sister group to the Bromeliiflorae is the Zingiberiflorae (demonstrated by showy perianths). The Commeliniflorae are sister to the Bromeliiflorae–Zingiberiflorae clade. The monophyly of this three-superorder complex is supported by three synapomorphies: sculptured and oriented epicuticular wax ("*Strelitzia*-type"), endosperm with copious starch, and cell walls with UV-fluorescent compounds.

## OBJECTIVES AND HYPOTHESES

Given the variety of classifications and suggested phylogenetic relationships for the Bromeliiflorae–Commeliniflorae–Zingiberiflorae, our main objective was to obtain new information regarding the relationships among the constituent families in these groups. This new information consists of a cladistic analysis of nucleotide sequences of the plastid gene *rbc*L, which codes for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase.

We have constructed four hypotheses for evaluation by DNA sequence comparisons. We chose Dahlgren's system as a framework for our initial hypothesis. Although there have been many suggestions about the possible relationships of the complex, those of Dahlgren and his associates are the most comprehensive and the closest to being explicit cladistic hypotheses (Dahlgren & Bremer, 1985). However, we have modified the polytomy (Velloziales, Bromeliales, all other Bromeliiflorae) in Dahlgren's Bromeliiflorae to reflect the study by Gilmartin & Brown (1987). This change shows the Bromeliaceae and Velloziaceae to be sister taxa. We have also modified the polytomy (Haemodorales, Pontederiales, Typhales) to reflect relationships suggested by Simpson (1987, 1990). This change shows the Haemodoraceae/Haemodorales and Pontederiaceae/Pontederiales to be sister taxa. Accordingly, our initial hypothesis for the phylogenetic relationships of the three superorder complex is summarized in Figure 1.

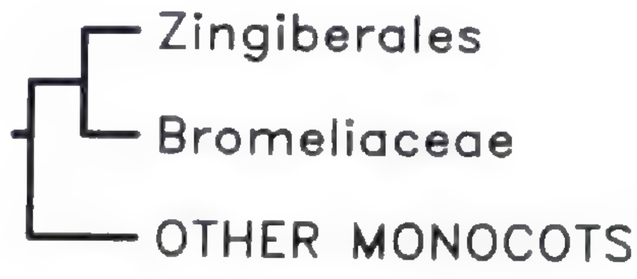

FIGURE 2. Hypothesis 2: Closest outgroup status of the Bromeliaceae to the Zingiberales.

Our second hypothesis is that the Bromeliaceae and Zingiberales are sister taxa (Fig. 2). This explanation is based in part on suggestions of Cronquist (1988) regarding the putative common ancestor to the two groups. It also incorporates the observation of Kress (1990) that, at present, the Bromeliaceae are the best outgroup to the Zingiberales.

Our third hypothesis is that the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex is a monophyletic group, as suggested by Dahlgren & Rasmussen (1983). This group is held together by the three synapomorphies mentioned previously. However, at the moment, there is no clear guidance for suggesting a putative sister group to this complex. Thus, this hypothesis is the most incomplete of the four examined in this study. Nevertheless, a tentative proposal might include the Arecales, whose members also possess UV-fluorescent cell walls (Fig. 3).

Our fourth hypothesis is that the Bromeliaceae and Commelinaceae are together in a "commelinoid–bromelioid" clade (Fig. 4), which precludes the Bromeliaceae–Zingiberales proposed in the second hypothesis (Fig. 2). The fourth hypothesis derives from the inclusion of bromeliads within the Commelinales by Thorne (1992), from the putative derivation of the Bromeliales from the Commelinales proposed by Hutchinson (1973), and from the common origin of the Bromeliidae and Commelinidae suggested by Walker (1986). However, this alternative hypothesis cannot be developed enough at the moment to predict with certainty which

FIGURE 3. Hypothesis 3: Monophyly of the three-superorder complex and closest outgroup status of the Arecaceae to the complex. Synapomorphies marked on the cladogram are: 1, UV-fluorescent cell walls; 2, copious endosperm; 3, *Strelitzia*-type epicuticular wax.

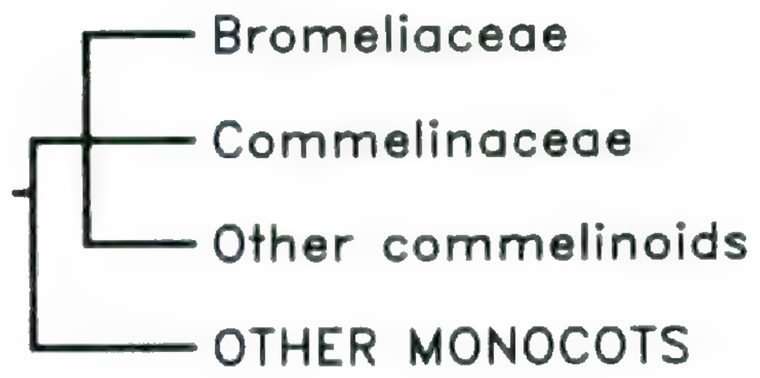

FIGURE 4. Hypothesis 4: Monophyly of a group containing the Bromeliaceae and Commelinaceae.

monocots, outside of the Bromeliaceae and Commelinaceae, should be considered as commelinoid.

There are undoubtedly other nontrivial hypotheses that we could have examined for this paper. However, focus on this particular set of hypotheses was guided by numerous preliminary analyses as the project grew. For this reason, our method is not only abductive and predictive but also in part retrodictive. The method is retrodictive because we chose our hypotheses after we examined preliminary results. Nevertheless, we believe that this mixed process has enabled us to make significant progress in monocot systematics.

Our hypotheses are not completely mutually exclusive, but neither can all be fully supported. This means that our results should be useful for evaluating morphological and chemical character evolution on *rbc*L-based trees. Accordingly, we can make preliminary character analyses of those traits that have traditionally been used for suggesting phylogenetic relationships.

## MATERIALS AND METHODS

Sequences were obtained from seven genera of the Bromeliaceae and one genus each from the Strelitziaceae, Pontederiaceae, Velloziaceae, and Rapateaceae. Other sequences used for comparison here either have been published or shared by other investigators. Sources for new sequences used in this report are listed in the Appendix.

In most instances total DNA was extracted from fresh leaf tissue using a Tris-EDTA buffer (Dellaporta et al., 1983). In contrast, samples of *Stegolepis*, *Vellozia*, and *Glomeropitcairnia* were extracted using the CTAB microextraction method of Learn (1987). Each preparation was used to provide a template for amplifying *rbc*L by the polymerase chain reaction (PCR). The PCR protocol was suggested by the supplier of *Taq* DNA polymerase (Promega Corp.). Primers for amplifying double-stranded DNA were designed from conserved regions in *atp*B from *Nicotiana tabacum*, in *rbc*L from *Zea mays*, and in ORF106 from *Oryza sativa* (Golenberg et al., 1990). Single-stranded DNA was made in a second round of PCR using the double-stranded product as a template. Single-stranded products were cleaned by precipitation in NaOAc. Both the coding strand and the complementary strand were amplified separately and subsequently sequenced. Sequencing followed Sanger et al. (1977) according to the Sequenase protocol (US Biochemical). Internal sequencing primers were provided by G. Zurawski (DNAX Corp., Palo Alto, California) from conserved regions in the *rbc*L sequence of *Zea mays*.

Sequence data were read directly from autoradiograms into files created by a sequence editor (SE; Matt Clegg, Riverside, California). Sequences were aligned by hand. Ultimately, all sequences were entered into an edit file in the NEXUS format for parsimony analysis with PAUP 3.0 (Swofford, 1991).

For this paper, a subset of genera was reanalyzed separately from the 499 taxa of seed plants used by Chase et al. (1993). This subset included 52 species of monocots from 20 families in the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex, plus the Arecaceae (Table 1). We deemed the analysis of this subset useful because of its potential for evaluating in more detail a smaller set of ingroup relationships. Fitch parsimony analyses (equal weighting) were performed on 10 random-addition data sets of the 52 taxa. Character-state changes were plotted using the ACCTRAN option. The most parsimonious trees from these analyses were also used as the starting point for a character-state weighted analysis of the 52 taxa (Albert et al., 1993).

## RESULTS

Figure 5 shows the relationships between the ingroup (i.e., the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex) for this study and other families of monocots. This cladogram was made by modifying Figures 5A and 6A from the 499-taxon analysis in Chase et al. (1993) to include only

family names and exclude names of genera. This simplification is justified because all of the families for which multiple genera were sampled are monophyletic in this cladogram, with the exception of the Melianthaceae.

Figure 5 shows not only the position of the ingroup relative to other monocots, but also the exclusion of the Velloziaceae from the ingroup. A sister-taxon relationship between the Velloziaceae and Bromeliaceae is clearly not supported by *rbc*L sequence data. The Velloziaceae are instead far removed from the three-superorder complex of interest here, to sister status with a Pandanaceae–Cyclanthaceae clade. This result provides support for Cronquist's inclusion of the Velloziaceae in the Liliales, but an explicit hypothesis for this relationship is beyond the scope of this paper. Nevertheless, this finding provides direction for future studies on the relationships of the Velloziaceae.

Figure 6 is modified from Chase et al.'s (1993) 499-taxon analysis to show relationships among the ingroup families for this study. Most multiple-sample families are again monophyletic, the exceptions being the Juncaceae and Cyperaceae. Figure 6 shows Dahlgren's Bromeliiflorae and Commeliniflorae to be paraphyletic. The only family from Dahlgren's Bromeliiflorae that diverges with the bromeliads is the Typhaceae. All of the other families in this clade are members of Dahlgren's Commeliniflorae. In addition, the bromeliad-containing clade shows the Bromeliaceae to be basal within it. This implies that there is no single sister family to the Bromeliaceae.

The remaining bromeliiflorean families in Figure 6, plus the Commelinaceae, diverge with the Zingiberales. Regardless of the lack of support for Dahlgren's concept of the Bromeliiflorae and Commeliniflorae, these results do support the monophyly of the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex (minus the Velloziaceae). Furthermore, the Arecaceae appear as the outgroup to this three-superorder complex, as also suggested in Figure 5.

Reanalysis (unrooted) to include just the Arecaceae and the ingroup of interest yielded 198 most-parsimonious trees of length 1665 by Fitch parsimony. A strict consensus showed that differences among trees were due to within-family rearrangements in the Bromeliaceae and Poaceae (data not shown), so all family-level nodes were fully resolved (Fig. 7A). Character-state weighting yielded 30 most parsimonious trees, each of which converted to 1667 even-weighted steps. A strict consensus showed that differences among trees were again due to within-family rearrangements, so all family-level nodes were still fully resolved. However, there was one family-level difference between the Fitch analysis and the weighted analysis: the Commelinaceae moved from a position basal to the Pontederiaceae–Philydraceae–Haemodoraceae clade (Fig. 7A) to a position that is sister to the Pontederiaceae (Fig. 7B).

TABLE 1. Families analyzed in this study. (The first number in parentheses is the number of species examined; the second number is the approximate minimum number of species in the family according to Thorne, 1992.)

| | |
|---|---|
| Arecaceae (7/2780) | Marantaceae (2/500) |
| Bromeliaceae (7/1520) | Musaceae (1/42) |
| Commelinaceae (3/605) | Philydraceae (1/6) |
| Costaceae (2/150) | Poaceae (9/10,000) |
| Cyperaceae (2/5315) | Pontederiaceae (1/30) |
| Flagellariaceae (1/4) | Rapateaceae (1/80) |
| Haemodoraceae (1/80) | Restionaceae (1/407) |
| Heliconiaceae (1/250) | Strelitziaceae (3/7) |
| Juncaceae (3/300) | Typhaceae (1/30) |
| Lowiaceae (1/6) | Zingiberaceae (4/1000) |

Several changes occurred among family relationships by analyzing the smaller data set. Perhaps the most notable of these is that the four-family clade containing the Commelinaceae shifted from the Zingiberales-containing clade to a more conventional position near the Cyperales and other commelinoid monocots (Fig. 7A). In so doing, the Commelinaceae-containing clade replaced the Flagellariaceae as a sister group to the Cyperales. The Flagellariaceae, in turn, moved to a position basal to the Restionaceae–Poaceae family pair. An internal rearrangement in the Commelinaceae-containing clade also put the Haemodoraceae and Philydraceae together as sister taxa, which roughly conforms to the recent cladistic analysis by Simpson (1990). The difference is that our results show the Philydraceae and not the Pontederiaceae as the sister group to the Haemodoraceae. The Pontederiaceae are instead basal to the Philydraceae–Haemodoraceae clade.

Finally, results from this analysis also show a sister family relationship between the Bromeliaceae and the Rapateaceae. The Bromeliaceae–Rapateaceae clade is sister to a clade containing all the remaining families of the Bromeliiflorae and Commeliniflorae in the ingroup.

## DISCUSSION

The results reported here provide little support for Dahlgren's view of the Bromeliiflorae. Moreover, there is no evidence from *rbc*L sequence comparisons that the Velloziaceae are the sister

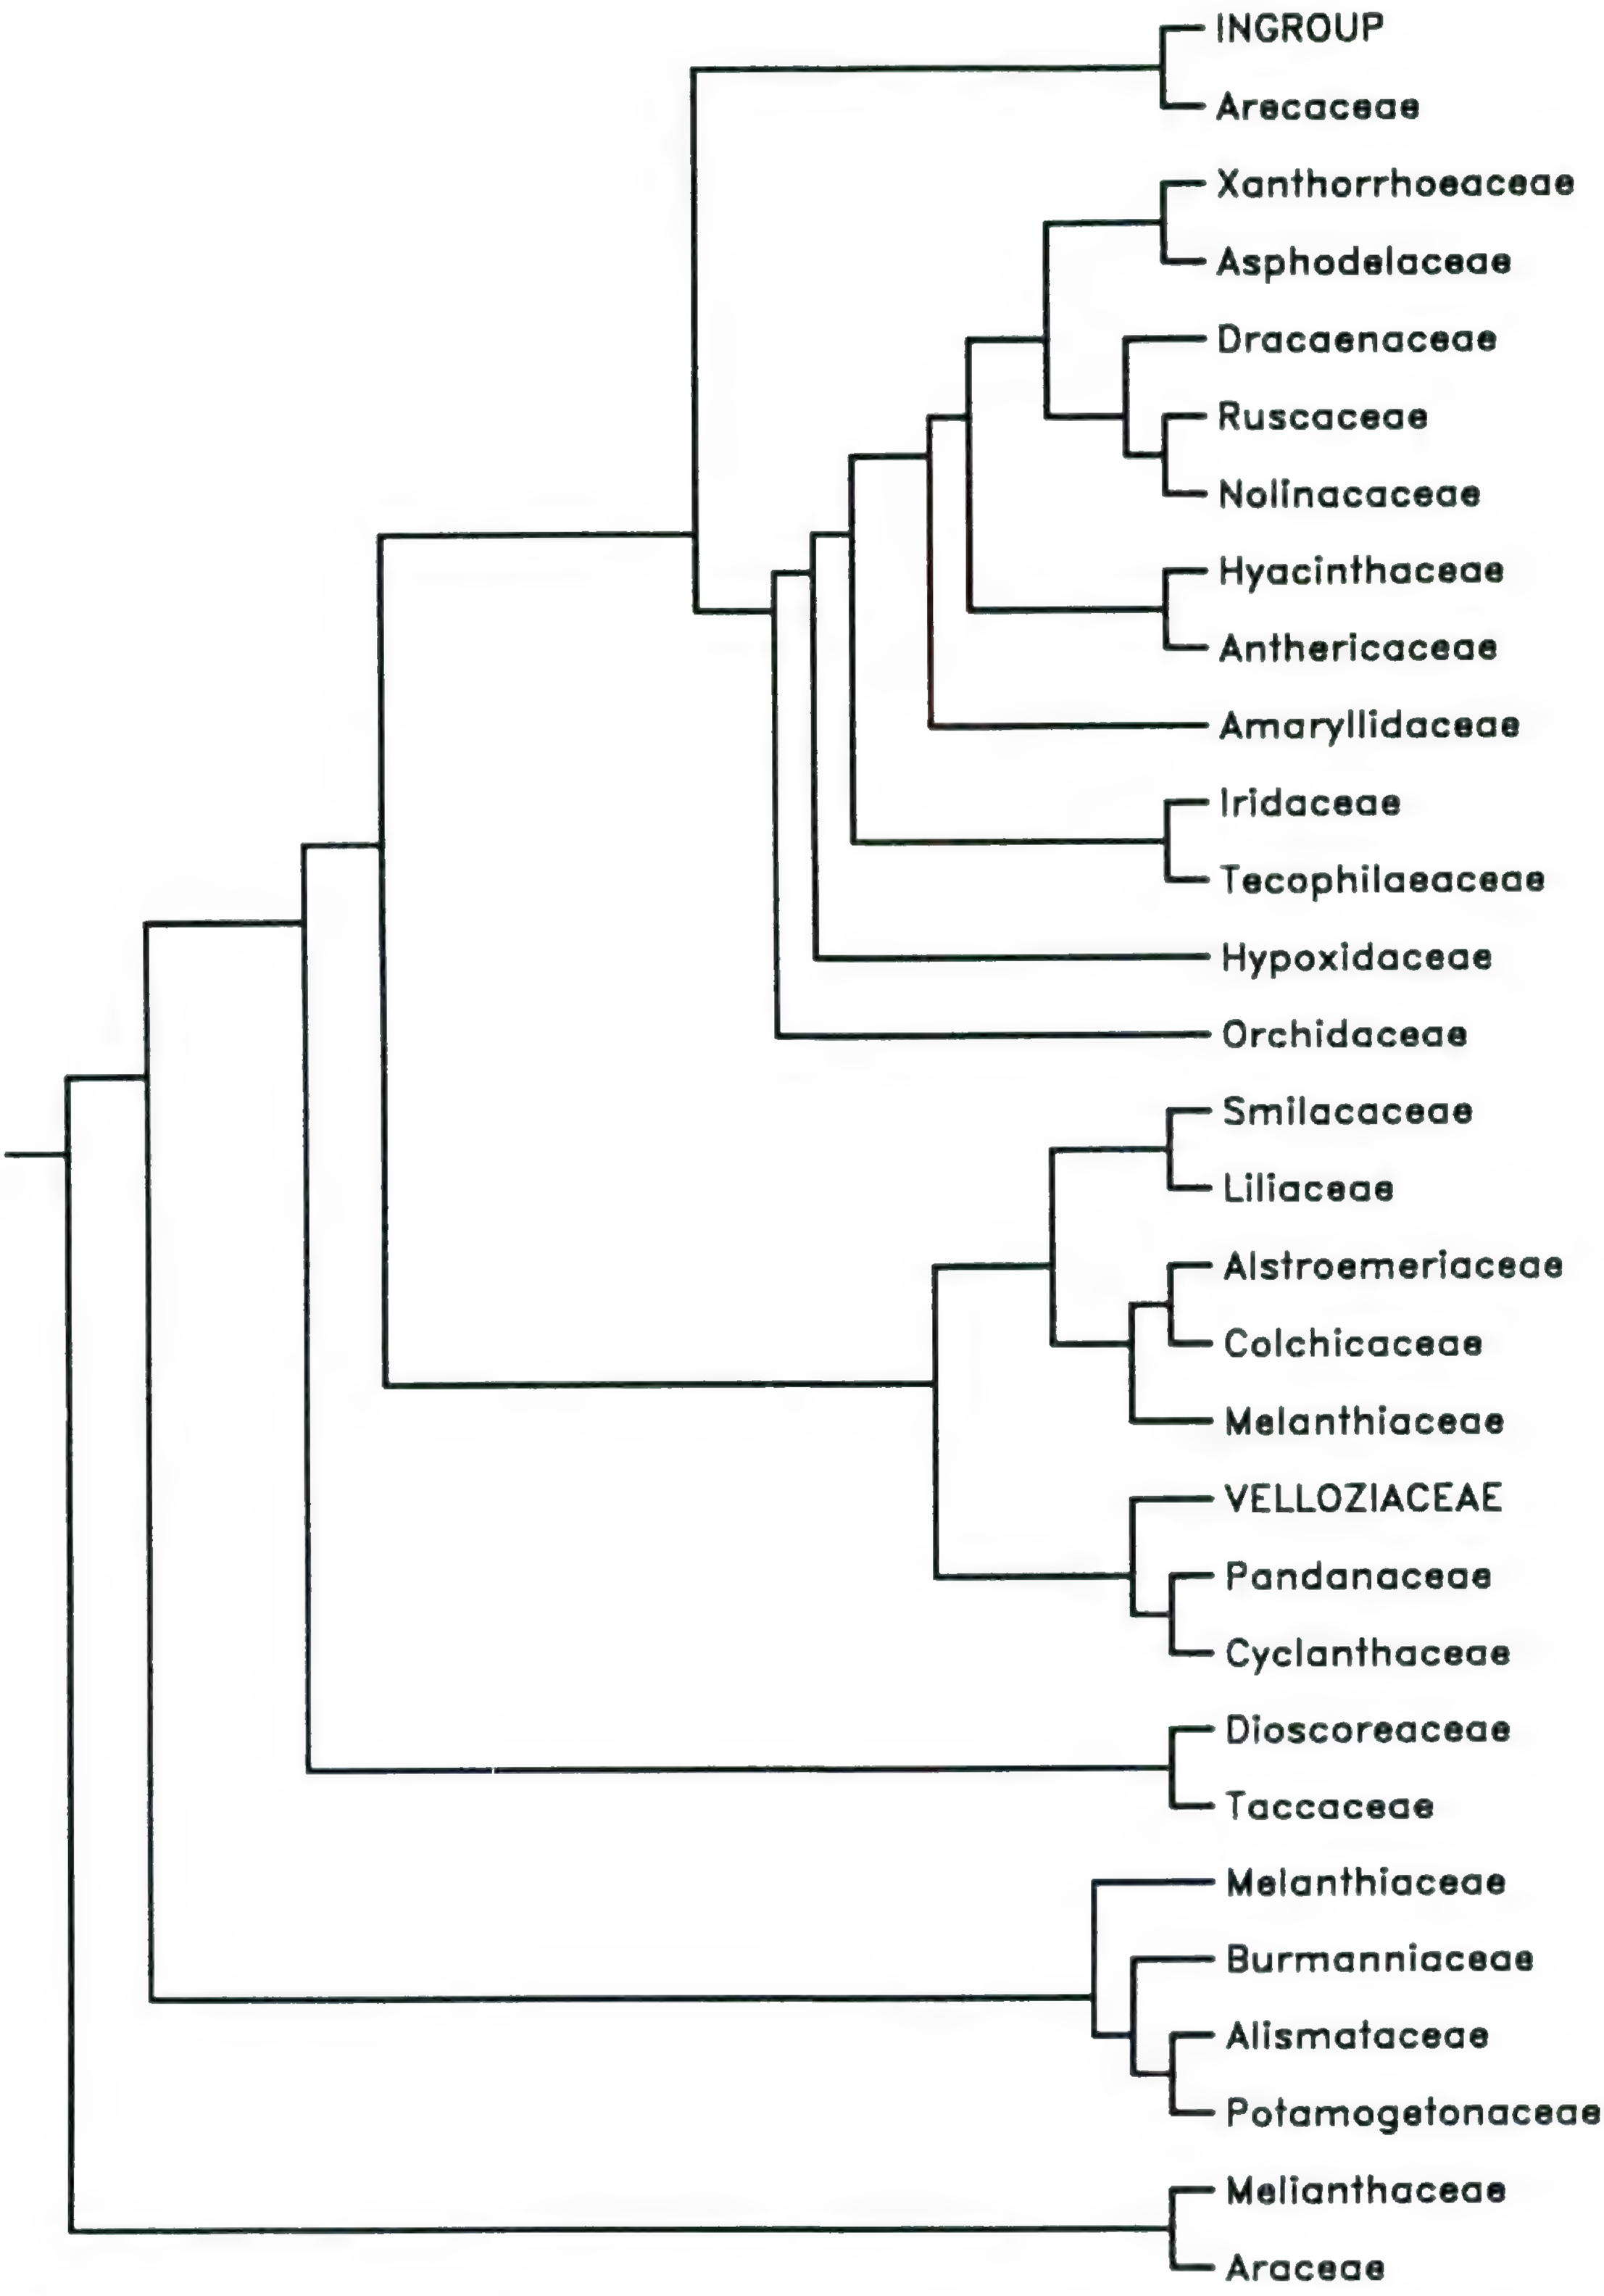

FIGURE 5. Relationships of the INGROUP/Arecaceae clade to other monocot groups according to unrooted parsimony analysis of a 499-taxon data set of seed plants. INGROUP = Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex, minus the Velloziaceae. Modified from Chase et al. (1993).

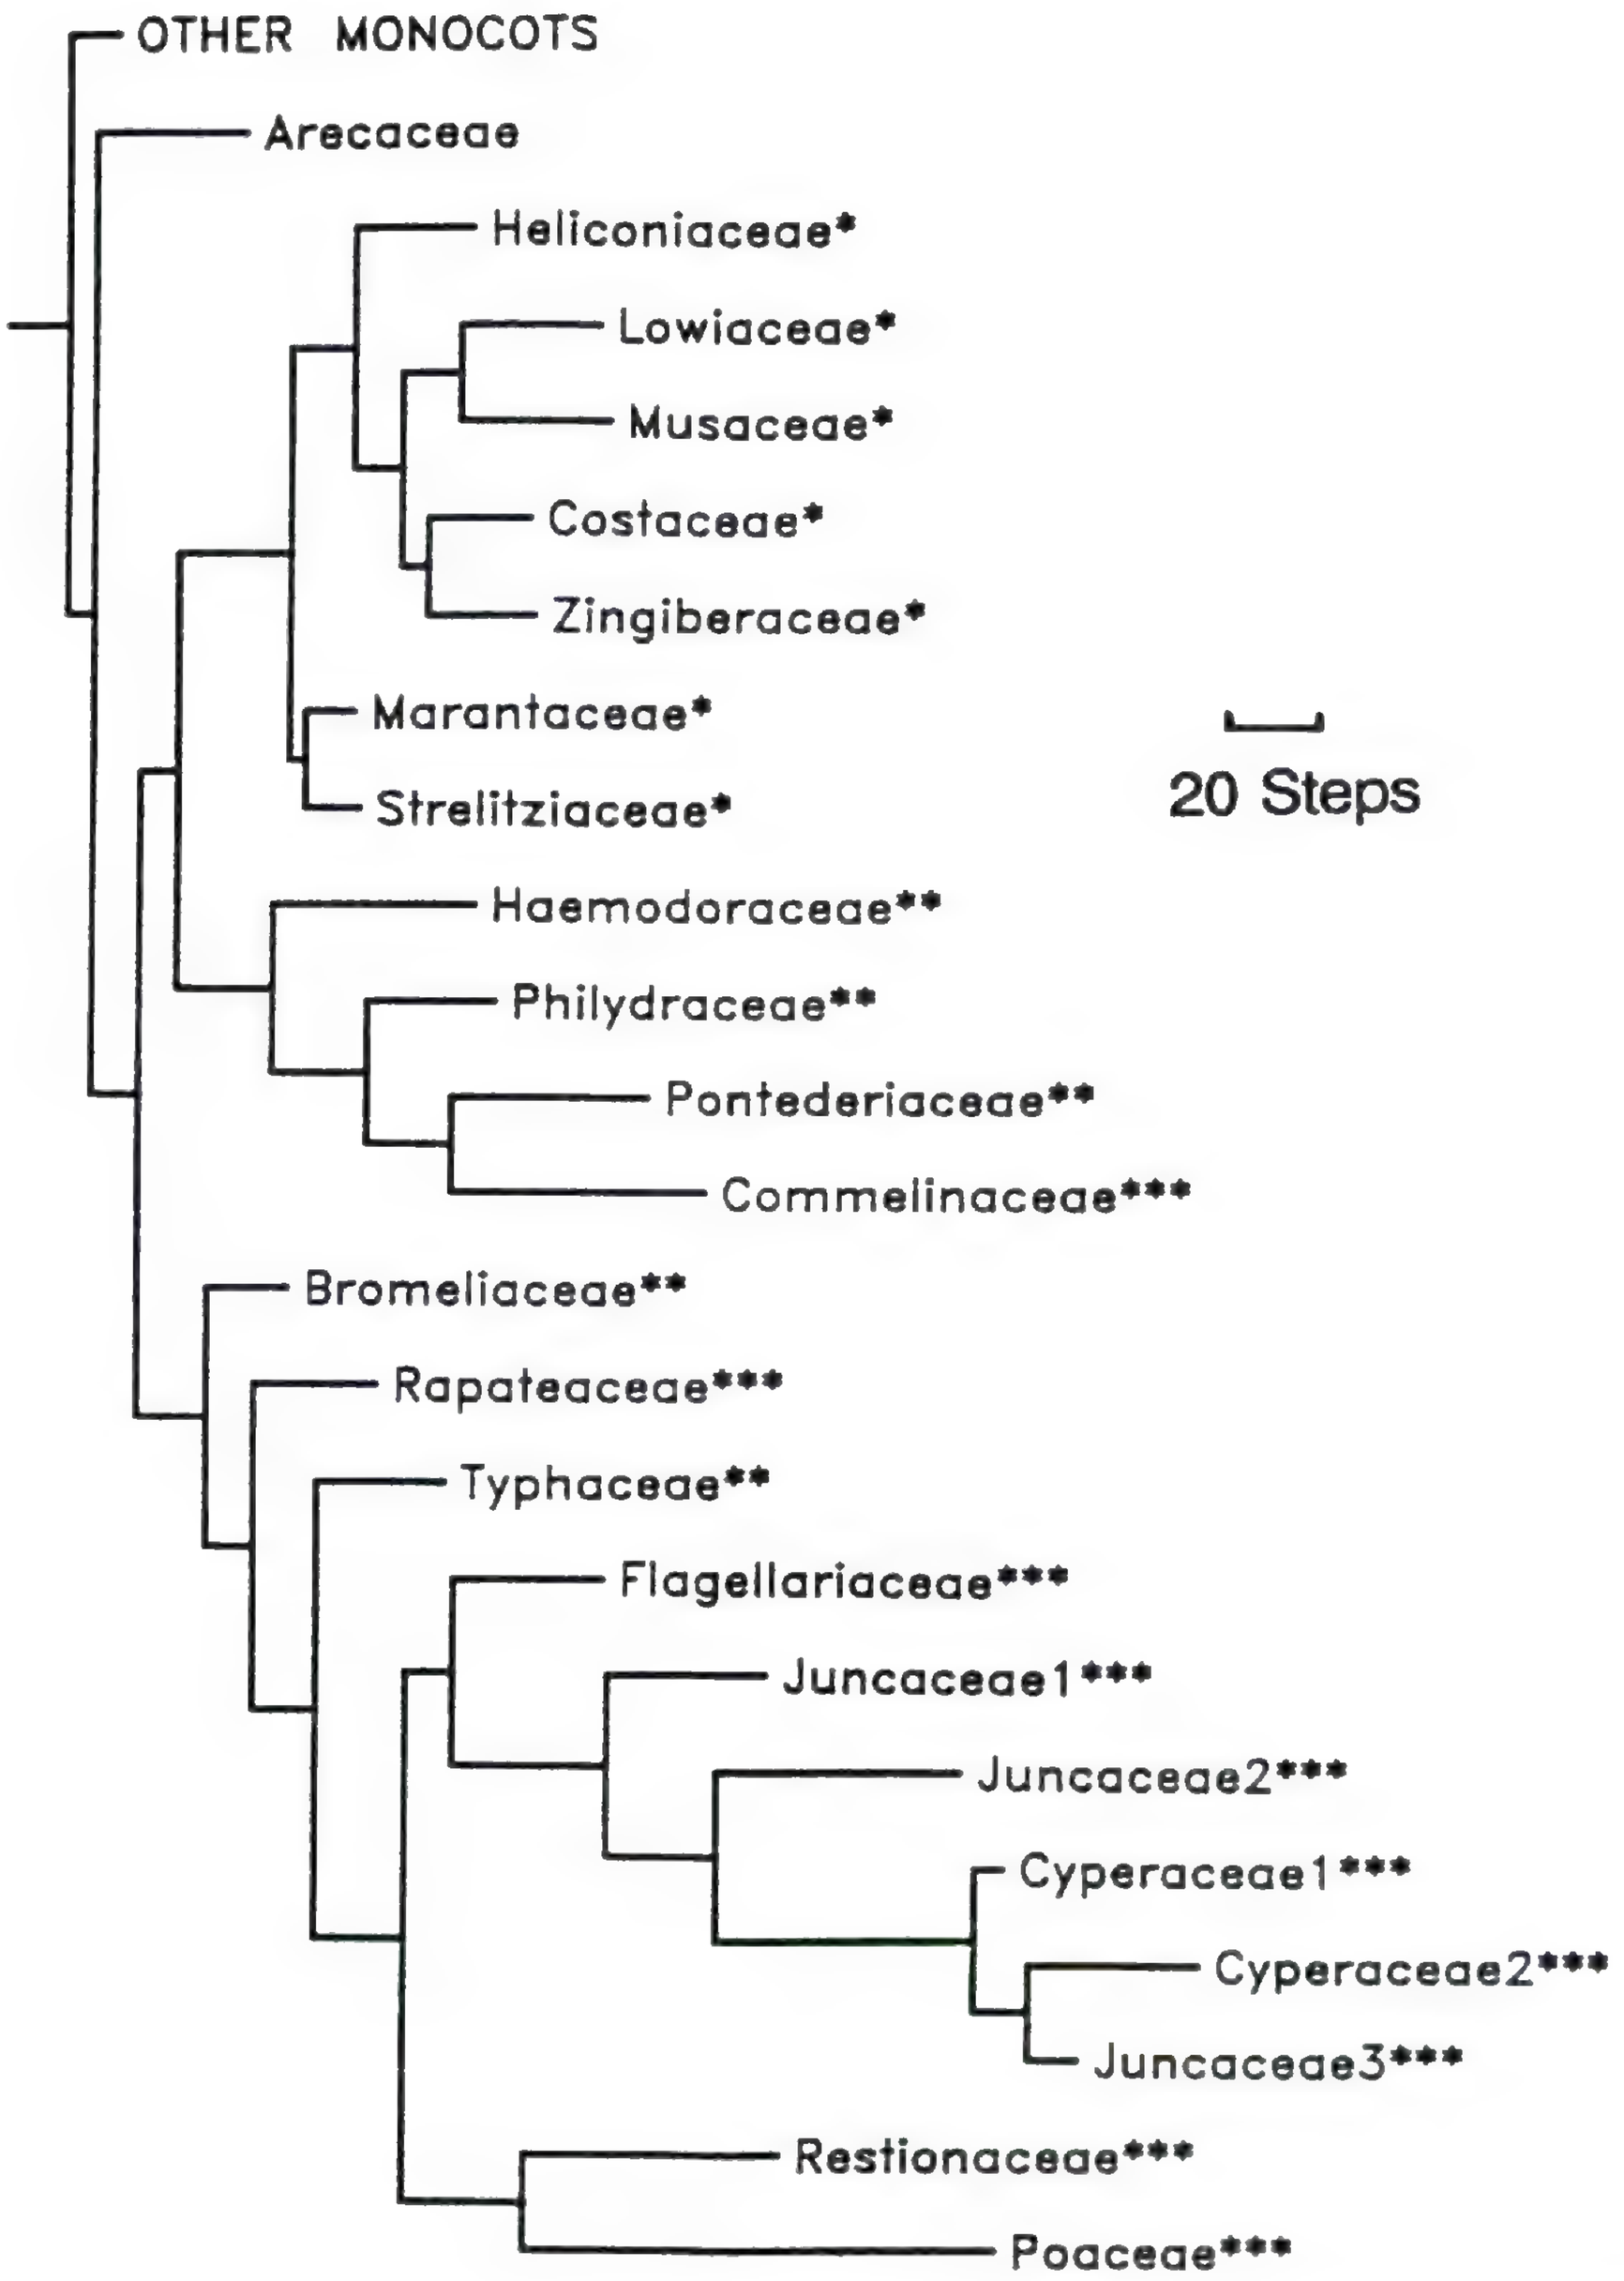

FIGURE 6. Family-level relationships within the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex according to unrooted parsimony analysis of a 499-taxon data set of seed plants. Modified from Chase et al. (1993). * = Zingiberiflorae; ** = Bromeliiflorae; *** = Commeliniflorae.

family to the Bromeliaceae. Therefore, we reject our first hypothesis. The rejection of Dahlgren's Bromeliiflorae comes as no surprise, since this superorder is held together by a single provisional synapomorphy, a variant form of helobial endosperm. In general, helobial endosperm is characterized by a division of the primary endosperm nucleus, which is followed by the formation of a transverse cell wall. This cell division makes a larger micropylar chamber and a smaller chalazal chamber (Dahlgren & Clifford, 1982). However, all but the Pontederiaceae of Dahlgren's Bromeliiflorae are known to have a much smaller, starch-free chalazal chamber. Dahlgren & Rasmussen (1983) suggested that the Pontederiaceae probably have this subtype of helobial endosperm. In addition, this character is homoplastic because a very small, starch-free chalazal chamber also occurs in the helobial endosperm of *Thismia javanica* of the Burmanniaceae (Dahlgren & Clifford, 1982), a

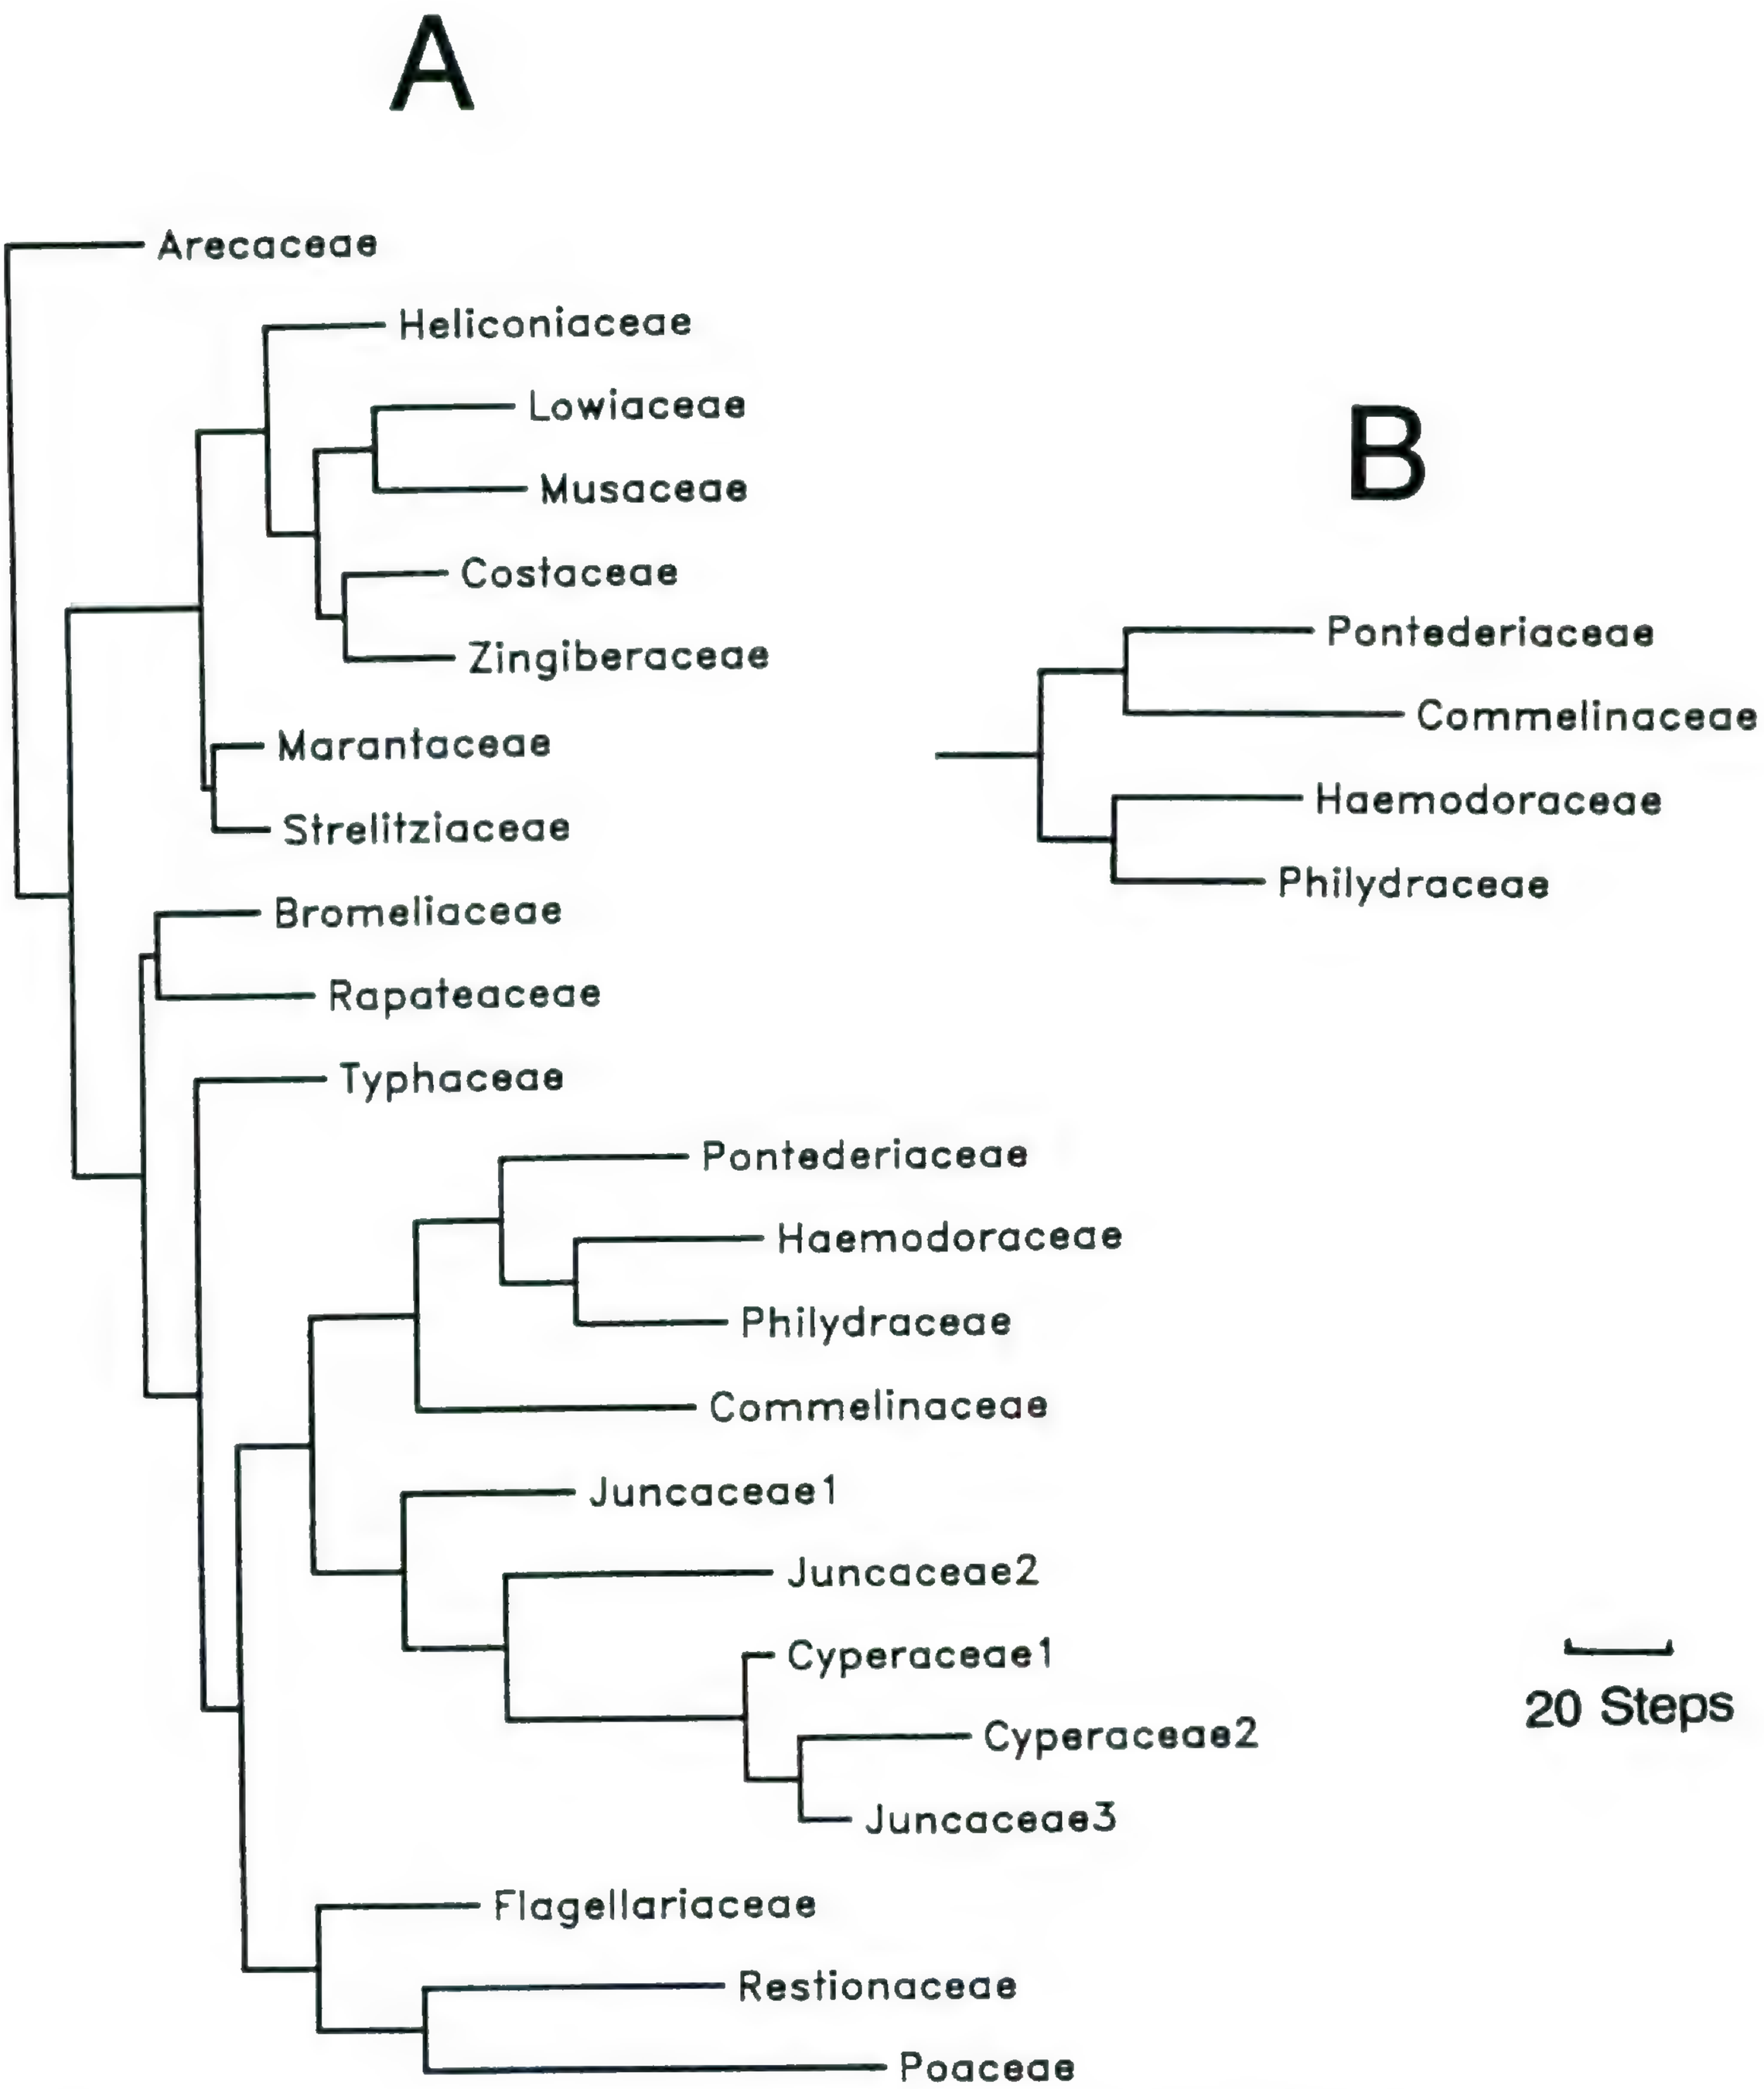

FIGURE 7. Family-level relationships within the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex according to unrooted parsimony analyses of a 52-taxon data set of monocots. (A) Strict consensus of 198 trees generated by Fitch analysis (equal-weighting); length = 1665. (B) Family-level rearrangement generated by character-state weighted parsimony analysis, strict consensus of 30 trees; length = 1667. Changes among trees in both analyses occurred only within families (not shown).

family that is not believed to have a close relationship with the Bromeliiflorae (Dahlgren & Bremer, 1985).

The occurrence of biflavonoids in *Xerophyta plicata* (Velloziaceae) and their absence in the Bromeliaceae lends no support to a close relationship between the Bromeliaceae and the Velloziaceae. Biflavonoids are extremely rare in monocots, so their occurrence in the Velloziaceae may be autapomorphic. If biflavonoids are of phylogenetic sig-

nificance among monocot families, then hypotheses regarding the relationship of the Velloziaceae, Cyclanthaceae, and Pandanaceae should be examined. The latter two families are the closest to the Velloziaceae according to analysis of *rbc*L sequences (Chase et al., 1993; Duvall et al., 1993).

We also reject our second hypothesis, that the Zingiberales and Bromeliaceae form a monophyletic lineage. This means that the conventional characters shared by these groups (large, showy bracts and petaloid perianth parts) do not support a unique relationship; these character states are better interpreted as plesiomorphies. Other groups also have showy bracts (Orchidaceae and some Araceae, among others) or petaloid perianth parts (Commelinales and nearly all of Dahlgren's Liliiflorae). Such a diverse distribution suggests that these characters are either nonhomologous (Kress, 1990), homoplastic, or symplesiomorphic. Regardless, they do not appear to be synapomorphic for the Bromeliaceae and Zingiberales. Furthermore, initial evidence for a common ancestry based on flavonoid chemistry (Williams & Harborne, 1977) was quickly refuted following a more detailed examination of the Bromeliaceae (Williams, 1978). Thus, our results show that the Zingiberidae of Cronquist are paraphyletic, and the traditional chemical and morphological characters that support their monophyly are equivocal or unlikely to be informative.

Monophyly of the Bromeliiflorae–Commeliniflorae–Zingiberiflorae complex is supported by Chase et al.'s (1993) 499-taxon analysis (Fig. 6). Furthermore, the Arecaceae are the sister group to this triumvirate. This result supports our third hypothesis regarding the common ancestry of these three superorders. Therefore, we accept the hypothesis and agree with Dahlgren's view of this relationship, even though we reject his proposed ingroup phylogeny (first hypothesis). We also accept our tentative proposal to designate the Arecaceae/Arecales as the sister group to the three-superorder complex. Such designation clarifies the speculation by Dahlgren & Bremer (1985) that the Arecales are somehow related to the Commelinales. Their suggestion was speculative because they showed no synapomorphies to support it. On the other hand, similar speculation that the Pandanales and Cyclanthales might belong to Bromeliiflorae or Commeliniflorae, respectively, is not supported by *rbc*L comparisons (see Chase et al., 1993, fig. 5A).

By supporting our third hypothesis, we also make sense of the phylogenetic distribution of three apomorphies. These are a sculptured and oriented epicuticular wax ("*Strelitzia*-type"), an endosperm with copious starch, and UV-fluorescent cell walls (Fig. 3). The significance of these synapomorphies comes from their occurrence in the Arecales as well as in the ingroup. We therefore have strong, independent support for an Arecales-ingroup relationship. It is notable that the three characters in question are informative at a high taxonomic level. There are few other examples of such extensive support for higher categories. However, the distribution of these apomorphies does not preclude a Poales–Arecales relationship, as suggested by Dahlgren & Bremer (1985). But our *rbc*L analysis provides no support for such a relationship.

The main problems with the above synapomorphies lie in incompleteness of sampling and in inconsistency of distribution, which are perhaps expected consequences of circumscribing such a large group. For example, most Zingiberales have starchy perisperm or chalazasperm instead of starchy endosperm. Starchy endosperm may also be a synapomorphy for the Arales (Dahlgren & Rasmussen, 1983), thereby making this character homoplastic within the monocots. Moreover, the significance of starchy endosperm in the unripe seeds of some Burmanniaceae is unclear. All starch in these seeds is exhausted by the time they ripen. Thus, homology is uncertain for this character.

Similarly, *Strelitzia*-type epicuticular wax is common only in the Arecaceae, Cannaceae, Cyperaceae, Heliconiaceae, Juncaceae, Poaceae, Strelitziaceae, and Typhaceae and rare in the Bromeliaceae, as well as Velloziaceae (Behnke & Barthlott, 1983). In addition, smooth or nonoriented wax crystals often occur in the Poaceae, Cyperaceae, Marantaceae, Rapateaceae, Restionaceae, Xyridaceae, and Haemodoraceae. Wax crystals are absent from some Bromeliaceae, Haemodoraceae, Rapateaceae, Marantaceae, and Velloziaceae and from all taxa that were examined in the Zingiberaceae, Pontederiaceae, and Joinvilleaceae (Barthlott & Frölich, 1983).

Upon first inspection, the problem of inconsistency also seems to plague the distribution of UV-fluorescent cell walls within the monocots. For example, certain taxa in the Haemodoraceae do not have UV-fluorescent cell walls (Harris & Hartley, 1980). However, these taxa are more appropriately included in the Tecophilaeaceae, a family that is not closely related to the Haemodoraceae (Simpson, 1985, 1990). Fluorescent cell walls also occur in the Cyclanthaceae and the Xanthorrhoeaceae, which seems to indicate homoplasy for this character. However, the cell walls of these two families are fluorescent because of *p*-coumaric acid. Cell

wall fluorescence in other monocots is due to a combination of *p*-coumaric acid, ferulic acid, and diferulic acid. The latter combination is found only in the Arecales, the Bromeliiflorae, the Commeliniflorae and the Zingiberiflorae. Therefore, UV-fluorescence by ferulic acid and its dimer is a unique synapomorphy. (One minor exception may be the absence of diferulic acid in the cell walls of *Restio oligocephalus* [Restionaceae] (Harris & Hartley, 1980); we suspect that this compound will yet be found in this and other species of the family.) It is also notable that, among the taxa of interest here, only the Hydatellaceae, Costaceae and Heliconiaceae have not been examined for cell-wall ferulates.

Aside from the monocots, cell-wall ferulate is apparently synapomorphic for the Caryophyllales (Hartley & Harris, 1981) and perhaps for the Coniferophyta (Strack et al., 1988). In these groups, ferulic acid itself is the consistent character, whereas the distributions of *p*-coumaric acid and diferulic acid are more variable. In addition, the phylogenetic relevance of ferulic acid for the Coniferophyta is not known because no other nonflowering seed plants have been examined.

Ferulic acid is a relatively simple and probably common constituent of plants (Molgaard & Ravn, 1988), but it dimerizes and links cell-wall components only in certain plants of close affinity within the monocots, the dicots and perhaps the conifers. Because of their unique linkage to cell walls, these compounds constitute a potentially rich source of biochemical data for phylogenetic study. Specifically, a molecular systematic approach to the ferulate-cell wall pathway should yield strong evidence on the homology or nonhomology of this pathway in monocots and dicots. Such evidence would be important for evaluating the potential role of this pathway in the evolutionary origin of lignification (Fry, 1983; Kubitzki, 1987).

When all 499 genera of seed plants are analyzed (Chase et al., 1993), the Bromeliaceae and Commelinaceae are not in the same clade as predicted by our fourth hypothesis. This analysis instead shows the clade (Haemodoraceae, (Philydraceae, (Commelinaceae, Pontederiaceae))) to be the sister group of the Zingiberales; the Bromeliaceae are shown to be basal to another lineage. Support for the sister status of the Commelinaceae-containing clade and the Zingiberales comes from one potential synapomorphy: root hair cells that are shorter than other epidermal cells. This character state is not shared, however, with the Philydraceae and Pontederiaceae (Dahlgren & Bremer, 1985). On the other hand, there is no known support from morphology for distinguishing a Bromeliaceae-containing clade from a Commelinaceae-containing clade.

In contrast to the broad 499-taxon analysis of Chase et al. (1993), evaluation of a smaller *rbc*L data set (52 taxa) that included only the ingroup plus the Arecaceae did support our fourth hypothesis that the Bromeliaceae and Commelinaceae are part of the monophyletic group (Fig. 7A). However, there are no synapomorphies from morphology to corroborate this result at this time. The smaller analysis also showed a sister-taxon relationship between the Bromeliaceae and Rapateaceae (Fig. 6). These families were not sister taxa in the broad analysis, but the Bromeliaceae were shown to be basal to a clade that includes the Rapateaceae as its basal member.

## Conclusions

Analysis of *rbc*L sequences supports Dahlgren's concept of a clade consisting of his Bromeliiflorae, Commeliniflorae, and Zingiberiflorae. Furthermore, analysis of a 499-taxon data set showed the Areciflorae (Arecales only) to be basal to this complex (Chase et al., 1993). However, Dahlgren's concept of the Bromeliiflorae is no longer tenable. Most of the families and orders in this superorder show a complex pattern of affinities with his Commeliniflorae and Zingiberiflorae. The Velloziaceae are removed from the complex entirely. The Bromeliaceae are not the sister to the order Zingiberales. Instead, the Bromeliaceae are better placed at or near the base of the clade that is next to the zingiberalean lineage.

Three straightforward decisions on classification can be made based on our conclusions. One is to remove the Cyclanthaceae and Pandanaceae from the Areciflorae. The Areciflorae are thereby comprised of one family, the Arecaceae. The second decision is to remove the Velloziaceae from the ingroup of this study (i.e., the Bromeliiflorae, Commeliniflorae, Zingiberiflorae clade). Both of these decisions are in agreement with the broader molecular analysis of monocots presented by Duvall et al. (1993) and are supported by the synapomorphic distribution of UV-fluorescent cell walls in the Areciflorae and in the ingroup.

The third decision is to submerge the Bromeliiflorae into Dahlgren's Commeliniflorae. However, at this time there are no objective criteria for determining whether the Commeliniflorae are paraphyletic (Fig. 6) or monophyletic (Fig. 7A). The Arecaceae-ingroup portion of the tree in Figure 6, which supports the former, is 1663 steps, whereas the latter is indicated by the 1665-step tree in

Figure 7A. The choice between these two possibilities must await further study.

Many family-level topologies are not firm enough to warrant conclusions at this time. However, the topologies shown here should be used as hypotheses for further study. Additional work should include analyses of molecular data from more genera of the larger families that are included here (e.g., Cyperaceae, Juncaceae, Commelinaceae, Haemodoraceae, Zingiberaceae, Costaceae, and Marantaceae) as well as from families that were not included in this study: Cannaceae, Centrolepidaceae, Eriocaulaceae, Hydatellaceae, Mayacaceae, Sparganiaceae, Thurniaceae, Xyridaceae, and Joinvilleaceae. Family-level topologies should be examined among gene trees of genes that are less conservative than *rbc*L. Most importantly, future studies should include cladistic evaluations of morphological and chemical data. Preliminary data from UV-fluorescent cell walls, helobial endosperm, and *Strelitzia*-type epicuticular wax show the potential of these kinds of characters for evaluating competing gene trees. Comprehensive surveys of these and other independent data will be necessary for making the best phylogenetic inferences among families of the Bromeliiflorae–Commeliniflorae–Zingiberiflorae lineage.

# NOTES ON MAGNOLIACEAE III: THE MAGNOLIACEAE OF CHINA[1]

*Chen Bao Liang*†[2] *and*
*Hans P. Nooteboom*[3]

ABSTRACT

Five genera of Magnoliaceae occur in China; these and the 81 indigenous and 7 cultivated species they contain are described here. In *Magnolia*, 28 wild and 4 cultivated species are recognized. *Magnolia nitida* var. *robusta* is newly described, and *Magnolia lotungensis* is reduced to *Magnolia nitida* var. *lotungensis*. In *Manglietia*, 17 indigenous and 1 cultivated species are recognized. Section *Manglietiastrum* is transferred from *Magnolia* to *Manglietia*, and *Magnolia sinica* is renamed *Manglietia sinica*. *Manglietia forrestii* is reduced to *Manglietia fordiana* var. *forrestii*, *Manglietia kwangtungensis* is reduced to *Manglietia fordiana* var. *kwangtungensis*, and *Manglietia calcarea* is reduced to *Manglietia fordiana* var. *calcarea*. In *Kmeria*, one species is recorded for China. In *Michelia*, 34 indigenous and 1 cultivated species are recognized. Section *Tsoongiodendron*, based on *Tsoongiodendron* W. Y. Chun, is recognized with one species, *Michelia odora*; section *Paramichelia*, based on *Paramichelia* H. H. Hu, is recognized with one species in China. *Michelia elliptilimba* is newly described. *Michelia crassipes* is reduced to *Michelia figo* var. *crassipes*. In *Liriodendron* one indigenous and one cultivated species are recognized. An identification list of all the collections studied, as well as a bibliography of Chinese Magnoliaceae, is given at the end of the paper.

The first author collected specimens of Magnoliaceae over a period of several years in China, especially in Yunnan. Apart from describing many new species, he wrote his thesis (in Chinese) on the Magnoliaceae of China. Because he did not have the opportunity to study the types in Western herbaria, or enough collections from southern Asia outside China, his earlier work could only be preliminary.

The second author published on the generic delimitation of Magnoliaceae and gave an account of the genera and species occurring in Malesia (Nooteboom, 1985, 1987). The present publication is the result of a joint Dutch–Chinese cooperation spanning 18 months at the Rijksherbarium at Leiden.

Sadly, soon after Chen Bao Liang returned to China in May 1991, he died from cancer.

## TERMINOLOGY

A few terms are used in this study that are not familiar to all taxonomists. Pedicle is not a pedicel, but the internode, if present, between the uppermost bract and the perianth. Literally, a brachyblast is a short shoot. In Magnoliaceae it means the shoot that bears the flower: it is terminal in Magnolieae and axillar in Michelieae. In Magnolieae, however, this character is called a peduncle because often it is longer. Innovations are the youngest parts of the twigs, often including stipules, that are still growing.

A list (List 1) of taxa and keys in the order in which they appear in the text follows the Bibliography. The numbering system in the text corresponds to that of List 1, Page 1096.

**Magnoliaceae** A.L. de Jussieu, Gen. Pl. 280. 1789 (Magnoliae).

Trees or shrubs, glabrous, or with an indumentum of single hairs. Leaves spirally arranged, simple, entire or 2–10-lobed, penninerved, evergreen or deciduous; stipules present, at first enclosing and protecting the buds, early caducous and leaving an annular scar around the node. Flowers terminal or pseudoaxillary on a short shoot (brachyblast) in the axils of the leaves, bisexual, rarely unisexual. Brachyblast or peduncle bearing 1 or more caducous spathaceous bracts, which leave annular scars. The highest bract either directly below the perianth or a pedicle present between bract and perianth. Perianth spiral or spirocyclic,

[1] We thank the directors and curators of P, K, E, and BM for the opportunity to study their collections and of the following herbaria for sending collections on loan: A, BM, E, GXMI, IBSC, K, KUN, LBG, MO, NY, P, PE, SYS, US, W. We thank the Dutch minister of Science and Education for providing, in the framework of the Chinese-Dutch Scientific Cooperation, the funds for Chen Bao Liang to spend 18 months in the Netherlands.

[2] Zhongshan University, Guangzhou, China.

[3] Rijksherbarium/Hortus Botanicus, P.O. Box 9514, 2300 RA Leiden, The Netherlands.

undifferentiated or differentiated into a (pseudo-) calyx and corolla, perianth members 6 or more, free, imbricate. Stamens numerous, free, spirally arranged; filaments short or ± elongated; anthers linear, 2-locular dehiscing introrsely, latrorsely, or rarely extrorsely; connective usually ± produced into an appendage. Gynoecium sessile or stipitate (and then a gynophore present); carpels numerous to few (rarely one), spirally arranged, free or sometimes concrescent; ovules 2 or more, biseriate on the ventral suture. Fruit apocarpous, sometimes syncarpous; fruiting carpels (follicles) opening along the dorsal and/or ventral suture, or circumscissile, rarely indehiscent. Seeds 1 or more in each fruiting carpel, large, in dehiscent carpels with arilloid testa and pendulous from the elongated spiral vessels of the funiculus (in *Liriodendron*, with indehiscent fruits, adherent to the endocarp and not arilloid); endosperm copious, oily; embryo minute.

*Note 1.* Nooteboom (1985) provided an introduction to the family with chapters on anatomy, embryology, phytochemistry, palynology, morphology, and subdivision of the family. Dandy (1927a) gave an account of the genera, which he emended in Hutchinson (1964a) and Praglowski (1974). Praglowski (1974) gave an account of the pollen. The cultivated species were extensively treated by Treseder (1978).

*Note 2.* As in many other families, the delimitation of species in Magnoliaceae is often difficult because of high variability. Because recently many more collections, and also types of species that were described before World War II, became available, many species could be reduced to synonymy. It should be kept in mind that even within populations variability is high. For example, *Magnolia sprengeri* Pampanini, when grown from seed, displays much variability. The beautiful *Magnolia* var. *diva* is vegetatively propagated because the seedlings often are disappointing, showing a spectrum of offspring with not always attractive flowers. Several botanists would be inclined to describe these seedlings and their mother tree as many different species.

KEY TO THE GENERA OF MAGNOLIACEAE

1. Leaves 2–10-lobed, the apex truncate or widely emarginate; anthers extrorse; fruits samaroid. ..... **V.** *Liriodendron*
1. Leaves entire or occasionally 2-lobed or emarginate; anthers introrse or latrorse; follicles dehiscent or circumscissile, not samaroid. ..... 2
2(1). Growth monopodial; flowers on brachyblasts in the axils of the leaves; gynoecium distinctly stipitate. ..... **IV.** *Michelia*
2. Growth sympodial; flowers terminal on the twigs. ..... 3
3(2). Flowers unisexual; tepals 6–7, subequal. ..... **III.** *Kmeria*
3. Flowers bisexual or androdioecious; tepals 9 or more, sometimes the outer whorl calyxlike. 4
4(3). Ovules 4 or more in each carpel; the hair base replaces a normal epidermal cell, so that the loss of a hair leaves a pore in the cutical membrane. ..... **II.** *Manglietia*
4. Ovules 2 in each carpel (4 in *Magnolia kachirachirai*, 2–5 in *Magnolia cathcartii*), sometimes 4 in the lower carpels; the hair base consists of at least two epidermal cells, and a hair does not leave a pore after it is shed. ..... **I.** *Magnolia*

## MAGNOLIACEAE subfamily MAGNOLIOIDEAE

Leaves entire or occasionally 2-lobed at the apex; stipules free from the petiole or adnate to it. Anthers introrse or latrorse. Follicles longitudinally dehiscent or circumscissile and then at least the base remaining adnate to the torus, free or concrescent into a syncarp. Testa free from the endocarp, externally arilloid.

TRIBES

Tribe **Magnolieae**

Growth sympodial (flowers terminal on the twigs). Follicles free or concrescent. Genera: *Magnolia*, *Manglietia*, and *Kmeria*.

Tribe **Michelieae** Law Yuh-wu, Acta Phytotax. Sinica 22: 106. 1984.

Growth monopodial (flowers arising on brachyblasts in the axils of the leaves). Genera: *Elmerrillia* Dandy, with four species in Malesia, none in China, and *Michelia* L. (See page 1052.)

TRIBE MAGNOLIEAE

**I. Magnolia** L., Sp. Pl. 535. 1753. TYPE SPECIES: *Magnolia virginiana* L. (eastern United States).

*Talauma* Juss., Gen. Pl. 281. 1789. *Magnolia* sect. *Talauma* Baill., Adansonia 7: 3, 66. 1866. *Magnolia* subg. *Talauma* Pierre, Fl. For. Cochinch. 1: sub t. 1. 1880. TYPE SPECIES: *Talauma plumierii* (Schwartz) A. DC. (*Magnolia plumierii* Schwartz).

*Aromadendron* Blume, Bijdr.: 10. 1825. *Talauma* sect. *Aromadendron* Miq., Ann. Mus. Bot. Lugd.-Bat. 4: 70. TYPE SPECIES: *Aromadendron elegans* Blume = *Magnolia elegans* (Blume) H. Keng.

*Blumia* Nees, Flora 8: 152. 1828 nom. rejec., non *Blumea* DC., nom. cons. *Magnolia* sect. *Blumia* (Nees) Baill., Adansonia 7: 2. 1866. TYPE SPECIES: *Talauma*

*candollii* Blume = *Magnolia candollii* (Blume) H. Keng.

*Yulania* Spach, Hist. Natur. Veget., Phanerog. 7: 462. 1839. TYPE SPECIES: *Yulania conspicua* Spach = *Magnolia heptapeta* (Buchoz) Dandy.

*Tulipastrum* Spach, Hist. Natur. Veget., Phanerog. 7: 481. 1839. TYPE SPECIES: *Magnolia acuminata* L.

*Lirianthe* Spach, Hist. Natur. Veget. Phanerog. 7: 485. 1839. TYPE SPECIES: *Lirianthe grandiflora* Spach = *Magnolia pterocarpa* Roxb.

*Buergeria* Siebold & Zucc., Abh. Math.-Phys. Cl. Kon. Bayer. Ak. Wiss. 4, 2: 186. 1846. TYPE SPECIES: *Buergeria stellata* Siebold & Zucc. = *Magnolia stellata* (Siebold & Zucc.) Maxim.

*Alcimandra* Dandy, Kew Bull. 1927: 260. 1927. TYPE SPECIES: *Alcimandra cathcartii* (Hook. f. & Thomson) Dandy = *Magnolia cathcartii* (Hook f. & Thomson) Noot.

*Svenhedinia* Urban, Repert. Spec. Nov. Regni Veg. 24: 3. 1927. TYPE SPECIES: *Svenhedinia minor* (Urban) Urban (*Talauma minor* Urban).

*Parakmeria* Hu & Cheng, Acta Phytotax. Sin. 1(2): 1. 1951. TYPE SPECIES: *Parakmeria omeiensis* Hu & Cheng (= *Magnolia omeiensis* (Hu & Cheng) Dandy).

*Micheliopsis* H. Keng, Quart. J. Taiwan Mus. 8: 207, t. 345. 1955. TYPE SPECIES: *Micheliopsis kachirachirai* (Kaneh. & Yamam.) H. Keng = *Magnolia kachirachirai* (Kaneh. & Yamam.) Dandy.

*Dugandiodendron* Lozano-Contreras, Caldasia 11: 33. 1975. TYPE SPECIES: *Dugandiodendron mahechae* Lozano.

Trees or shrubs, stipules adnate to or free from the petiole. Flowers terminal, solitary, bisexual. Tepals 9–21, 3–5-merous, subequal or more rarely the outer whorl forming a calyx. Anthers introrse to latrorse; connective produced into a longer or shorter appendage or rarely unappendaged. Gynoecium sessile or in some species stipitate; carpels many to few, usually free but not connate in *Magnolia* subg. *Talauma*, in young fruits of *Magnolia* sect. *Gynopodium*, and in some other species. Follicles free, crowded, dehiscent along the dorsal suture; in *Magnolia* subg. *Talauma* the basal parts of the mature carpels staying adnate to the torus, the apical parts falling and thus exposing the seeds which hang from the lengthened funiculus, sometimes the apical parts during or before falling dorsally dehiscing; in some species of *Magnolia* sect. *Gynopodium* the carpels are connate but tear apart when maturing and dehisce dorsally. Ovules generally two in each carpel, rarely 3 or 4 in the lower carpels, in a few species to 4 or 5 in all carpels. Ripe seeds often hanging from the funicles, which lengthen through uncoiling of the spiral vessels.

*Distribution.* About 120 species, of which ca. one-third grow in the New World from southeastern North America to southern Brazil and the West Indies, the remainder in temperate and tropical Southeast Asia from the Himalayas to China, Japan, and Malesia.

KEY TO THE SUBGENERA AND SECTIONS OF *MAGNOLIA*

1. Fruits at least finally consisting of free follicles, which dehisce along the dorsal suture; stipules free from the petiole or connate to it; anthers introrse, sublatrorse or latrorse; plant evergreen or deciduous; midrib of leaves usually impressed, rarely prominent above. ..... 2
1. Fruits with connate carpels, when mature the apical parts of them circumscissile and falling, dehiscing along the dorsal suture, the basal parts remaining attached to the torus; stipules adnate to the petiole up to its apex; anthers introrse; plant evergreen; midrib of leaves prominent for the whole length (in the absence of fruits this section cannot be distinguished from section *Gwillimia*). ..... **Ic.** Subgenus *Talauma* **1.** Section *Blumiana*

2(1). Anthers dehiscing laterally or sublaterally; flowers precocious and/or with a much reduced calyxlike outer whorl of tepals; plant deciduous; fruit cylindric or oblong, usually ± distorted. **Ib.** Subgenus *Yulania*. ..... 3
2. Anthers dehiscing introrsely; flowers neither precocious nor with a much reduced (calyxlike) outer whorl of tepals; plant evergreen or deciduous. **Ia.** Subgenus *Magnolia*. ..... 5

3(2). Tepals subequal; flowers appearing before the leaves, white to rose or purple. ..... **Ib-1.** Section *Yulania*
3. Tepals very unequal, those of the outer whorl forming a calyx; flowers appearing before, together, or after the leaves. ..... 4

4(3). Flowers appearing before the leaves; inner (large) tepals white, sometimes tinged with rose or purple. ..... **Ib-2.** Section *Buergeria*
4. Flowers appearing together or after the leaves; inner tepals purple or green to yellow. ..... **Ib-3.** Section *Tulipastrum*

5(2). Stipules adnate to the petiole, leaving a scar on its surface; plants evergreen or deciduous; gynoecium sessile. ..... 6
5. Stipules free from the petiole, the latter unscarred; plants evergreen; gynoecium stipitate. ..... 8

6(5). Plants evergreen; flower buds at first enclosed in one or more spathaceous bracts, which leave as many annular scars on the peduncle. ..... **Ia-1.** Section *Gwillimia*
6. Plants deciduous; flower buds at first enclosed in a single spathaceous bract, which leaves a single annular scar on the peduncle. ..... 7

7(6). Leaves crowded into false whorls at the ends of the twigs, usually large or very large; connective of anthers produced into a short or long appendage. .. **Ia-2.** Section *Rytidospermum*
7. Leaves not crowded into false whorls at the end of the twigs; connective of anthers not produced into an appendage, blunt or retuse. ..... **Ia-3.** Section *Oyama*

8(5). Carpels usually with 2–5 ovules; flowers bisexual; fruits cylindrical, 1–4 seeds in each follicle; stamens with short filament and very long anther, hiding the gynoecium; at least twigs hairy. ..... **Ia-5.** Section *Alcimandra*
8. Carpels usually with 2 ovules, rarely with 4;

flowers androdioecious; plant entirely glabrous; anthers much shorter. ..... **Ia-4.** Section *Gynopodium*

KEY TO THE SPECIES OF *MAGNOLIA*
(primarily based on floral characters)

1. Leaves crowded at the end of the branchlets in false whorls, glaucous beneath. ..... 2
1. Leaves evenly distributed. ..... 3
2(1). Twigs and stipules glabrous; young leaves with rather long, crisped brown hairs beneath, base rounded, apex mucronate; pedicle 13 mm; outer tepals oblong-elliptic; inner tepals 11–13 cm long; stamens 14–17 mm long; gynoecium cylindric. ..... 9. *Magnolia rostrata*
2. Twigs and stipules hairy; leaves scattered, colorless hairy beneath, base cuneate, apex rounded or acute; pedicle 2–6 mm; outer tepals obovate; inner tepals 8–10 cm long; stamens 30–40 mm long; gynoecium ovoid. ..... 8. *Magnolia officinalis*
3(1). Anthers dehiscing laterally or sublaterally. 4
3. Anthers dehiscing introrsely. ..... 13
4(3). Tepals very unequal, outer tepals 0.8–2.7 cm long. ..... 5
4. Tepals subequal, outer tepals 5–14 cm long. 7
5(4). Inner tepals 4–5 cm long; tree to 12 m high; outer tepals 8–11 mm. ..... 25. *Magnolia biondii*
5. Inner tepals 5.5–10 cm long; shrub or treelet to 3–10 m high; outer tepals 10–27 mm. ..... 6
6(5). Leaves glabrous to pubescent with long, undulate, colorless hairs beneath; leaf base attenuate-cuneate; flowers appearing together or after the leaves, purple or red; filaments 2 mm long; peduncle 6–8 mm thick ..... 29. *Magnolia quinquepeta*
6. Leaves with fine, straight, colorless hairs beneath; leaf base cuneate or narrowly cuneate; flowers appearing before the leaves, white; filaments 3 mm long; peduncle 4–5 mm thick. ..... 26. *Magnolia cylindrica*
7(4). Gynoecium 8–15 mm high. ..... 8
7. Gynoecium 20–40 mm high. ..... 9
8(7). Twigs yellow-, black-, or gray-brown; leaves not glaucous beneath, reticulation coarse; flower purple or red. ..... 22. *Magnolia sargentiana*
8. Twigs yellowish to green turning reddish brown; leaves glaucous beneath, reticulation fine; flower white. ..... 20. *Magnolia dawsoniana*
9(7). Peduncle 24–30 × 7–10 mm. ..... 19. *Magnolia campbellii*
9. Peduncle 2–20 mm long. ..... 10
10(9). Twigs hairy at least when young. ..... 21. *Magnolia heptapeta*
10. Twigs glabrous. ..... 11
11(10). Stamens 9–10 mm long; leaf apex acuminate or acute ..... 18. *Magnolia amoena*
11. Stamens 15–17 mm long; leaf apex rounded or short-acuminate. ..... 12
12(11). Filaments 4 mm long; shrub to 7 m high; terminal winter buds long-hairy, sericeous; nerves in 8–12 pairs; leaf base broadly cuneate or rounded; flowers appearing before the leaves, purple or red. ..... 24. *Magnolia zenii*
12. Filaments 5–7 mm long; tree up to 20 m high; terminal winter buds densely villous; nerves in 6–8 pairs; leaf base cuneate or narrowly cuneate; flowers appearing together or after the leaves, white. ..... 23. *Magnolia sprengeri*
13(3). Stipules free; gynoecium stipitate. ..... 14
13. Stipules adnate to petiole; gynoecium not stipitate. ..... 20
14(13). Gynoecium exserted from stamens. ..... 15
14. Gynoecium entirely hidden within androecium. ..... 17
15(14). Peduncle 3–4 mm thick; leaves elliptic or obovate, base cuneate. ..... 14. *Magnolia kachirachirai*
15. Peduncle 5–6 mm thick; leaves ovate or narrowly elliptic, base broadly cuneate, narrowly cuneate, or rounded ..... 16
16(15). Midrib of leaf not prominent above; leaves narrowly elliptic, base narrowly cuneate; connective appendage 1.5 mm long; filaments 7 mm; outer tepals oblong. ..... 16. *Magnolia omeiensis*
16. Midrib of leaf prominent above, at least toward base; leaves ovate, base broadly cuneate or rounded; connective appendage 2–4 mm long; filaments 1–3 mm; outer tepals obovate or spathulate. ..... 15a. *Magnolia nitida* var. *nitida*
17(15). Outer tepals 5.5–6 cm long; plant hairy at least in innovations; twigs hairy at least when young; stipules pubescent; leaf base broadly cuneate or rounded, reticulation of leaf fine; petiole hairy; peduncle 2 mm thick; inner tepals 5.5 cm long, 25 mm broad. ..... 17. *Magnolia cathcartii*
17. Outer tepals 2.5–3.8 cm long; plant entirely glabrous; leaf base cuneate or narrowly cuneate, reticulation of leaf coarse; peduncle 5–9 mm thick; inner tepals 2.2–4.2 cm long, 1.2–18 mm broad. ..... 18
18(17). Outer tepals 3.8 cm long; leaf base narrowly cuneate, midrib not prominent above; outer tepals oblong; inner tepals 3.5–4.2 cm long. ..... 16. *Magnolia omeiensis*
18. Outer tepals 2.5–3 cm long; leaf base cuneate, midrib prominent above, at least toward base; outer tepals ovate; inner tepals 2.2–3 cm long. ..... 19
19(18). Nerves in 8–15 pairs; reticulation distinct; connective appendage 0.5 mm long; gynoecium narrowly ovoid; scars of perianth and stamens along torus under fruit 6–7 mm long; fruiting twigs ca. 8 mm thick. ..... 15c. *Magnolia nitida* var. *robusta*
19. Nerves in 9–13 pairs; reticulation rather obscure; connective appendage 2–4 mm long; gynoecium ovoid; scars of perianth and stamens along torus under fruit 2–4 mm long; fruiting twigs 4–6 mm thick. ..... 15b. *Magnolia nitida* var. *lotungensis*
20(13). Gynoecium hairy; reticulation fine. ..... 21

20. Gynoecium glabrous; reticulation coarse. 23
21(20). Carpels 55–64; twigs densely appressed, yellow, woolly; leaf base acute to rounded, rarely cordate; gynoecium ovoid. ..... 4. *Magnolia delavayi*
21. Carpels 15–24; twigs pubescent or silky; leaf base broadly to narrowly cuneate; gynoecium narrowly ovoid or ellipsoid. ..... 22
22(21). Leaves not glaucous beneath; twigs colorless to yellowish pubescent; peduncle slender; connective appendage triangular; gynoecium ellipsoid; follicles glabrous. ..... 2. *Magnolia championii*
22. Leaves glaucous beneath; twigs silky; peduncle stout; connective appendage short-pointed; gynoecium narrowly ovoid; follicles hairy. ..... 1. *Magnolia albosericea*
23(20). Peduncle hairy; plant deciduous; connective of anther not produced into an appendage, retuse or blunt. ..... 24
23. Peduncle glabrous; plant evergreen; connective produced into a short or long appendage. ..... 27
24(23). Gynoecium 23–25 mm high. ..... 10. *Magnolia globosa*
24. Gynoecium 13–20 mm high. ..... 25
25(24). Leaves not glaucous beneath; leaf apex rounded or mucronate; pedicle 13–17 mm; inner tepals ovate. ..... 12. *Magnolia sinensis*
25. Leaves glaucous beneath; leaf apex acuminate or acute; pedicle 2–7 or 8–15 mm; inner tepals obovate, spathulate, or oblong. 26
26(25). Leaves ovate or narrowly ovate; twigs villous; stipules silky; reticulation coarse but distinct; outer tepals elliptic; filaments 2 mm long; gynoecium ovoid or cylindric; fruiting peduncles 3–4.5 cm long. ..... 13. *Magnolia wilsonii*
26. Leaves obovate; twigs pubescent; stipules pubescent or sparsely hairy; reticulation rather obscure; outer tepals obovate; filaments 3 mm long; gynoecium ellipsoid; fruiting peduncles 6.2–7 cm long. ..... 11. *Magnolia sieboldii*
27(23). Leaves 2.5–5 cm broad, midrib not prominent above; petiole 5–15 mm; peduncle 14–20 mm long. ..... 3. *Magnolia coco*
27. Leaves 8–22 cm broad; midrib prominent above at least toward base; petiole 25–110 mm; peduncle 23–120 mm long. ..... 28
28(27). Plant hairy at least in innovations. ..... 29
28. Plant glabrous. ..... 30
29(28). Pedicle absent; connective appendage 3 mm long; filaments 3 mm long; gynoecium ellipsoid; fruits with connate carpels, when mature the apical parts of the carpels circumscissile and falling, dehiscing along the dorsal suture or not, the basal parts remaining adnate to the torus; fruits ellipsoid. ..... 30. *Magnolia candollii* var. *obovata*
29. Pedicle present; connective appendage 1 mm long; filaments 1–2 mm long; gynoecium narrowly ovoid; fruits ovoid to ovoid-cylindric, at least finally consisting of free carpels which dehisce along the dorsal suture. ..... 5. *Magnolia henryi*
30(28). Peduncle 5–13 mm thick; tree to 25 m high; leaf apex rounded or short-acuminate; outer tepals thick-fleshy; gynoecium ellipsoid. ..... 30. *Magnolia candollii* var. *obovata*
30. Peduncle 4 mm thick; shrub to 3 m high; leaf apex acuminate; outer tepals thin-coriaceous; gynoecium narrowly ovoid. ..... 6. *Magnolia phanerophlebia*

## Key to the Species of *Magnolia*
(primarily based on fruit characters)

1. Fruits with connate carpels, when mature the apical parts of the carpels circumscissile and falling, dehiscing along the dorsal suture or not, the basal parts remaining adnate to the torus. ..... 2
1. Fruits at least finally consisting of free carpels which dehisce along the dorsal suture. 3
2(1). Tree to 25 m high; apex of leaf rounded or short-acuminate; peduncle 5–13 mm thick. ... 30. *Magnolia candollii* var. *obovata*
2. Shrub or treelet to 3 m high; apex of leaf acuminate; peduncle 4 mm thick (fruits not known). ..... 6. *Magnolia phanerophlebia*
3(1). Stipules free; gynoecium stipitate. ..... 4
3. Stipules adnate to petiole; gynoecium not stipitate. ..... 10
4(3). Midrib of leaf not prominent above. ..... 5
4. Midrib of leaf, at least toward base, prominent above. ..... 7
5(4). Twigs hairy at least when young; stipules pubescent; base of leaf broadly cuneate or rounded, apex acuminate, reticulation distinct, fine, petiole hairy. ..... 17. *Magnolia cathcartii*
5. Twigs and stipules glabrous; base of leaf cuneate or narrowly cuneate, apex short-acuminate or acute, reticulation rather obscure, coarse, petiole glabrous. ..... 6
6(5). Leaves narrowly elliptic, base narrowly cuneate (fruits not known). ..... 16. *Magnolia omeiensis*
6. Leaves elliptic or obovate, base cuneate. ... 14. *Magnolia kachirachirai*
7(4). Leaves ovate. ..... 8
7. Leaves elliptic or narrowly elliptic. ..... 9
8(7). Leaves 7–16.5 cm long, reticulation distinct, base cuneate, apex rounded, acuminate, or acute, petiole 16–47 mm; fruiting twigs ca. 8 mm thick. ..... 15c. *Magnolia nitida* var. *robusta*
8. Leaves 6–12(–14) cm long, reticulation rather obscure, base broadly cuneate or rounded, apex short-acuminate, petiole 15–25 mm; fruiting twigs 5–6(–8) mm thick. ..... 15a. *Magnolia nitida* var. *nitida*
9(7). Fruiting twigs ca. 8 mm thick; leaves 7–16.5 cm long, reticulation distinct, petiole 16–47 mm; scars of perianth and stamens along torus under fruit 6–7 mm long. ..... 15c. *Magnolia nitida* var. *robusta*
9. Fruiting twigs 4–5(–6) mm thick; leaves 6–11 cm long, reticulation rather obscure, petiole 15–20 mm; scars of perianth and stamens along torus under fruit 2–4 mm long. .. 15b. *Magnolia nitida* var. *lotungensis*

10(3). Leaves crowded in false whorls terminal on the branchlets. ..... 11
10. Leaves evenly distributed. ..... 12
11(10). Twigs glabrous; stipules glabrous; young leaves beneath with brown hairs, base rounded, apex mucronate; pedicle 13 mm; fruit cylindric, 12–20.5 cm long, follicles with a beak of 6–8 mm. ..... 9. *Magnolia rostrata*
11. Twigs hairy at least when young; stipules sparsely hairy; young leaves beneath with colorless hairs, base cuneate, apex rounded or acute; pedicle 2–6 mm; fruit usually oblong-ovoid, 8–16 cm long, follicles with a beak of 1–3 mm. 8. *Magnolia officinalis*
12(10). Follicles hairy. ..... 13
12. Follicles glabrous. ..... 14
13(12). Twigs, stipules, and leaves glabrous, leaves not glaucous beneath, midrib at least toward base prominent above, reticulation coarse, petiole dilated at base; peduncle glabrous, 25 mm long, 4 mm thick; carpels 11 (fruits not known). 6. *Magnolia phanerophlebia*
13. Twigs hairy at least when young; stipules silky; leaves hairy beneath at least when young, glaucous beneath, midrib not prominent above, reticulation fine, petiole hairy, not dilated at base; peduncle hairy, 15 mm long, 6 mm thick; carpels 22. ..... 1. *Magnolia albosericea*
14(12). Leaves glaucous beneath. ..... 15
14. Leaves not glaucous beneath. ..... 19
15(14). Fruiting peduncles 6.2–7 cm long. ..... 16
15. Fruiting peduncles 1–4.5 cm long. ..... 17
16(15). Leaves elliptic or ovate, reticulation distinct; nerves in 8–11 pairs; stipules yellowish silky or brown-villous; fruits 2.5–9 × 2–2.5 cm. ..... 10. *Magnolia globosa*
16. Leaves obovate, reticulation rather obscured; nerves in 6–8 pairs; stipules pubescent or sparsely hairy; fruits 3–4 × 1.2–1.7 cm. ..... 11. *Magnolia sieboldii*
17(15). Fruiting peduncles 2–3 mm thick; stipules silky, reticulation of leaf coarse; stipular scars on petiole 10–25 mm long. ..... 13. *Magnolia wilsonii*
17. Fruiting peduncles 8–10 mm thick; stipules woolly, pubescent, or villous, reticulation of leaf fine, stipular scars 3–65(–85) mm long. 18
18(17). Evergreen tree; twigs and stipules densely appressed-woolly with yellowish hairs; pairs of lateral nerves of leaf 11–16(–21), petiole 45–65(–85) mm with stipular scar 40–65(–85) mm long; fruits ovoid. ..... 4. *Magnolia delavayi*
18. Deciduous tree; twigs glabrous to sparsely pubescent; stipules pubescent, pairs of lateral nerves of leaf 8–10, petiole 15–30 mm with stipular scar 3–4 mm long; fruits cylindric. ..... 20. *Magnolia dawsoniana*
19(14). Fruiting peduncles 2.5–9.5 cm long. ..... 20
19. Fruiting peduncles 1–2 cm long. ..... 27
20(19). Leaves 26–38(–65) cm long, midrib prominent above, at least toward base. ..... 21
20. Leaves 7–23 cm long, midrib not prominent above. ..... 22
21(20). Tree to 20 m high; plant hairy at least in innovations; stipules pubescent, stipular scars 55–110 mm long; apex of leaf rounded or acute; peduncle 6–10 mm thick; fruits ovoid to ovoid-cylindric, 7.5–14.5 × 3.5 cm. ..... 5. *Magnolia henryi*
21. Shrub to 3 m high; plant entirely glabrous; stipular scars 7–25 mm long, apex of leaf acuminate; peduncle 4 mm thick (fruits not known). ..... 6. *Magnolia phanerophlebia*
22(20). Peduncle 21–65 mm long. ..... 23
22. Peduncle 2–20 mm long. ..... 25
23(22). Shrub or tree to 5 m high; stipular scars 20–30 mm long; fruiting peduncles slender. ..... 12. *Magnolia sinensis*
23. Tree to 20–30 m high; stipular scars 2–7 mm long; fruiting peduncles stout. ..... 24
24(23). Twigs yellow-brown or black-brown to gray-brown, glabrous; petiole glabrous, stipular scars 2–5 mm long; fruits 3–20.5 cm long; flower purple or red; gynoecium 8–12 mm high. ..... 22. *Magnolia sargentiana*
24. Twigs purple-brown, sometimes brown to gray when dry, glabrous or pubescent; petiole glabrous or yellowish pubescent, stipular scars 3–7(–11) mm long; fruits 8.5–17 cm long; flower pink or white; gynoecium 25–40 mm high. ..... 19. *Magnolia campbellii*
25(22). Plant an entirely glabrous evergreen shrub, leaf apex acuminate; fruit ca. 3 cm long. ..... 3. *Magnolia coco*
25. Plant hairy at least in innovations, a deciduous tree, leaf apex rounded, short-acuminate, or acute; fruit 3–20.5 cm long. 26
26(25). Treelet to 7 m high; petiole hairy; leaf apex short-acuminate; peduncle 2–8 mm long. ..... 24. *Magnolia zenii*
26. Tree to 20 m high; petiole glabrous; leaf apex rounded or acute; peduncle under fruit 20–35 mm long. 22. *Magnolia sargentiana*
27(19). Twigs hairy at least when young. ..... 28
27. Twigs glabrous. ..... 33
28(27). Evergreen tree; fruits ovoid-elliptic; hairs colorless or yellowish. ..... 2. *Magnolia championii*
28. Deciduous tree; fruits cylindric, hairs colorless. ..... 29
29(28). Leaves appressed-pubescent with fine, short, straight hairs. ..... 26. *Magnolia cylindrica*
29. Young leaves different hairy beneath. ..... 30
30(29). Leaves obovate. ..... 31
30. Leaves elliptic, ovate, narrowly elliptic, or narrowly obovate. ..... 32
31(30). Shrub to 3.5 m high; twigs 2–4 mm diam., glabrous or sometimes hairy on a few nodes near the peduncles; leaf base attenuate-cuneate, apex acuminate or acute; fruits 3–6.5 × 1–2 cm. ..... 29. *Magnolia quinquepeta*
31. Tree to 20 m high; twigs 3–7 mm diam., finely appressed-pubescent when young; leaf base cuneate or rounded, apex short-acuminate; fruits 7.5–15 × 2.5–5 cm. ..... 21. *Magnolia heptapeta*

32(30). Shrub to 3.5 m high; leaves elliptic, base attenuate-cuneate; fruits 3–6.5 cm long. ..... 29. *Magnolia quinquepeta*
32. Tree to 12 m high; leaves ovate, narrowly elliptic, or narrowly obovate, base cuneate or rounded; fruits 6–14.5 cm long. ..... 25. *Magnolia biondii*
33(27). Leaves 31–36 × 9.5–17 cm. ..... 6. *Magnolia phanerophlebia*
33. Leaves 6–21.7 cm long. ..... 34
34(33). Plant evergreen, entirely glabrous. ..... 3. *Magnolia coco*
34. Plant deciduous, hairy at least in innovations. ..... 35
35(34). Leaf apex rounded or short-acuminate. ..... 36
35. Leaf apex acuminate or acute. ..... 37
36(35). Treelet to 7 m high; leaf base broadly cuneate or rounded; nerves in 8–12 pairs; petiole 6–15 mm; fruits 5–20 cm long; flowers appearing before the leaves. ..... 24. *Magnolia zenii*
36. Tree to 20 m high; nerves in 6–8 pairs; leaf base (narrowly) cuneate; petiole 10–35 mm; fruits 6–10 cm long; flowers appearing together or after the leaves. ..... 23. *Magnolia sprengeri*
37(35). Fruiting peduncles 4.1–6 mm thick. ..... 38
37. Fruiting peduncles 3–4 mm thick. ..... 39
38(37). Shrub to 3.5 m high; leaves elliptic or obovate, base attenuate-cuneate; stipular scars the entire length of the petiole; fruits 3–6.5 cm long; flowers appearing together or after the leaves. ..... 29. *Magnolia quinquepeta*
38. Tree to 12 m high; leaves ovate, narrowly elliptic, or narrowly obovate, base cuneate or rounded; stipular scar only at the base of the petiole; fruits 6–14.5 cm long; flowers appearing before the leaves. ..... 25. *Magnolia biondii*
39(37). Shrub to 3 m high; stipular scars as long as petiole, 3–15 mm long; leaf with 8–10 pairs of lateral nerves, base attenuate-cuneate; flowers appearing together or after the leaves. ..... 29. *Magnolia quinquepeta*
39. Tree to 12 m high; stipular scars adnate to base of petiole, 1–3 mm long; leaf with 10–13 pairs of lateral nerves, base cuneate, somewhat oblique; flowers appearing before the leaves. ..... 18. *Magnolia amoena*

## Ia. **Magnolia** subgenus **Magnolia**

Anthers dehiscing introrsely. Flowers neither precocious nor with a much reduced (calyxlike) outer whorl of tepals. Leaves evergreen or deciduous.

### Ia-1. **Magnolia** section **Gwillimia** A. DC., Syst. Nat. 1: 455, 548. 1817. TYPE SPECIES: *Magnolia coco* (Lour.) DC.

Evergreen shrub or tree. Stipules adnate to petiole to its apex. Leaves evenly distributed; midrib prominent above, at least toward base, or not prominent above. Flowers bisexual; tepals subequal. Outer tepals coriaceous; connective produced into a short or long appendage; anthers dehiscing introrsely. Gynoecium not stipitate. Number of ovules per carpel 2, sometimes 4 in the lower carpels. Scars of bracts 1–4. Fruits at least finally consisting of free follicles, which dehisce along the dorsal suture; follicles short-beaked, beak not dorsally flattened.

KEY TO THE SPECIES OF *MAGNOLIA* SECTION *GWILLIMIA*

1. Gynoecium hairy; reticulation of leaf fine. ..... 2
1. Gynoecium glabrous; reticulation of leaf coarse. 4
2(1). Leaves not glaucous beneath; twigs colorless to yellowish pubescent; peduncle slender; gynoecium ellipsoid. ..... 2. *Magnolia championii*
2. Leaves glaucous beneath; twigs white silky or yellowish woolly; peduncle stout; gynoecium ovoid or narrowly ovoid. ..... 3
3(2). Petiole 4–8.5 cm long; carpels 55–64; twigs and stipules yellowish woolly; leaf base acute to cordate, apex acute; outer tepals oblong; connective appendage of anthers triangular; gynoecium ovoid, fruits ovoid, follicles glabrous. ..... 4. *Magnolia delavayi*
3. Petiole 1–3.5 cm long; carpels ca. 22; twigs and stipules silky; leaf base cuneate or narrowly cuneate, apex acuminate; outer tepals elliptic; connective appendage of anthers short pointed; gynoecium narrowly ovoid; fruits obovoid or ellipsoid; follicles hairy. ..... 1. *Magnolia albosericea*
4(1). Leaves 10–17 cm long, 2.5–5 cm broad, midrib not prominent above, pairs of lateral nerves 8–10; petiole 5–15 mm; peduncle 14–20 mm long; gynoecium ellipsoid. ..... 3. *Magnolia coco*
4. Leaves 26–38 cm long, 8–17 cm broad, midrib prominent above, at least toward base, pairs of lateral nerves 13–20; petiole 30–110 mm; peduncle 23–50 mm long; gynoecium narrowly ovoid. ..... 5
5(4). Peduncle 6–10 mm thick; tree to 20 m high, hairy at least in innovations; stipules pubescent; apex of leaf rounded or acute; stipular scars 55–110 mm long. ..... 5. *Magnolia henryi*
5. Peduncle 4 mm thick; shrub to 3 m high, entirely glabrous, apex of leaf acuminate, stipular scars 7–25 mm long. ..... 6. *Magnolia phanerophlebia*

1. **Magnolia albosericea** Chun & C. H. Tsoong. Acta Phytotax. Sin. 9(2): 117. 1964. TYPE: China. Hainan: Poting, *F. C. How 72740* (holotype, IBSC; isotype, A).

Evergreen treelet to 8 m high; bark gray; young twigs, stipules, leaves beneath, midrib both sides, petioles, bracts, peduncles, and tepals outside white-sericeous, glabrescent; gynoecium yellow pubescent; young twigs ca. 4 mm diam. Stipules adnate

to the petiole, stipular scars nearly to the base of the blades, 9–34 mm long. Leaves coriaceous, dark green above, glaucous below, elliptic, narrowly elliptic or narrowly obovate-elliptic, 18–30(–40) × 6–9(–15) cm; apex acuminate, base cuneate to narrowly cuneate; midrib impressed above, prominent beneath; nerves fine, prominent below, in 15–20 pairs, reticulations finely netted, visible on both sides. Petiole 1–3.5 cm long. Peduncle ca. 1.5 × 0.6 cm. Tepals 9, the outer 3 long-elliptic, greenish, white sericeous outside at the midrib and the base, 4.5–5.5 × 1.3–2.5 cm, the inner tepals 6, very unequal, the innermost ones smaller than the others, spathulate-elliptic to broadly obovate, usually constricted basally into a short claw, 3–6.2 × 1.8–3.4 cm; stamens ca. 120, 1.5–2 cm long, anthers introrsely dehiscing, 6–8 mm long, connective appendage short-acute; gynoecium narrowly ovoid, ca. 20 mm high, carpels ca. 22, 8–13 mm long. Fruits ellipsoid to obovoid, 7–10 × 4–5 cm; mature carpels coriaceous, narrowly elliptic, brownish pubescent with short hairs and inconspicuously papillate, 2–2.5 cm long, beak recurved, 5–7 mm long. Seeds 14 × 6 mm.

*Distribution.* China and Vietnam. In CHINA: **Hainan, Baoting, Lingshui**: *Feng K.M. 72059; Zheng P. 12506; How F.C. 72059; 72740.*

*Ecology.* In evergreen broad-leaved forests along streams. Altitude: 500–800 m. Flowering April–May, fruiting August–September.

*Collector's notes.* Bark gray; leaves deep green, lustrous above, glaucous, green beneath; fruits green.

*Notes.* This species was treated as *Magnolia fistulosa* (Finet & Gagnep.) Dandy in W. Y. Chun (1963) and as *Magnolia champacifolia* Dandy ex Gagnep., nomen nudum, in Humbert (1938).

2. **Magnolia championii** Benth., Fl. Hongkong: 8. 1861. *Magnolia pumila* var. *championii* Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 36. 1905. *Magnolia lilifera* var. *championii* Pamp., Bull. Soc. Tosc. Ortic. 4(1): 136. 1916. TYPE: *Champion 37* (holotype, K).

*Magnolia tenuicarpella* Chang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 54. 1961. TYPE: *McClure 20099* (holotype, SYS).

*Magnolia odoratissima* Law & R. Z. Zhou, Bull. Bot. Res. (China), 6, 2: 139. 1986. TYPE: *R. Z. Zhou 0054* (holotype, IBSC).

Evergreen shrub or small tree to 11 m high; young twigs 3–5 mm diam., yellow-green, brown when dry, smooth, at first colorless to yellowish appressed-pubescent, finally glabrescent, or glabrous. Stipules adnate to the petiole, stipular scars to halfway to whole length of the petiole, 3–30 mm long. Leaves dark bright green, olive-green, to brown when dry, glabrous or pubescent with scattered hairs that are too minute to be visible above, somewhat pale green, glabrous or pubescent with long, straight, white, yellowish to brownish hairs, especially on the midrib and nerves beneath, thinly coriaceous to coriaceous, elliptic, narrowly obovate-elliptic to obovate, 8–17.5(–30) × 3.5–7(–10.5) cm; apex acute or acuminate to cuspidate with a 1.5–2.5-cm-long tip, base narrowly to broadly cuneate; midrib impressed above, nerves fine, prominent below when dry, in 8–14(–16) pairs, straight, anastomosing and meeting in a looped intramarginal vein at some distance from the margin, reticulations densely netted, visible on both sides. Petiole pubescent or glabrous, erect to slightly recurved, 6–30 mm long. Peduncles glabrous or yellowish pubescent, erect or slightly curved, 1–2(–4) × 0.3–0.5 cm, pedicles 3–4 mm long; bracts 2–3, white or yellowish pubescent outside. Flowers heavily fragrant; tepals 9, the outer 3 thinly coriaceous, greenish, oblong-elliptic to obovate, 3.5–6 × 2–3 cm, the inner tepals 6, white, broadly obovate to obovate-spathulate, basally with a short claw, fleshy, 4–5 × 2–4.5 cm; stamens white, 7–15 mm long, anthers dehiscing introrsely, connective appendage triangular, ca. 1 mm long, filaments 1–1.5 mm long; gynoecium ellipsoid, 1.5–2 × 0.5–0.8 cm, carpels 15–24, densely yellow pubescent, 8–10 mm or longer. Fruiting peduncles 14–17 × 3.5–5.5 mm, pedicles ca. 4 mm long. Fruits ovoid-elliptic, 4–6 cm long, ripe carpels 1–3 cm long, apex with a 2–3-mm-long beak; scars of perianth and stamens 5–7 × 5–7 mm. Seeds narrowly oblong or irregularly ovate, ca. 8–9 mm long.

*Distribution.* China and Vietnam. In CHINA. **Southern and southwestern Guangdong**: Ding Hu Shan, *Ting K.C. & K.L. Shi 1590*; Mao Ming, *Tang L. s.n.*; Shi Wan Da Shan, *Liang H.Y. s.n.* **Guangxi**: Da Ming Shan, *Chun S.H. 12003, Chen B.L. 86 G 7, Chen M.L. 3-5535, Cai C.X. 5465 29-V*; Dong Xing Xian, *Li T.Z. 1458*; Huan Jiang Xian, *Huan Jiang Exped. 4-3-1459.* **Guizhou**: Du Shan Xian, *Li Bo Exped. 1170.*

*Ecology.* In evergreen broad-leaved forests. Altitude: 400–1,000 m. Flowering May–June; fruiting September–October.

*Uses.* Tree cultivated as an ornamental.

*Notes.* *Magnolia championii* is quite variable in habit, shape, and size of the leaves, measurement of the flowers, and number of the carpels. We doubted at first whether the species mentioned above were conspecific. However, after carefully comparing type specimens and other collections, we came to the conclusion that they are indeed. In fact, the differences are related to the distribution: in Guangdong the species usually is a shrub with smaller flowers and leaves that are somewhat cuspidate at the apex; in Hainan the species possesses relatively narrow, long leaves with a seemingly impressed midrib and nerves; in Yunnan it has broader leaves and bigger flowers. Finally, the Vietnamese *Magnolia fistulosa* and *Magnolia talaumoides* should be mentioned. The former is similar to *Magnolia championii* in all characters except its larger leaves and greater number of carpels. The latter differs from *Magnolia championii* by its glabrous twigs, leaves, and peduncles. There are arguments to support treating *Magnolia talaumoides* as a variety of *Magnolia championii*, but for the moment we refrain from that.

*Magnolia championii* was misidentified as *Talauma pumila* (Andr.) Blume by Champion (1851) and included in *Magnolia pumila* Andr. by F. Forbes & Hemsley (1886). It was included in *Magnolia coco* (Lour.) DC. by Rehder & E. Wilson (1913) and Merrill (1923).

3. **Magnolia coco** (Lour.) DC., Syst. Nat. 1: 459. 1817. *Liriodendron coco* Lour., Fl. Cochinch.: 347. 1790. *Talauma coco* (Lour.) Merr., Sp. Blancoan.: 12. 1918. TYPE: *Loureiro* (not seen).

*Magnolia pumila* Andr., Bot. Repos. 4: t. 226. 1802. *Talauma pumila* (Andr.) Blume, Fl. Javae, Magnoliaceae: 38, t. 12c. 1828. *Liriopsis pumila* (Andr.) Spach ex Baillon, Adansonia 7: 4. 1866. TYPE: t. 226 (Andr., 1802).

Evergreen shrub to small tree 2–4 m high; plant glabrous; bark gray; twigs shining green, brown-yellow when dry, smooth, ± angular. Stipules adnate to high on the petiole, stipular scars nearly up the entire length of the petiole, 5–15 mm. Leaves coriaceous, dark glossy green, usually olive green when dry above, greenish beneath, elliptic, narrowly elliptic, ovate-elliptic, to obovate-elliptic, 10–17 × 2.5–5 cm; apex long-acuminate, sometimes acute, base cuneate to broad-cuneate; margin slightly undulate; midrib not prominent on the upper surface; nerves in 8–10 pairs, curved upward and meeting in an intramarginal vein at some distance from the margin, reticulation coarsely netted, nerves and reticulation yellow to brown and prominent on the under surfaces. Petiole 5–15 mm long. Peduncles gray-black when dry, covered with a waxy substance, pendulous, with 3 bract scars, 1.4–2 cm long, pedicles 2–3 × 3–4 mm. Flowers nodding, subglobose, 3–4 cm diam., heavily scented, usually opening in the night; tepals 9, unequal, obovate, dorsal faces convex, the outer 3 greenish, thin coriaceous, 2–2.6 × 1.2–1.7 cm, the inner tepals 6, white, fleshy, oblong to obovate-oblong, 3–4 × 4 cm; stamens white, 5–7 mm long, anthers dehiscing introrsely, filaments 1.5–2 mm long, connective appendage rounded to acute; gynoecium obovoid-ellipsoid, ca. 1 × 0.7 cm, carpels 8–12, 5–6 mm long, styles short, torus with the scars of perianth and stamens 4–5 × 3–5 mm. Fruits can be seen occasionally, ca. 3 cm long, ripe carpels subligneous.

*Distribution.* China and northern Vietnam. In CHINA. **Fukien, Kushan**: *Chung H.H. 779; 8492.* **Guangdong**: Canton, *Gaudichaud Voy. sur la Bon 232*; Lofoushan, *Tsiang Y. 1757*; Lokchong, *Tso C.L. 20671*; Shiuchow, *To Kang Peng CCC herb. 2856*; Ting Wu Shan, *Chun W.Y. 6481 A.* **Guangxi**: He Pu, *Liang C.F. 33243.* **Guizhou**: *Esquirol 3061.* **Zhejiang**: Wenchow, *Ching R. C. 1904.* HONGKONG: *Kit Yock Chan 1352, Chun W.Y. 4520, Hu S.Y. 5393, 10194, 10201.* Also in Fujian anad Taiwan. Cultivated in Southeast Asia.

*Ecology.* In evergreen broad-leaved forest. Altitude: 600–900 m. Flowering April–October.

*Uses.* Used for medicinal purposes and to extract volatile oil; also grown as an ornamental.

*Note.* No original Loureiro specimen has been traced.

4. **Magnolia delavayi** Franchet, Pl. Delavay: 33, tt. 9–10. 1889. TYPE: *Delavay 2231* (holotype, P).

Evergreen tree to 18 m high and 25 cm diam., bark black-gray, becoming yellow-gray when dry, rough, fissured; young twigs dull green, densely appressed-woolly with yellowish hairs, provided with obvious orbicular and punctiform lenticels, old ones black-brown and glabrescent. Stipules covered with

same indumentum as young twigs, adnate to high on the petiole, stipular scars nearly to the end of the petiole, 4–6.5(–8.5) cm long. Leaves coriaceous, green, pubescent, glabrescent above, glaucous, densely appressed-woolly with curly, yellow hairs to glabrescent beneath, ovate, narrowly ovate to elliptic, 14.5–26(–30) × 7–15.5(–18) cm; apex acute, occasionally retuse, base acute to rounded, rarely cordate; midrib and nerves conspicuously elevated below, nerves in 11–16(–21) pairs, reticulation densely netted, prominent on both sides. Petiole at first densely yellowish pubescent, later glabrescent, 4–6.5(–8.5) cm long. Peduncles stout, pubescent, glabrescent, 1.2–2.5 × 0.7–0.9 cm, pedicle short, 1–5 mm long. Flowers slightly fragrant, usually fading one day after opening, creamy white, 15–20 cm diam., tepals 9(or 10), the outer 3 thin coriaceous, greenish, oblong, 6–8(–10) × 2.5–3(–4) cm, reflexed later, the inner tepals 6, white, spathulate obovate, fleshy, 7–9.5(–11) × 3–5 cm, the innermost tepals 3, usually erect and then enclosing androecium and gynoecium; stamens 1.5–2 cm long, anthers dehiscing introrsely, connective appendage triangular, 1.5–4 mm long, filaments 1–2 mm long; gynoecium ovoid, 1.5–2.2 × 1–1.2 cm, carpels 55–64, yellowish pubescent basally. Fruiting peduncles 1–4 × 0.8–1 cm, pedicles 2–5 × 8–10 mm. Fruits ovoid, 7–11 × 3–5 cm, ripe carpels narrowly elliptic, 2.5–4 cm long in the lower and 1.7–2 cm long in the upper carpels, with a 4–10-mm-long beak apically.

*Distribution.* CHINA. **Sichuan**: Hsiangyun distr., *Forrest G. 57*. **Yunnan**: throughout, Chenkang Hsien, *Forrest G. 27979*, *Wang C.W. 72469*; Yu long shan, Li kiang, *Wang C.W. 71760*; Huei-li Hsien, *Yu T.T. 1429*; Kien-shuei Hsien, *Tsai H.T. 53143*; Kouang yu ten (Langkong), *Delavay 2231*; Li-kiang Hsien, *Wang C.W. 71464*; Lunan Xian, Changhu, *Sino-Amer. Bot. Exped. 1630* and many other collections. Southwestern Guizhou.

*Ecology.* In broad-leaved forest. Altitude: 1,500–2,800 m. Flowering April–June; fruiting August–October.

*Uses.* Bark used for medicinal purposes, the tree as an ornamental.

5. **Magnolia henryi** Dunn, J. Linn. Soc. Bot. 35: 484. 1903. TYPE: *Henry 12782A* (lectotype, selected here, A; isolectotypes, E, MO, NY, US).

*Talauma kerrii* Craib, Kew Bull. 1922: 226. 1922. TYPE: *Kerr 5060* (K).

*Manglietia wangii* Hu, Bull. Fan. Mem. Inst. Biol. (Peiping) 8: 33. 1937. TYPE: *C. W. Wang 76888* (holotype, PE; isotypes, A, TIE).

Evergreen tree to 20 m high; young twigs brown-yellow, 5–7 mm diam., glabrous or sparsely yellowish pilose, smooth, ± angular. Stipules densely yellowish hairy, adnate to the petiole, scars up to the bases of the blades, 5.5–11 cm long. Leaves coriaceous, dark glossy green, glabrous above, green, glabrous or sparsely appressed-pubescent with straight, yellow-brown hairs beneath, obovate-oblong, oblong to ovate, 26–38(–65) × 8–13.5(–22) cm; apex rounded or acute, occasionally retuse, base cuneate, sometimes rounded; midrib and nerves prominently elevated below, nerves in 14–20 pairs; reticulation coarse, visible on both surfaces. Petiole glabrous or appressed-hairy, 5.5–11 cm long. Flower buds ovate; peduncles 2.3–5 × 0.6–1 cm, glabrous, usually recurved, covered with waxy substance, pedicles ca. 12 mm long; spathaceous bracts 2–3, glabrous; tepals 9, subsimilar, the outer 3 pale green outside, white inside, ovate-elliptic, the inner tepals 6, white, fleshy, obovate to spathulate, 5–6 × 2–3 cm; stamens 1.2–1.5 cm long, anthers introrsely dehiscing, connective appendage triangular, ca. 1 mm long, filaments 1–2 mm long; gynoecium long ovoid, 4–5 × 1.3–1.5 cm, carpels many; scars of perianth and stamens along the torus 1.5–1.7 × 1–1.3 cm. Fruiting peduncles 7–9.5 cm long × 7–10 mm. Fruits ovoid to ovoid-cylindric, 7.5–14.5 × 3.5 cm, ripe carpels 1.3–2 cm long, apically with beaks of 3–5 mm long. Seeds irregularly shaped, ca. 5–12 × 7 mm.

*Distribution.* China, Upper Burma, Thailand, Laos. In CHINA. **Southwestern Yunnan**: Xi Shang Ban Na, *Feng K.M. 22710*; Fo Hai, *Wang C.W. 76002*; Lang-tsang Hsien, *76518*; Lung-huk, Jenn-Yeh Hsien, *80116*; Meng Hai, *Li Y.H. 3607*; Meng La, *Tsai H.T. 59-10917*; Nan Chiao, *Wang C.W. 76888*; Szemoa, *Henry A 12782 A*.

*Ecology.* In evergreen broad-leaved forest. Altitude: 540–1,500 m.

*Collector's note.* Flowers white or ivory, very fragrant.

6. **Magnolia phanerophlebia** B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 107. 1988. TYPE: *B. L. Chen & C. N. Mai 87T001* (holotype, SYS).

Evergreen shrub or treelet ca. 3 m high and 6 cm diam., plant glabrous. Young twigs 5–7 mm diam., gray to yellow-gray when dry, terete, smooth. Stipules adnate to the base of the petiole, stipular scars 7–19(–25) mm long. Leaves coriaceous, dark green and shiny above, greenish beneath, obovate to elliptic, 31–34.5(–36) × 9.5–14(–17) cm; apex

acuminate, acumen 1–2 cm, base cuneate, decurrent with two ridges into the petiole; midrib conspicuously elevated beneath; nerves in (11–)13–17(–19) pairs, much impressed above, anastomosing and meeting in an intramarginal vein that is more prominent than the coarsely netted reticulation on both surfaces. Petiole obviously thickened toward its base, (1–)3–6(–7) cm. Peduncle recurved, ca. 2.5 × 0.4 cm; spathaceous bracts 3, one toward the base of peduncle and one at the base of perianth, the third at the middle of peduncle or higher. Tepals 8–9, subequal, the outer 3 greenish, thin coriaceous, the inner tepals 5–6, white, fleshy. Stamens numerous. Gynoecium narrowly ovoid, carpels ca. 11. Fruits not seen.

*Distribution.* CHINA. **Southeastern Yunnan**: Maguan, *Chen B.L. 87 T 1, 87 T 3.*

*Ecology.* In evergreen broad-leaved forest. Altitude 500–700 m.

*Notes.* The description is drawn from limited material with only flower buds. This species is quite similar to *Magnolia candollii* var. *obovata*, from which it differs by its shorter peduncles and fewer carpels. Because so far the mature flowers and fruits have not been gathered, we were unable to compare it with *Magnolia candollii* var. *obovata*; thus *Magnolia phanerophlebia* is temporarily maintained as a species here in section *Gwillimia*.

### Ia-2. **Magnolia** section **Rytidospermum**

Spach, Hist. Nat. Veget. Phanerog. 7: 474. 1839. TYPE: *Magnolia tripetala* L.

Deciduous trees. Stipules adnate to petiole. Leaves large, crowded at the end of the branchlets in false whorls; midrib not prominent above. Flowers bisexual; tepals subequal; connective produced into a short or long appendage; anthers dehiscing introrsely. Gynoecium not stipitate. Number of ovules per carpel 2, sometimes 4 in the lower carpels. Scars of bracts 1. Fruits at least finally consisting of free follicles, which dehisce along the dorsal suture.

KEY TO THE SPECIES OF *MAGNOLIA* SECTION *RYTIDOSPERMUM*

1. Twigs glabrous, yellow to purple-brown when dry ..... 2
1. Twigs densely appressed-hairy, soon glabrescent, yellow to yellowish gray, 8–14 mm diam.; filaments red, stout, 4 mm long. ..... 8. *Magnolia officinalis*
2. Twigs 6–8 mm diam., purple-brown, conspicuously supplied with semicircular to elliptic leaf scars; filaments crimson, ca. 12 mm long. ..... 7. *Magnolia hypoleuca*
2. Twigs 7–14 mm diam., yellow to purple-brown when dry, smooth, covered with a gray waxy substance; filaments 4–5 mm long. ..... 9. *Magnolia rostrata*

7. **Magnolia hypoleuca** Siebold & Zucc., Abh. Math.-Phys. Cl. Königl. Bayer. Akad. Wiss. 4(2): 187. 1845. TYPE: *L-908-126-1201* (L).

*Magnolia hypoleuca* [var.] *β concolor* Siebold & Zucc., Abh. Math.-Phys. Cl. Königl. Bayer. Akad. Wiss. 4, 2: 187. 1845. TYPE: *L-908-126-1103* (L).

Deciduous tree to 30 m high; bark gray, longitudinally fissured; young twigs 6–8 mm diam., purple-brown, glabrous, conspicuously supplied with semicircular to elliptic leaf scars; terminal winter buds large, ovoid-cylindric, ca. 4 cm long, glabrous and glaucous. Stipules glabrous, adnate to the base of the petiole, scars 1.5–2.5 cm long. Leaves crowded at the end of the twigs, thinly chartaceous, green, glabrous, sometimes pubescent along the midrib above, glaucous, pubescent with stout, long, crisped, colorless hairs everywhere as well as with slender, straight, colorless hairs along the midrib and nerves beneath, obovate, 20–38(–45) × 12–18(–20) cm; apex apiculate or short-acuminate, base broadly cuneate to obtuse; midrib and nerves prominently elevated below, nerves in 15–20 pairs, reticulation coarsely netted, obscured on both sides. Petiole glabrous to sparsely pubescent, lenticellate, 3–4.5 cm long. Flowers appearing after the leaves, cup-shaped, fragrant, 14–20 cm diam., peduncles glabrous, ca. 2.5 × 1 cm, pedicles ca. 5 × 8 mm; tepals 9–12, the outer 3 broadly oblong, greenish, pale reddish tinged, ca. 8 × 4 cm, the inner tepals 7–9, spathulate, creamy white, ca. 11 × 4.7 cm; stamens whitish, ca. 2.6 cm long, anthers introrsely dehiscing, connective appendage triangular, ca. 1 mm long, filaments crimson, ca. 12 mm long; gynoecium greenish, cylindric, ca. 3.5 × 1 cm, torus with the scars of perianth and stamens ca. 8 × 10 mm. Fruiting peduncles ca. 3.5 × 1 cm, pedicles 1.7 cm long. Fruits ovoid-cylindric, 12–13.5 × 4.5–6 cm; ripe carpels 1.5–2.5 cm long, apically with recurved beaks 5–10 mm long; scars of perianth and stamens along the torus ca. 2 × 1.2 cm.

*Distribution.* Native of Japan, cultivated in northern China.

*Uses.* Wood fine-textured, light and soft, generally used for construction work, furniture, musical instruments, and boards; tree grown as an ornamental because of its big and magnificent flowers.

*Note.* Ueda (1985, 1986) discussed the synonymy. For a long time the name *Magnolia obovata* Thunb., nom. illeg., was used, e.g., by Rehder & E. Wilson in Sargent (1913), Johnstone (1955), H. Hara (1977), Ohwi (1978), and Kitamura & Murata (1981) for this species. The species was named *Magnolia hoonoki*, nom. nudum, by Siebold (1830) and Millais (1927). More information on misapplied names used for this species follows here:

*Magnolia glauca* auct. non L.: Thunb. [var.] *β* Thunb., Fl. Jap.: 236. 1784b, only for the Japanese name Fo no Ki and the descr. *Magnolia obovata* [Thunb., Trans. Linn. Soc. London 2: 336. 1794a only for the Japanese name Fo no Ki and the descr. (*Thunberg 12885*, UPS) nom. illeg.; Mus. Nat. Acad. Upsal. 16: 137, sine descr. 1794b; Pl. Jap. Nov. Sp.: 8, 1824; sine descr.]. E. Wils., Gard. Chron. 39: 234. 1906.

*Magnolia longifolia* auct. non Sweet: Yanagida, J. Soc. Forest. (Japan) 16, 3: 268, t. 413. 1934. *Magnolia obovata* Thunb. var. *yanagidana* Hatusima, Acta Phytotax. Geobot. 4: 209. 1935. TYPE not known.

8. **Magnolia officinalis** Rehder & E. H. Wilson in Sarg., Pl. Wilson 1: 391. 1913. TYPE: *E. H. Wilson 652* (holotype, A; isotypes, E, GH, US).

*Magnolia officinalis* var. *biloba* Rehder & E. H. Wilson in Sarg., Pl. Wilson 1: 392. 1913. *Magnolia biloba* (Rehder & E. H. Wilson) Cheng & Law, Iconogr. Cormoph. Sinicorum 1: 787, t. 1574. 1972. *Magnolia officinalis* subsp. *biloba* (Rehder & E. H. Wilson) Cheng & Law in W. C. Cheng, Sylva Sinica 1: 449, t. 134. 1983. TYPE: *E. H. Wilson 1649* (holotype, A; isotypes, E, US).

*Magnolia officinalis* var. *pubescens* C. Y. Deng, J. Nanjing Inst. Forest. 1: 145. 1986. TYPE: *C. Y. Deng 84182* (not seen).

Deciduous tree to 20 m high, bark thick, gray, smooth; young twigs stout, 8–14 mm diam., yellowish to gray, sometimes brown, densely appressed-hairy, with short, straight to undulate, colorless to brown hairs, soon glabrescent, the old ones brownish gray; terminal buds large, narrowly ovoid, brown-hairy, 3.5–5.5 × 1–1.2 cm. Stipules membraneous to chartaceous, sparsely hairy with long hairs, scattered glandular punctate, adnate to the petiole, scars 0.5–2.7 cm long. Leaves large, thinly coriaceous, 7–8 crowded together at the top of the twigs, green, glabrous above, pale green, glaucous, scattered-pubescent with short, straight to slightly curly, colorless hairs as well as rather long, crisped, colorless hairs everywhere, later glabrescent beneath, obovate, 16.5–37.5(–46) × 9–20(–24) cm; apex acute, obtuse, emarginate to obcordate, base cuneate; both midrib and nerves prominently elevated, covered with slender, straight to undulate, colorless hairs below, nerves in 14–25(–40) pairs, reticulation coarsely netted, visible on both sides. Petiole stout, densely brown or gray hairy, glabrescent, 1.9–5 cm long. Flowers appearing with or after the leaves, white, sometimes flushed with purplish red, fragrant, 10–15 cm diam.; peduncles 3–5 × 0.5–0.8 cm, densely pubescent with long, straight, crisped, gray hairs, pedicles 2–6 mm long; tepals 9–12(–17), thick fleshy, the outer 3 pale green outside, obovate, usually reflexed, the inner tepals 6–9(–14), obovate to spathulate, 8–10 × 2.5–5 cm; stamens 3–4 cm long, anthers introrsely dehiscing, connective appendage triangular, ca. 1 mm long, filaments red, stout, 4–8 mm long; gynoecium ovoid, 2.5–3.5 × 1 cm; torus with the scars of perianth and stamens 1–1.8 × 1.2 cm. Fruiting peduncles glabrous to densely gray-hairy 3–5 × 0.5–0.8 cm. Fruits oblong-ovoid, occasionally cylindric, straight to slightly distorted by abortion of part of the carpels, 8–16 × 4.5–5 cm; ripe carpels 1–3 cm long, with 1–3-mm-long beaks at the apex; the scars of perianth and stamens along the torus ca. 1.4–2 × 1.5 cm. Seeds ovoid to irregularly shaped, ± compressed, 8–10 × 6–9 mm.

The species is also reported from southern Shaanxi.

*Ecology.* In forest. Altitude: 300–1,300 m. Flowering May–June; fruiting August–October.

*Uses.* Bark, root-bark, flowers and seeds all used for medicinal purposes; seeds also for extraction of oil; wood yellowish brown, straight-grained and fine-textured, soft, used for construction, ve-

neer, furniture, and musical instruments. Because of its dense crown, large leaves, and beautiful flowers, the tree is grown as an ornamental.

*Collector's notes.* Leaves whitish beneath; bark smooth, gray; flowers white or purple; fruits erect, green, turning purplish or purple-red; seeds scarlet.

*Notes.* *Magnolia officinalis* resembles *Magnolia hypoleuca* in many characters except in the shape of the basal follicles of the ripe fruits, the degree of the indument of the pedicles, and the color of the twigs. In this regard, Spongberg (1976) has already compared the two species in detail; we agree with his observations. However, there are not sufficient collections available, particularly of living material, to settle the problem. Therefore, the two are treated as distinct species here.

This species was included as *Magnolia hypoleuca* auct. [non Siebold & Zucc. (1845)] by Diels (1900), Finet & Gagnepain (1905, pro parte), E. Wilson (1906) excluding description of the fruit., and Fang Wen Pei (1942).

9. **Magnolia rostrata** W. W. Smith., Notes Roy. Bot. Gard. Edinburgh 7: 213. 1920. TYPE: *Forrest 15052* (lectotype, selected here, E; isolectotype, K).

Deciduous tree to 24 m high; bark pale gray; twigs stout, 7–14 mm diam., yellow to purple-brown when dry, glabrous and smooth, covered with a gray waxy substance. Stipules glabrous, dull yellow-green, usually covered with waxy substance, adnate to the base of the petiole, stipular scars 1.5–3.5 cm long. Leaves thinly coriaceous, green, glossy and glabrous above, glaucous, sparsely scattered-pubescent with rather long, crisped, brown hairs, glabrescent beneath, 5–7 crowded together at the end of the twigs, obovate, 31–36.5(–53) × 19–20.5(–28) cm; apex broadly rounded, with a ca. 3-mm-long short-acute tip, base obtuse; midrib conspicuously elevated beneath, nerves prominent beneath, in 28–36 pairs, reticulation coarsely netted, visible on both sides. Petiole stout, pubescent, glabrescent, 2.5–6 cm long. Peduncles ca. 2.5 × 1 cm, pedicles ca. 1.3 cm long. Flowers appearing after the leaves, heavily scented; tepals 10–11, the outer 3 green, slightly flushed with pink outside, pink inside, oblong-elliptic, 8–13 × 2.5–5.6 cm, reflexed, the inner tepals 6, white, erect, spathulate to obovate, 11–13 × 4–4.5 cm; stamens purple-red, 1.4–1.7 cm long, anthers dehiscing introrsely, connective appendage triangular, 1–1.5 mm long, filaments 4–5 mm long; gynoecium cylindric, glabrous, 2.3–4 × 1–1.3 cm, carpels many; torus with the scars of perianth and stamens 1.2–1.9 × 0.6–1 cm. Fruiting peduncles 1.5–3.5 × 1–1.7 cm, pedicles 2–10 × 8 mm, sometimes absent, both glabrous. Fruits cylindric, erect, 12–20.5 × 3–5 cm, apex gradually narrowing, base broadly rounded; ripe carpels 1–1.5 cm long in the lower and 0.7–1.2 cm long in upper carpels, beak to 6–8 mm long, incurved. Seeds irregularly shaped, flat, ca. 7 × 5 mm.

*Distribution.* Northeastern Burma and China. In CHINA. **Xizang**: Mt. Kenichunpo, Upper Salween River, *Rock J.F. 22607*; Salween ridge, Champutong, *10160*; Mt. Kenyichunpo, Champutong, *11215*; Tsarong, *Forrest G. 20827*. **Yunnan**: Mount Gitsa, *Rock J.F. 17097, 18394*; N Waikha-Salwin divide, 26°30′N, *Forrest G. 18246*; Salween-Kui Chiang divide, 27°N, 98°35′E, *Forrest G. 25751*; Taron-Taru divide, Ahtemai, *Yu T.T. 20894*.

*Ecology.* In broad-leaved forest. Altitude: 2,400–2,800 m. Flowering April–May; fruiting September–October.

*Collector's note.* Leaves very large; flowers sweet-smelling, tepals 10–12, thick and fleshy, white, ivory, to white flushed rose or rose-pink, appearing before the foliage.

*Note.* The description of the flowers in Smith (1920) does not apply to this species.

**Ia-3. Magnolia** section **Oyama** Nakai, Fl. Sylv. Koreana 20: 117. 1933. *Magnolia* sect. *Cophantera* Dandy, Curtis Bot. Mag. 159: sub. t. 9467. 1936. TYPE: *Magnolia sieboldii* K. Koch.

Deciduous shrub or tree. Stipules adnate to petiole. Leaves ± pale green or glaucous, evenly distributed; midrib not prominent above. Flowers bisexual; tepals subequal; connective not produced into an appendage, retuse or blunt; anthers dehiscing introrsely. Gynoecium not stipitate. Scars of bracts 1. Fruits at least finally consisting of free follicles, which dehisce along the dorsal suture.

KEY TO THE SPECIES OF *MAGNOLIA* SECTION *OYAMA*

1. Leaves not glaucous beneath; pedicles 13–17 mm; nerves in 9–12 pairs; gynoecium 15–20 mm high. ..... 12. *Magnolia sinensis*
1. Leaves glaucous beneath. ..... 2
2(1). Gynoecium 23–25 mm high; nerves in 8–11 pairs; pedicles 5–25 mm. 10. *Magnolia globosa*
2. Gynoecium 13–20 mm high. ..... 3
3(2). Reticulation rather obscure; nerves in 6–8 pairs; pedicle 2–2.8 mm. 11. *Magnolia sieboldii*
3. Reticulation distinct; nerves in 10–12 pairs; pedicle 5–7 mm. ..... 13. *Magnolia wilsonii*

10. **Magnolia globosa** Hook. f. & Thomson, Fl. Ind. 1: 77. 1855. TYPE: Sikkim, alt. 2,700–3,000 m, *J. D. Hook. s.n.* (holotype, K; isotype, GH).

*Magnolia tsarongensis* W. W. Smith & Forrest, Notes Roy. Bot. Gard. Edinburgh 12: 215. 1920. TYPE: *G. Forrest 18870* (lectotype, selected here, A; isolectotypes, E, K).

Deciduous small tree to 10 m high, flowers appearing at the same time or before the leaves; young twigs purple-brown or dull brown, 4–5 mm diam., at first densely appressed or shaggily hairy with yellowish, brown to rusty-brown hairs, soon glabrous; terminal winter buds densely brown pubescent. Stipules yellowish sericeous or brown villous, adnate to higher on the petiole, stipular scars usually over half the length of the petiole, 15–42 mm long. Leaves membranous, dark green, usually dull brown when dry, sparsely pubescent along the midrib and nerves above, glaucous, villous with long, undulate to crisped, colorless or brownish hairs, later glabrescent beneath, ovate, broadly ovate, elliptic, occasionally obovate, 12.5–21(–26) × 6–11.5(–15) cm; apex acute to rounded, base rounded to somewhat cordate or truncate; midrib and nerves prominent beneath, nerves in 8–11 pairs, reticulation coarse, visible below. Petiole densely pubescent, glabrescent, 2–5 cm long. Flowers fragrant, cup-shaped to subglobose, pendent or nodding, 6–7.5 cm diam., peduncles densely villous with gray, brown, or rusty-brown hairs, 3.7–6.5(–7.5) × 0.2–0.4 cm, pedicles 5–25 mm long; tepals 9–12, creamy white, subequal, obovate to spathulate, 4–7.5 × 2–4 cm, apex rounded, base obtuse, usually constricted into short claws; stamens crimson, 12–18 mm long, anthers dehiscing introrsely, connective retuse or rounded, filaments 1–4 mm long; gynoecium green, ellipsoid, 2.3–2.5 × 0.5–0.8 cm. Fruiting peduncles 6.5–9 × 0.3–0.5 cm, glabrous or hairy. Fruits cylindric, 2.5–9 × 2–2.5 cm; ripe carpels 1.7–3 cm long in the lower and 1–2 cm long in the upper carpels, apically with beaks 3–6 mm long; scars of perianth and stamens along the torus 6–12 × 7–11 mm. Seeds ovoid, ca. 10 × 8 mm.

*Distribution.* Northeastern Assam, eastern Himalaya, China, northern Burma. In CHINA. **Southwestern Sichuan**: Wen Chaun Hsien, *Wilson E.H. 1422*. **Southeastern Xizang**: Mountains of Champutong, *Rock J.F. 22047*; Putsang River, Rong To valley, Zayul, *Kingdon Ward F. 10973*. **Northwestern Yunnan**: Salween-Kui Chiang divide, 23°24′N, 98°28′E, *Forrest G. 20866*; Salwin-Kiu Chiang divide, Si chi to, 28°45′N, 98°18′E, *21722*; Tsarong, Salwin-Kui Chiang divide 28°24′N, 98°24′E, *20303*; Meng-hua, Chukai, *Yu T.T. 15854*; Salween-Djiou-Djiang, under Tschamputong, *Hand.-Mazz. 9212*; Salwin-Kiukiang divide, *Yu T.T. 19251*; Sikang, *Li M.K. 2329*; Sitiping, between Lipiang and Weihsi, *Ching R.C. 22016*; Wei si Hsien, *Wang C.W. 63981*; Xue long Shan, *Feng K.M. 4813*.

*Ecology.* In mixed forest or thickets. Altitude: 1,900–3,300 m. Flowering May–July; fruiting August–September.

*Uses.* Seeds and leaves used for volatile oil, tree cultivated as an ornamental.

*Collector's notes.* With brown hairs on bracts, petioles, and under leaves; flowers snow white, creamy white, or greenish white, pendent and fragrant; fruits greenish, fleshy; seeds red.

*Note.* *Yulania japonica* Spach var. *globosa* (Hook. f. & Thomson) P. Parmentier (1895) is a nomen nudum.

11. **Magnolia sieboldii** K. Koch, Hort. Dendrol.: 4. 1853. *Magnolia oyama* Kort, Revue Horticulture Belge 31: 258. 1905. *Magnolia verecunda* Koidz., Bot. Mag. (Tokyo) 40: 339. 1926. SYNTYPES: *K. Ito s.n. L 908-126-1110*, fertile (L), sine leg. *L-908-126-1043* (L).

Deciduous treelet to 10 m high; young twigs slender, 1–2 mm diam., yellow-brown, dark brown, or purple-brown, at first densely appressed-pubescent with yellowish white hairs, later glabrous, smooth. Stipules sparsely to densely hairy with gray-yellow or brownish hairs, adnate to the petiole, scars up to over or under halfway on the petiole, 5–40 mm long. Leaves chartaceous, dark bright green, glabrous to sparsely pubescent with fine hairs above, glaucous, sparsely to densely covered with appressed short or long, colorless or brownish, usually straight to rarely undulate hairs beneath; obovate or broadly obovate, 3–15(–20) × 2–9(–12) cm; apex acute to acuminate with acumen 5–10 mm long, base rounded to truncate; midrib and nerves prominent below, nerves in 6–8 pairs, reticulation coarse, obscured. Petiole appressed-hairy, 1–4(–6.5) cm long. Flowers together with the leaves, cup-shaped to saucer-shaped, nodding or pendent, fragrant, 7–10 cm diam.; peduncles slender, densely hairy with gray-white or brownish hairs, 3.8–4.5 × 0.1–0.2 cm, pedicles 2–2.8 mm long, sometimes absent; tepals 9–12, white, subequal, 3.5–6 × 2–3.5 cm, the outer 3 obovate, reflexed in full bloom, the inner tepals 6, spathulate to broadly obovate, usually with short claw at the bases; stamens purple-red, 8–15 mm long, anthers dehiscing introrsely, connective blunt, ca. 0.5 mm long, filaments ca. 3 mm long; gynoecium green, ellipsoid, 1.5–1.7 × 0.4–0.6 cm; carpels narrowly

elliptic, ca. 1 cm long. Fruiting peduncles glabrous to densely brownish pubescent, 6.2–7 × 0.2–0.3 cm. Fruits cylindric, rarely ovoid, 3–4 × 1.2–1.7 cm; ripe carpels apically with 4–12-mm-long beaks, erect or recurved; torus with scars of perianth and stamens 4–10 × 3–5 mm. Seeds subcordate to irregularly shaped, ca. 6–7 × 6 mm.

*Distribution.* China, Korea, and Japan. In CHINA. **Anhui**: San Hua Wu, Huangshan, *Deng & Yao 79192.* **Northern Guangxi**: Quan Xian, *Chun Y.F. 81654*; Xing An, *Chen Z.Z. 51165*; Zi Yuan, *Tsoong C.H. 83515.* **Guizhou**: Lei Gong Shan, *Cao Zi-yu 369*; Lei Shan Xian, *Jian Z.P. 50796.* **Liaoning**: Huan Ren Xian, *Wang W.1191, Wang C.S. 4065.* **Sichuan**: Ma-pien Hsien, *Wang F.T. 22816*; Wenchuan Hsien, *Wang F.T. 21080.* **?Yunnan**: *Wang C.W. 89858.*

*Ecology.* In forest. Altitude 1,500–1,800 m. Flowering May–June; fruiting August–September.

*Uses.* Used for medicinal purposes; grown as an ornamental.

*Collector's notes.* Small tree or shrub; flowers nodding, white and fragrant; stamens creamy white, with rose tip.

*Notes.* Siebold & Zuccarini (1845) treated this species as *Magnolia parviflora* [non Blume (1825)], while Komarov (1904) used the name *Magnolia conspicua* [non Salisbury (1806)].

12. **Magnolia sinensis** (Rehder & E. H. Wilson) Stapf, Bot. Mag. (Curtis) 149: t. 9004. 1924. *Magnolia globosa* Hook. f. & Thomson var. *sinensis* Rehder & E. H. Wilson in Sarg., Pl. Wilson. 1: 393. 1913. *Magnolia sieboldii* K. Koch subsp. *sinensis* (Rehder & E. H. Wilson) Spongberg, J. Arnold Arbor. 57: 279, f. 3, h–i. 1976. TYPE: *E. H. Wilson 1422* (holotype, A; isotypes, E, GH, US).

Deciduous shrub or small tree to 5 m high; young twigs purple-brown, dark purple, purple-gray to gray, slender, ca. 3 mm diam., densely yellow or brownish villous at first, glabrescent later, old twigs brown-gray, smooth, glabrous to barely hairy. Stipules densely appressed-pubescent with brownish or yellowish hairs, adnate to the petiole, scars 2–3 cm long. Leaves chartaceous, green, finely pubescent over the surface or only along midrib and nerves above, pale green, at first densely covered with rather long, crisped, colorless or brownish hairs, soon glabrescent beneath, elliptic, broadly elliptic, obovate to broadly obovate, 10–16(–21.5) × 6–9(–13) cm; apex rounded or mucronate, base obtuse; nerves visible below, in 9–12 pairs, reticulation coarse. Petiole densely yellowish villous, 2.5–4(–7) cm long. Flowers appearing with the leaves, nodding, fragrant, cup-shaped, 8–12(–15) cm diam. when fully open; peduncles densely or sparsely pubescent, 3.5–6.5 × 0.2–0.5 cm, pedicles 1.3–1.7 cm long; tepals 9, white, subequal, the outer 3 ovate to elliptic, 4–5.5 × 1.7–2.7 cm, the inner tepals 6, broadly obovate, with short claw at the bases, 4.5–7 × 3–5.6 cm; stamens red, 9–14 mm long, anthers dehiscing introrsely, connective rounded to mucronulate, ca. 0.5 mm long, filaments 1–2 mm long; gynoecium green, narrowly obovoid-ellipsoid, 1.5–2 × 0.4–0.7 cm, carpels narrow and long, styles 3–4 mm long. Fruiting peduncles 4–6.5 × 0.2–0.5 cm. Fruits cylindric, 5.5–7.5 × 1.3–1.7 cm; ripe carpels ellipsoid, 1.7–2.5 cm long in the lower and 1–1.3 cm in the upper carpels, beaks 2–5 mm long, recurved; torus with scars of perianth and stamens 8–10 × 4–9 mm.

*Distribution.* CHINA: northwestern **Sichuan**.

*Uses.* The tree is used as an ornamaental.

*Note.* There is still disagreement about the rank of this species. Ueda's (1980) observation and judgment dealing with this species seem accurate. We agree with his view that *Magnolia sinensis* should not be treated as a subspecies of *Magnolia sieboldii.*

13. **Magnolia wilsonii** (Finet & Gagnep.) Rehder in Sarg. Pl. Wilson. 1: 395: 1913. *Magnolia parviflora* var. *wilsonii* Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 39. 1905. TYPE: *E. H. Wilson 3137* (holotype, A; isotypes, BM, K, US).

*Magnolia taliensis* W. W. Smith, Notes Roy. Bot. Gard. Edinburgh 8: 341. 1915. *Magnolia lilifera* var. *taliensis* (W. W. Smith) Pamp., Bull. Soc. Tosc. Ortic. 41: 137. 1916. *Magnolia wilsonii* f. *taliensis* (W. W. Smith) Rehder, Man. Cult. Trees: 249. 1940. TYPE: *G. Forrest 7182* (holotype, E; isotypes, BM, K).

Deciduous shrub or small tree to 8 m high; bark gray-brown; young twigs slender, 2–3 mm diam., brown-purple to gray, densely villous with yellowish to brown hairs, later glabrescent, smooth and sparsely lenticellate, old twigs gray-black, glabrous, glabrescent. Stipules densely yellow to yellowish white villous with silky hairs, adnate to the petiole, stipular scars nearly up to the base of the blade, 1–2.5(–5.4) cm long. Leaves chartaceous, dark

green, glabrous or sparsely pubescent over the surfaces to only hairy along both midrib and nerves above; glaucous, glabrous, sometimes only pubescent along midrib and nerves, or thinly to densely pubescent with short to long, colorless to brownish, straight, slightly curved to rather crisped hairs everywhere beneath; usually narrowly ovate to obovate, sometimes broadly ovate to elliptic, 9–14.5(–22) × 3.5–6(–10) cm; apex acute or acuminate, base rounded or sometimes slightly cordate; midrib and nerves visible on both sides, nerves in 10–12 pairs, reticulation coarse. Petiole slender, densely covered with same indumentum as young twigs, soon glabrescent, 2–4(–5.6) cm long. Flowers appearing with the leaves, at first cup-shaped to saucer-shaped, later pendent, white, fragrant; peduncles slender, brown-villous with silky hairs, glabrescent, 13–45 × 2–3 mm, pedicles 5–7 mm long; bracts pubescent; tepals 9(–12), subsimilar, the outer 3 elliptic, apically rounded to acute, 4.5–6 × 1.5–3 cm, the inner tepals 6, broadly obovate to spathulate, apically rounded, basally short-clawed, 2.7–6.5 × 1.3–4.5 cm; stamens 9–12 mm long, purple-red, connective rounded, filaments ca. 2 mm long; gynoecium green, ovoid-cylindric, 13–20 × 5–6 mm; torus with the scars of perianth and stamens ca. 6 × 6 mm. Fruiting peduncles glabrous, 30–45 × 2–3 mm, pedicles 8–15 mm long. Fruits pendent, cylindric, 3–6.5 × 1–2 cm; ripe carpels ellipsoid, 1.7–2.6 cm long in the lower and 1–2 cm long in the upper carpels, with beaks 2–5 mm long. Seeds subcordate to irregularly shaped, 5–7 × 5–6 mm.

*Distribution.* CHINA. **Guizhou**: Xing Yi Xian, *An Shun Exped. 1112.* **Western & central Sichuan**: Naitan to pain yi pu, *Smith, Harry 1953*; Tachinhu, *Wilson E.H. 1374*; Wa shan, *838.* **Yunnan**: Tze-tchou-pa, *Maire E.E. 866*; Tali range, 25°40′N, 100°5′E, *Forrest G. 27941*; Yun Hsien, *McLarens's collectors L 66 A*; Liao Tseng, *C 92*; Kou ty, Pe yen tsin, *Ten Simeon 564*; Chienchuan–Mekong divide, *Forrest G. 23480*; N end of Cangshan, *Sino-British Exped. 655.*

*Ecology.* In forest. Altitude: 1,900–3,300 m. Flowering May–June, fruiting September–October.

*Uses.* Bark used for medicinal purposes; the tree is grown as an ornamental.

*Collector's notes.* Flowers saucer-shaped, drooping, fragrant, pure white; stamens bright red or violet.

*Note.* E. Wilson (1906) dealt with this species erroneously under *Magnolia globosa* Hook. f. & Thomson.

**Ia-4. Magnolia** section **Gynopodium** Dandy, Curtis Bot. Mag. 155: t. 16. 1948. TYPE SPECIES: *Magnolia nitida* W. W. Smith.

*Parakmeria* Hu & Cheng, Acta Phytotax. Sinica 1, 2: 1. 1951. TYPE SPECIES: *Parakmeria omeiensis* Hu & Cheng.

TYPE: *Kanehira*, 1924 (holotype, TAIF not seen).

Evergreen glabrous tree to 17 m high and 1.2 m diam., bark dark brown, smooth, young twigs 2–3 mm diam., dull dark brown, smooth, old ones gray, longitudinally fissured; terminal buds ovoid to elliptic, dull brown, 13–16 × 3–4 mm. Stipules free from the petiole. Leaves thinly coriaceous, dark green above, green beneath, elliptic to obovate, 6.5–12(–20) × 2–3(–5) cm; apex acute to short-acuminate, base cuneate; nerves fine, obscured above, visible below, in 9–12 pairs, reticulation rather coarse, faint on both sides. Petiole ca. 5–20 mm long. Peduncles 7–15 × 3–4 mm, pedicles usually absent, rarely present, ca. 1 mm long. The bisexual flowers yellowish green; tepals 9–12, subsimilar, obovate to spathulate, 2.5–4 × 1–1.5 cm; stamens 50–60, 1.4–1.8 cm long, anthers dehiscing introrsely, connective appendage narrowly triangular, ca. 1 mm long, filaments 2–2.5 mm long; gynoecium ovoid, slightly exserted from the androecium, 1.2–1.4 × 0.5 cm long, gynophore ca. 5–8 × 1.5 mm, carpels 10–18; torus with the scars of perianth and stamens ca. 5 × 4 mm; the male flowers not seen. Fruits subovoid, 2–2.5 × 1.2–1.5 cm; ripe carpels 8–12, ± connate, 2–2.5 cm long. Seeds reniform to subcordate, ca. 10 × 7 mm.

*Distribution.* CHINA. **Southeastern Taiwan**: Hengchun peninsula, *Henry A 2060, Chang C.E. 4384*; Taizhong, *Xie Z.Q. s.n.*

*Ecology.* In evergreen broad-leaved forest. Altitude: 500–1,300 m.

*Uses.* Wood used for general construction work; tree also grown as an ornamental.

15. **Magnolia nitida** W. W. Smith, Notes Roy. Bot. Gard. Edinburgh 12: 212. 1920. *Parakmeria nitida* (W. W. Smith) Law in W. C. Cheng, Sylva Sinica 1: 472. 1983. TYPE: *Forrest 15059* (lectotype, selected here, E; isolectotype, K).

*Magnolia lotungensis* Chun & C. T. Tsoong, Acta Phytotax. Sin. 8: 285. 1963. TYPE: *Chun & Tao 50122* (IBSC not seen).

*Magnolia yunnanensis* (Hu) Noot., Blumea 31, 1: 88. 1985. *Parakmeria yunnanensis* Hu, Acta Phytotax. Sin. 1: 2. 1951. TYPE: *C. W. Wang 83157* (KUN).

15a. **Magnolia nitida** var. **nitida**

Evergreen tree to 30 m high and 90 cm diam., entirely glabrous, bark faintly gray-brown or dark gray; young twigs 2–3 mm diam., olive green to brownish, fruiting twigs 5–6(–8) mm diam., old ones dull gray, longitudinally to irregularly fissured; terminal buds ovoid, ca. 17 × 5 mm. Stipules free from the petiole. Leaves rigid, coriaceous, dark glossy green, olive green to dull brown when dry above, green, greenish brownish to brownish when dry beneath, usually ovate to elliptic-ovate, occasionally obovate, 6–12(–14) × 3–4(–6.5) cm; apex short-acuminate, acumen 7–10 mm long, sometimes acute, base broadly cuneate to obtuse; midrib prominent above only near the base; nerves fine, visible on the underside, in 9–13 pairs, reticulation coarse, hardly visible on both surfaces. Petiole 1.5–2.5 cm long, without stipular scars. The bisexual flowers fragrant, peduncles 6–8 × 5 mm, pedicles 1.5–2 mm long; tepals 9–12, subsimilar, creamy yellow, slightly fleshy, flushed purplish outside, obovate to spathulate, 4–5 × 1–3 cm; apex rounded to short-acuminate, base tapering, sometimes short-clawed; stamens 1.3–2.5 cm long, anthers dehiscing introrsely, connective appendage linear, 2–4 mm long, filaments 1–3 mm long; gynoecium oblong, exserted from the androecium, ca. 16 × 5 mm, gynophore 6–8 × 2–3 mm; carpels green, styles crimson; the male flowers not seen. Fruiting peduncles 8–16 × 4–5 mm, pedicles 1.5–4 mm long. Fruits ovoid to oblong, sometimes distorted, 3.5–7.5 × 2–3 cm; ripe carpels 13–20, 1–2.5 cm long, apically with recurved beaks ca. 1 mm long, gynophores 4–12 × 4–6 mm; scars of perianth and stamens along the torus 5–10 × 4–7 mm. Seeds reniform, 10–13 × 5–10 mm.

*Distribution.* China and northern Burma. In CHINA. **Xizang**: Champutong, *Rock J.F. 10136*; Mt. Kenichunpo, W of Champutong, *Rock J.F. 22457*; Salween valley, Champutong, *10235*; Tsarong, *G. Forrest 20358.* **Yunnan**: Salwin-Kiu Chan divide, Champutong, 98°30′E, 28°16′N, *Forrest G. 21616*; Salwin-Kiu Chang divide, 28°24′N, 98°24′E, *20860*; Shweli-Salwin divide, 25°50′N, 98°45′E, *26381*; Meng Lun, *Chang H.T. 5022*; Shang pa Hsien, *Tsai H.T. 54858.*

*Ecology.* In mixed forest, growing on sandstone, shale, and granite. Altitude: 800–2,500 m. Flowering March–May; fruiting September–October.

*Uses.* Wood yellowish, durable, generally used for construction work and furniture.

*Collector's notes.* Widely branched evergreen tree, or half deciduous; leaves whitish beneath; flowers fragrant, creamy white, pale yellow or white washed purple toward base; fruits green.

*Notes.* This species is widely distributed, extending from northern Burma northward to Xizang and northern Yunnan, and northeastward to central and southeastern Yunnan. *Magnolia yunnanensis* is very similar to *Magnolia nitida* in all characters. It is obvious that the leaves, the mature fruits, the peduncles, and the gynophores become increasingly longer along a cline from Burma to southeastern Yunnan. No characters can be found that segregate *Magnolia nitida* from *Magnolia yunnanensis.*

15b. **Magnolia nitida** var. **lotungensis** (Chun & C. T. Tsoong) B. L. Chen & Nooteboom, stat. nov. *Magnolia lotungensis* Chun & C. T. Tsoong, Acta Phytotax. Sin. 8: 285. 1963. TYPE: *Chun & Tao 50122* (IBSC not seen).

Evergreen tree to 20 m high and 90 cm diam., bark pale gray to brownish gray; young twigs 2–3 mm diam., dull brown-green, fruiting twigs 4–5(–6) mm diam., old ones faint gray; terminal buds ovoid-ellipsoid, ca. 14 × 4 mm. Leaves coriaceous, dark green, shiny, olive green to dull brown when dry above, green, brownish when dry beneath, rigid, elliptic to narrowly elliptic, occasionally broadly elliptic, 6–11 × 2.5–3.5(–5) cm; apex acute to short-acuminate, base cuneate; midrib prominent on both sides, nerves fine, hardly visible above, prominent below, in 9–13 pairs, reticulation coarsely netted, obscured on both surfaces. Petiole ca. 1.5–2 cm long, without stipular scars. Flowers androdioecious, white; tepals 9–12, subsimilar, the outer 3 ovate, 2.5–3 × 1.2–2 cm, the inner tepals 6–9, obovate, slightly narrower than the outer; stamens 35–65, anthers 9–10 mm long, filaments ca. 1 mm long in the male flowers; stamens 17–22, gynoecium ovoid, entirely hidden by the androecium, carpels 15–20 or much less in the bisexual flowers. Fruiting peduncles 4–9 × 4–7 mm, pedicles absent. Fruits obovoid to ovoid-oblong, 3.5–4.5 × 2.5–3 cm; gynophore 1–5 × 5–6 mm; ripe carpels 10–13, rarely 1–4, ± connate, 1.8–2.2 cm long; scars of perianth and stamens along the torus 2–4 × 5–6 mm. Seeds ellipsoid to ovoid, 7–12 × 6–7 mm.

*Distribution.* CHINA. **Guangdong**: Ruyuan, *Ko S.P. 53691, Guangdong Mucai Yanjiu Zu 32*; Yangchung, *Liu J.H. 89847.* **Guangxi**: Da Miao Shan, *Lu Q.H. 2873*; Jia Xian, *Wang C. 40158*; Jin Xiu Xian, *Da Yao Shan Exped. 13429*; Da Ming Shan, *Cai C.X. 5470*; Lin Gui, *Deng X.F. 231*; Long Sheng, *Long Sheng Exped. 130.* **Guizhou**: Li Ping Xian, *Yuan J.M. 332.* **Hainan**: Dong Fang Xian, *Chen Y.W. 7620*; Fan Yah, *Chun N.K. & C.L. Tso 44041*; Loktung, *Lau S.K. 27375.* **Hunan**: Mang Shan, *Li B.G. et al. 59*; Xin Ning, *Liu L.Y. 15146.* **Zhejiang**: Tai Suan, *Ching R.C. 2167.*

*Ecology.* In forest. Altitude: 800–1,100 m. Flowering April; fruiting September–October.

*Uses.* Wood used for general construction work and furniture.

*Note.* This variety is so similar to *Magnolia nitida* that we do not distinguish them easily. In general, variety *lotungensis* has elliptic to narrowly elliptic leaves, fewer carpels, and the gynoecium is hidden by the androecium. Unfortunately, sufficient flowers of *Magnolia nitida* var. *lotungensis* were not available for comparison to be made.

15c. **Magnolia nitida** var. **robusta** B. L. Chen & Nooteboom, var. nov. TYPE: China. Annam, Massif de Bi-doup, 17 Oct. 1940, alt. 2,000 m, *Poilane 31039* (holotype, P; isotype, L). Figure 1.

A var. nitida differt ramulis crassioribus sub fructibus foliis grandioribus petiolis longioribus.

Tree 25–30 m high, ca. 1 m diam., glabrous; young twigs ca. 3 mm diam., fruiting ones stout, ca. 8 mm diam., dull olive-brown, old ones quite rough, longitudinally and transversely irregularly fissured; terminal buds ovoid to ovoid-ellipsoid, ca. 15 × 5 mm. Stipules free from the petiole. Leaves coriaceous, rigid, green, slightly glossy above, greenish beneath, ovate-elliptic to ovate, 7–16.5 × 3.5–6.5 cm; apex acute to acuminate or obtuse, base cuneate; midrib slightly prominent above, conspicuously elevated below, nerves visible on both sides, in 12–15 pairs, reticulation coarse, prominent on both sides. Petiole ± flat, dilatate toward the base, 1.6–4.7 cm long. In the male flower, peduncle 10–13 × 6–7 mm, pedicle absent; tepals not seen; scars of perianth and stamens ca. 10 × 6 mm. In the bisexual flower, peduncle ca. 5.2 × 9 mm, pedicle ca. 2 mm long; bracts 2, 2.2–3 cm long; tepals 9, the outer 3 much larger than the inner ones, the former ovate, ca. 2.5 × 1.5 cm, the latter 6, 2.2–2.5 × 1.2 cm, spathulate, obovate to narrowly obovate, tapering toward the

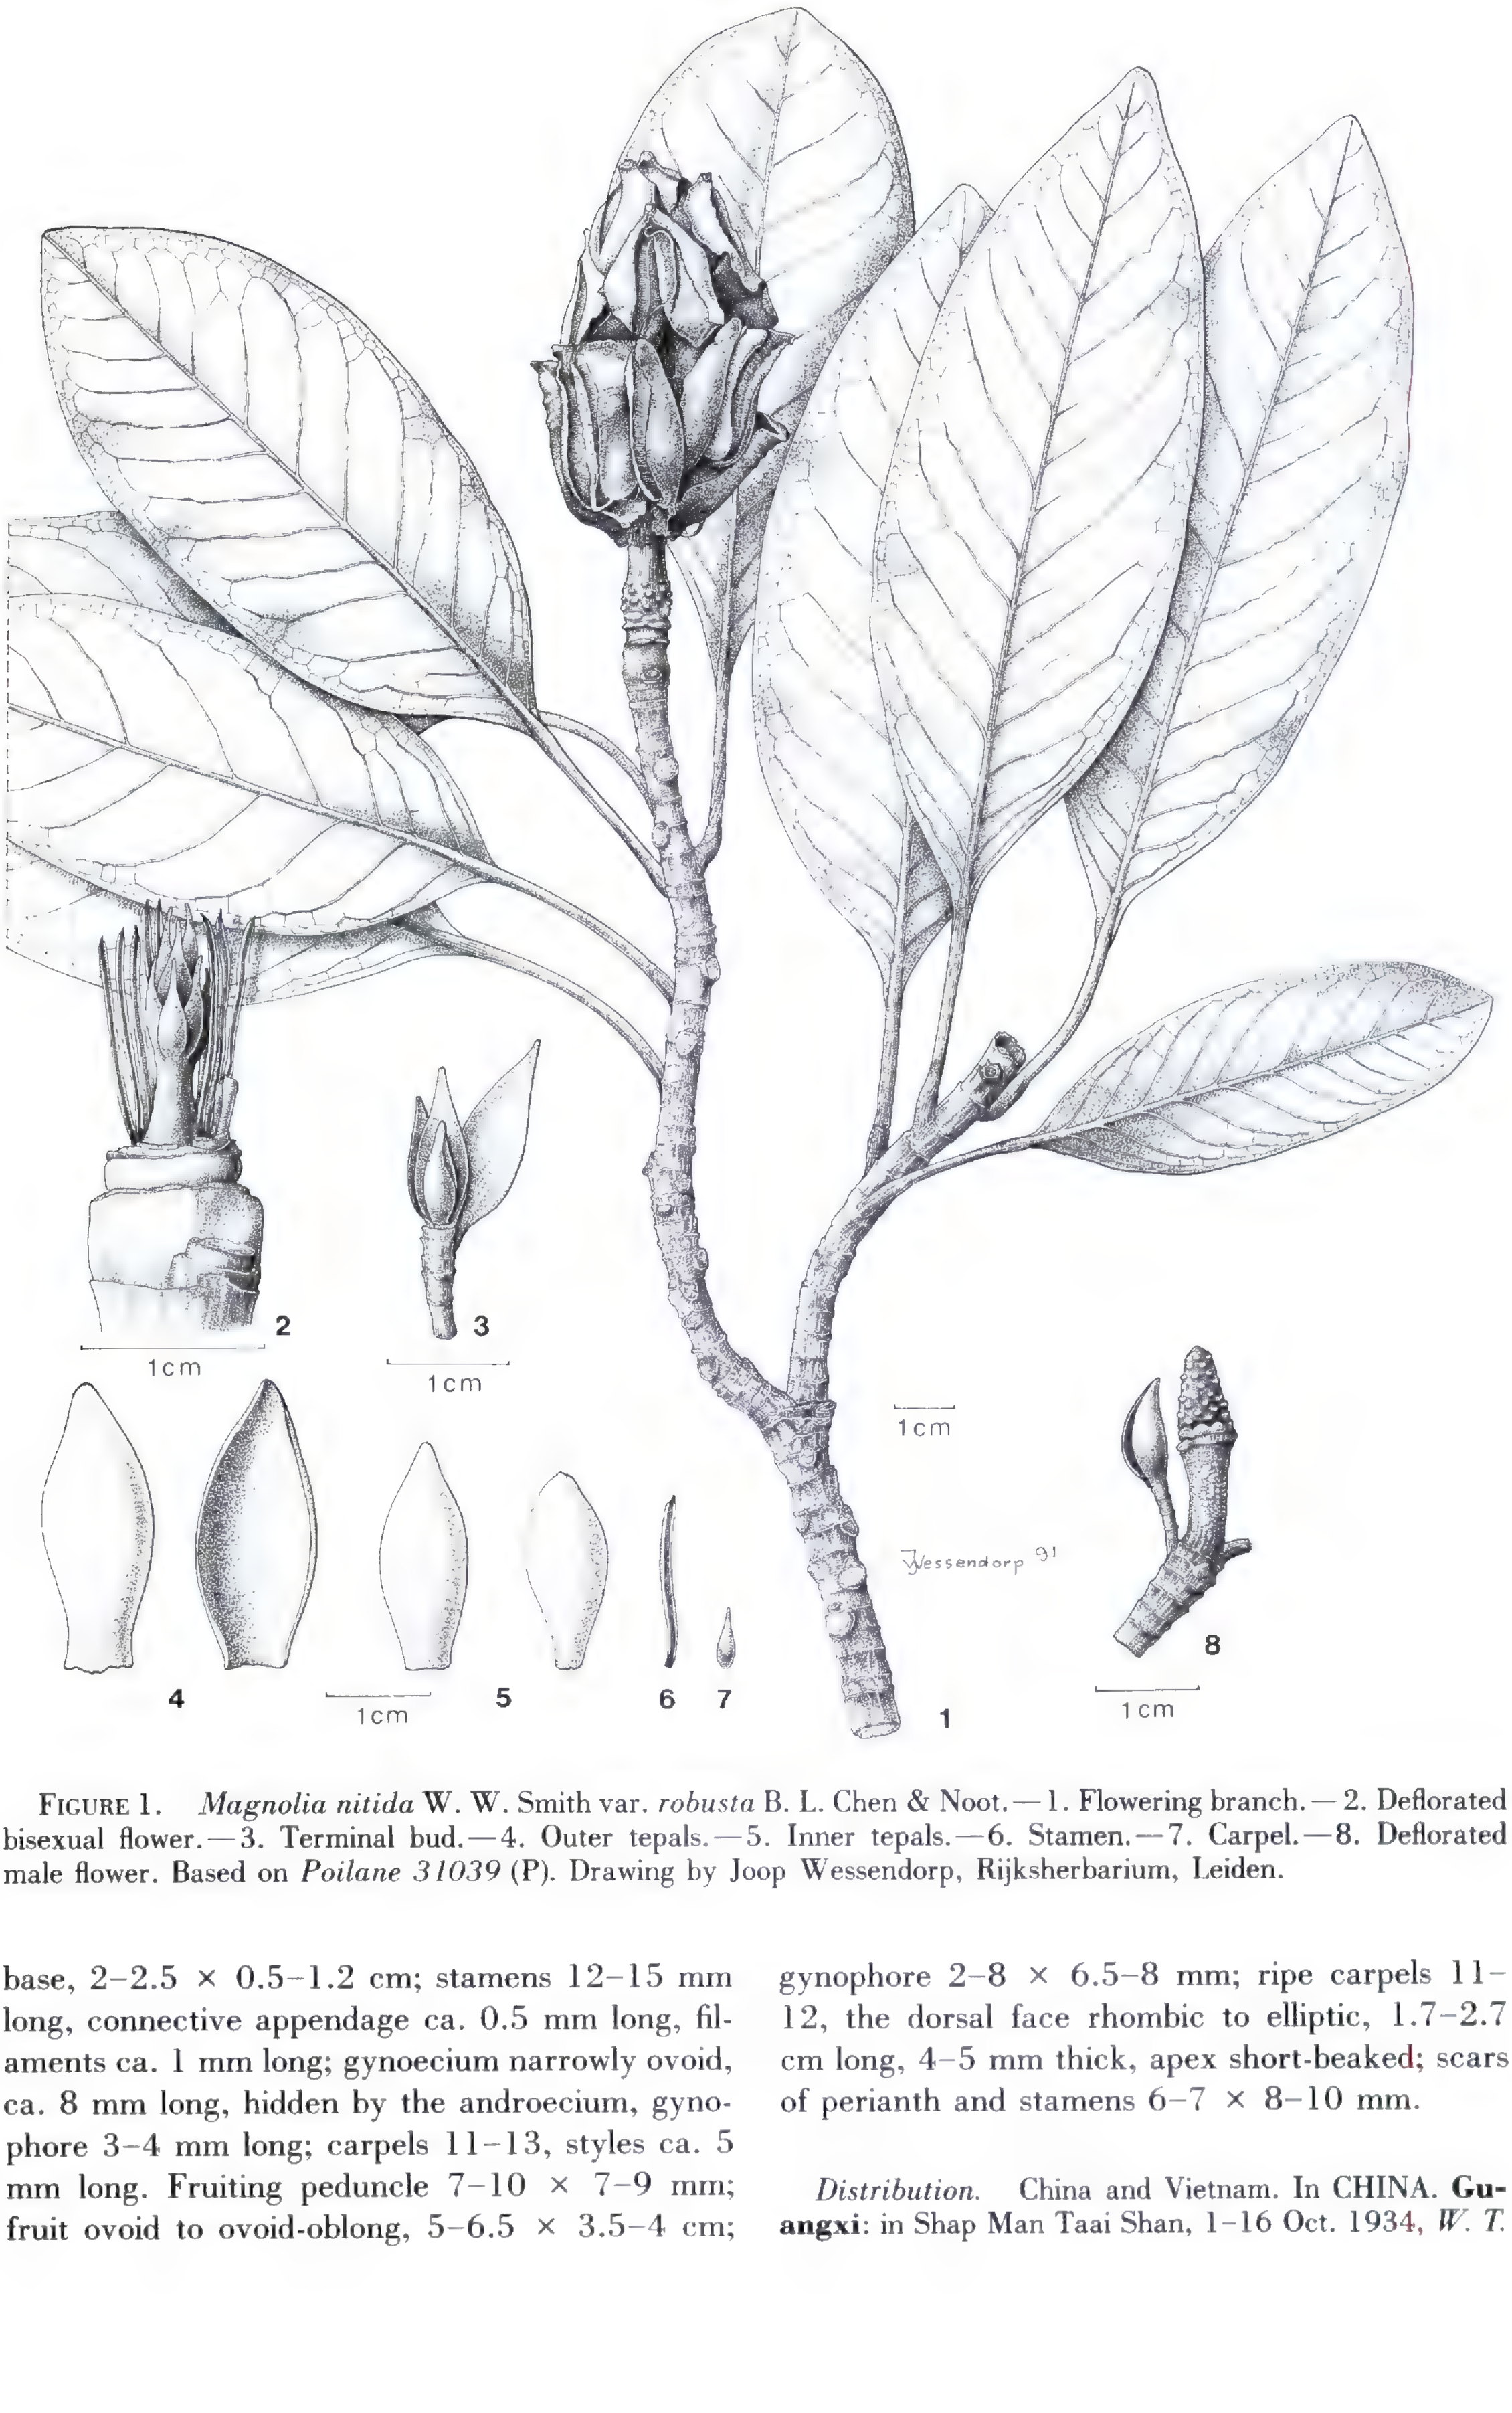

FIGURE 1. *Magnolia nitida* W. W. Smith var. *robusta* B. L. Chen & Noot.—1. Flowering branch.—2. Deflorated bisexual flower.—3. Terminal bud.—4. Outer tepals.—5. Inner tepals.—6. Stamen.—7. Carpel.—8. Deflorated male flower. Based on *Poilane 31039* (P). Drawing by Joop Wessendorp, Rijksherbarium, Leiden.

base, 2–2.5 × 0.5–1.2 cm; stamens 12–15 mm long, connective appendage ca. 0.5 mm long, filaments ca. 1 mm long; gynoecium narrowly ovoid, ca. 8 mm long, hidden by the androecium, gynophore 3–4 mm long; carpels 11–13, styles ca. 5 mm long. Fruiting peduncle 7–10 × 7–9 mm; fruit ovoid to ovoid-oblong, 5–6.5 × 3.5–4 cm; gynophore 2–8 × 6.5–8 mm; ripe carpels 11–12, the dorsal face rhombic to elliptic, 1.7–2.7 cm long, 4–5 mm thick, apex short-beaked; scars of perianth and stamens 6–7 × 8–10 mm.

*Distribution.* China and Vietnam. In CHINA. **Guangxi**: in Shap Man Taai Shan, 1–16 Oct. 1934, *W. T.*

*Tsang 24463*. VIETNAM. **Annam**: massif de Bi-doup, 23 Nov. 1914, alt. 2,000 m, *Poilane 31039* (TYPE); Binh Tri Thiên, 7 Oct. 1949, alt. 1,500 m, *J. E. Vidal 1034A*.

*Collector's note*. In rocky thicket, woody; flower yellow, fragrant.

*Note*. This variety is characterized by stout twigs, especially the fruiting twigs, larger leaves, longer petioles, whose length is usually less than 4 times that of the leaves, short peduncles, a few carpels, a thick wall of mature carpels, and the gynoecium hidden by the androecium instead of exceeding the androecium as in *Magnolia nitida* var. *nitida*. The specimen from Guangxi bearing smaller leaves, without any flowers or fruits, is here treated as this variety based on the shape of the leaves and the relative length of the blade and the petiole.

16. **Magnolia omeiensis** (Hu & Cheng) Dandy in Praglowski, World Pollen & Spore Fl. 3: 5. 1974. *Parakmeria omeiensis* Hu & Cheng, Acta Phytotax. Sin. 1(1): 2. 1951. TYPE: *W. C. Cheng 10525* (holotype, PE; isotype, A).

Tree to 20 m high and 40 cm diam., bark dark gray; plant entirely glabrous; twigs 2–2.5 mm diam., smooth, dull brown-black when dry. Stipules free from the petiole. Leaves coriaceous, dark green, shiny above, pale green beneath, narrowly elliptic, 7.5–12 × 2–4.5 cm; apex short-acuminate, sometimes acute, base narrowly cuneate; nerves fine, in 8–10 pairs, reticulation coarse, hardly visible on both sides. Petiole 1–2 cm long, without stipular scars. Peduncle ca. 10 × 6 mm, pedicle absent. Male flowers creamy white, tepals 12, the outer 3 thin, oblong, apex obtuse, ca. 3.8 × 1.3 cm, the inner tepals 6, spathulate to obovate, 3.5–4.2 × 1–1.5 cm; stamens crimson, 2–2.2 cm long, anthers dehiscing introrsely, connective appendage triangular, ca. 1.5 mm long, filaments ca. 7 mm long; torus ovate-orbicular, 4 mm long.

*Distribution*. CHINA. **Sichuan**: Emei Shan, *Cheng W.C. 10525, Chow H.C. 12095*.

*Ecology*. In evergreen broad-leaved forest. Altitude: 1,000–1,200 m.

*Note*. *Magnolia kachirachirai*, *Magnolia nitida*, and *Magnolia omeiensis*, which all belong to *Magnolia* sect. *Gynopodium*, can barely be distinguished by their vegetative characters; the knowledge of their flowers is still far from satisfactory. Unfortunately, we were unable to see enough material, especially collections with flowers. The delimitation of these species is obviously obscure. Until more material is available they are maintained as different species here.

**Ia-5. Magnolia** section **Alcimandra** (Dandy) Nooteboom, Blumea 31: 88. 1985. *Alcimandra* Dandy, Kew Bull. 1927: 260. 1927. TYPE SPECIES: *Magnolia cathcartii* (Hook. f. & Thomson) Noot.

Evergreen tree. Stipules free. Leaves evenly distributed; midrib not prominent above. Flowers bisexual; tepals subequal; connective produced into a short linguiform appendage; stamens with short filaments and long anthers, completely hiding the gynoecium; anthers dehiscing introrsely. Gynoecium stipitate. Number of ovules per carpel 2–5. Fruits at least finally consisting of free carpels, which dehisce along the dorsal suture.

17. **Magnolia cathcartii** (Hook. f. & Thomson) Nooteboom, Blumea 31: 88. 1985. *Michelia cathcartii* Hook. f. & Thomson, Fl. Ind. 1: 79. 1855. *Sampacca cathcartii* (Hook. f. & Thomson) Kuntze, Revis. Gen. Pl. 1: 6. 1891. *Alcimandra cathcartii* (Hook. f. & Thomson) Dandy, Kew Bull. 1927: 260. 1927. TYPE: Sikkim, *J. D. Hook. s.n.* (holotype, K; isotypes, A, GH, NY).

Tree to 25 m high and 50 cm diam.; young twigs dark brown, slender, 1–2 mm diam., densely appressed-pubescent with long, straight to ± undulate or curly, yellowish to gray hairs, old ones dull brown-gray, glabrescent, sparsely supplied with conspicuously elevated, elliptic to suborbiculate, white lenticels; terminal buds narrowly ovoid, covered with an indumentum as young twigs, 0.6–2.5 cm long. Stipules hairy, free from the petiole. Leaves coriaceous, dark green, shiny above, both sides glabrous, ovate to elliptic-ovate, occasionally obovate, 6.5–17 × 3–5.6 cm; apex long-acuminate, acumen 0.6–2 cm long, sometimes acute, base obtuse to broadly cuneate; midrib densely pubescent, glabrescent at both sides, nerves fine, prominently elevated on both surfaces, in 12–15 pairs, reticulation densely netted, visible on both sides when dry. Petiole pubescent, glabrescent above, 0.2–2 cm long, without stipular scars. Peduncles usually slender, rarely stout, ca. 15–20 × 2 mm, glabrous, pedicles 0–4 mm long; tepals 9, white, the outer 3 oblong, 5.5–6 × 2–2.5 cm, the inner tepals 6, obovate-elliptic, ca. 5.5 × 2.5 cm; stamens 3–4 cm long, anthers introrsely dehiscent, connective appendage tonguelike, ca. 2 mm long, filaments ca. 1 cm long; gynoecium stipitate, cylindric, ca. 2 cm long. Fruiting peduncles 15–35 × 2–4 mm. Fruits usually irregularly shaped, 3.5–6.5 × 1.5–2 cm; ripe carpels 3–16, compressed-subglobose, ca. 8–9 mm diam., white-lenticellate;

gynophore 5–8 × 2–4 mm; torus with the scars of perianth and stamens 4–7 × 4–5 mm. Seeds subellipsoid, ca. 8 × 7 mm.

*Distribution.* Sikkim, Assam, China, Upper Burma to Vietnam. In CHINA. **Southern & southeastern Xizang**: Yunnan, Jingdong Xian, *Xu S.G. 5024*; Kiukiang Valley, Muchietu, *Yu T.T. 21016*; Lan-Tsang Hsien, *Wang C.W. 76855*; Meng-soong, Dahmeng-lung, Che-li Hsien, *78440*; Shangpa, *Tsai H.T. 58698*; Wenshan, *Feng K.M. 22416.*

*Ecology.* In forest. Altitude: 1,800–2,800 m. Flowering May; fruiting August–October.

*Collector's notes.* In mixed woods; flowers yellow-green; fruits green, blue to brown-green; seeds black with orange-red fleshy coat.

**Ib. Magnolia** subgenus **Yulania** (Spach) Reichenbach, Der Deutscher Botaniker 1: 192. 1841. *Yulania* Spach, Hist. Natur. Veget., Phanerog. 7: 462. 1839. *Magnolia* subg. *Pleurochasma* Dandy, J. Roy. Hort. Soc. 75: 161. 1950. TYPE SPECIES: *Yulania conspicua* Spach = *Magnolia heptapeta* (Buchoz) Dandy.

Leaves evenly distributed, deciduous; midrib not prominent above. Flowers bisexual, precocious and/or with a much reduced calyxlike outer whorl of tepals; anthers dehiscing laterally or sublaterally, connective produced into a short or long appendage. Gynoecium not stipitate. Fruit cylindric or oblong, usually ± distorted, at least finally consisting of free carpels which dehisce along the dorsal suture.

**Ib-1. Magnolia** section **Yulania** (Spach) Dandy in Camellias and Magnolias Conf. Report: 72. 1950.

Flowers appearing before the leaves (or some late flowers with the leaves), pink, (greenish) white, purple, or red. Tepals subequal.

6(5). Twigs glabrous; tepals 12; terminal winter buds densely villous; reticulation of leaves distinct; flowers appearing together or after the leaves; filaments 5–7 mm long. 23. *Magnolia sprengeri*
6. Twigs finely appressed-pubescent; tepals 9; terminal winter buds sericeous; reticulation of leaves rather obscure; flowers appearing before the leaves; filaments 3–4 mm long. ..... 21. *Magnolia heptapeta*

18. **Magnolia amoena** W. C. Cheng, Contr. Biol. Lab. Sci. Soc. China Bot. Series 9: 280, f. 28. 1933. TYPE: *S. Chen 2692*, in flower (lectotype, selected here, PE; isolectotype, A).

Deciduous tree to 12 m high; bark gray or gray-white; young twigs 2–3 mm diam., slender, purple-brown, glabrous; terminal buds white sericeous with long hairs. Stipules adnate to the petiole, stipular scars 1–3 mm long. Leaves thinly coriaceous, glabrous above, curly hairy with long white hairs along the midrib, the nerves and at the junctions of the midrib and the nerves beneath, obovate to obovate-elliptic, 10–15 × 3.5–5 cm; apex acute to cuspidate with a ca. 15-mm-long tip; base cuneate, somewhat unequal; nerves in 10–13 pairs, nerves and reticulations prominent on both sides; petiole pubescent, 8–13 mm long. Flowers appearing before the leaves, fragrant, ca. 6 cm diam. Peduncles 6–8 × 4 mm, pedicles 3–4 × 4 mm, both densely yellowish to white hairy. Tepals 9, subsimilar, red to reddish, spathulate to oblanceolate, 5–6.5 cm long; stamens ca. 9–10 mm, connective appendage short-pointed, ca. 1 mm long, anthers dehiscing laterally, filaments purple, ca. 3 mm long; gynoecium cylindric, ca. 2 cm long, styles ca. 1 mm long. Fruits cylindric, 4–6 cm long, often curved as carpels partly abortive; fruiting peduncles long white pubescent, ca. 10 × 4 mm; ripe carpels oblong, apex rounded, papilliferous.

*Distribution.* CHINA. **Southern Anhui**: Huoshan, *Yin S.F. 14*. **Southern Jiangsu**: Zhejiang, W Tienmushan, *Cheng W.C. 4444 A.*

*Ecology.* In forests. Altitude: 700–1,000 m. Flowering April–May; fruiting September–October.

*Note.* The description was drawn from the type specimen only. There are no other collections available.

19. **Magnolia campbellii** Hook. f. & Thomson, Fl. Ind. 1: 77. 1855. TYPE: Sikkim, *J. D. Hook. & Thomson s.n.* (holotype, K; isotypes, GH, NY).

*Magnolia mollicomata* W. W. Smith, Notes. Roy. Bot. Gard. Edinburgh 12: 211. 1920. TYPE: *Forrest 14466* (lectotype, selected here, E).

Deciduous tree to 30 m high; bark gray-brown; young twigs usually purple-brown, sometimes brown to gray-green when dry, 4–7 mm diam., glabrous or pubescent, later glabrescent; terminal winter buds ovoid, yellowish sericeous. Stipules sparsely or densely pubescent with short or long yellowish hairs, adnate to the very base of the petiole, stipular scars 3–7(–11) mm long. Leaves thinly chartaceous, dark green, glabrous above, pale green, glabrous to scattered-pubescent with rather long, straight, undulate, crisped and colorless hairs everywhere or along the midrib and nerves beneath, elliptic, (broadly) ovate to obovate, 10–23( 33) × 4.5–10(–14) cm; apex rounded, acute, or short-acuminate, base rounded or broadly cuneate, usually oblique; nerves prominent beneath, in 7–13 pairs. Petiole glabrous or yellowish pubescent, 2–5 cm long. Peduncles glabrous to densely woolly with yellowish hairs, 2.5–3 × 0.7–1 cm, pedicles 1.5–2.5 × 0.3–1 cm. Flowers large, 15–25 cm diam., precocious, slightly fragrant; tepals 12–16, white, or pale rose at the base outside to pink outside, spathulate, oblong-ovate to -obovate, abruptly constricted into a short claw near the base, the outer 3 concave, outspread to reflexed, 6–14 × 4–8 cm, the innermost tepals 3, erect, connivent, enclosing the androecium and gynoecium, 8–10 × 4–6 cm; stamens 2–3 cm long, connective appendage 0.5–1 mm long, anthers laterally dehiscent, filaments purple, minutely pubescent, 4–9 mm long; gynoecium green, 2.5–4 cm long; scar of perianth and stamens on torus ca. 1.5–2 cm long. Fruiting peduncles 2.7–5 × 1–1.2 cm, pedicles 1.5–2.5 × 0.6–1.3 cm. Fruits erect, soon pendent, cylindric, 8.5–17 cm long, ripe carpels packed close to each other; scars of perianth and stamens along the torus 1–2.2 × 1.3–1.5 cm. Seeds 7–9 mm long.

*Distribution.* Northern India, Nepal, Bhutan, China, northern Burma. In CHINA. **Sichuan**: *Tsang H.L. 33747.* **Southern Xizang**: *Kingdon Ward F. 10365.* Western & northern Yunnan (Nujiang–Langchuanjian divide of Weixi Xian, Nujiang divide of Ruili Xian), Salwin–Kui Chiang divide, *Forrest G. 20841*; Mekong–Salwin divide, 28°15′N, *140*; Southeastern Xizang border: Tsarong, *Rock J.F. 23066*; Che-tse-lo, *Tsai H.T. 58573*; Duanqing, above Yangbi, *Sino-British Exped. 166.*

*Ecology.* In mixed forests. Altitude: 2,500–3,500 m. Flowering March–May; fruiting September–October.

*Uses.* Cultivated as an ornamental plant because of its spectacular flowers.

*Collector's notes.* Deciduous shrub or tree; leaves and bud-scales glabrous; flowers pure white, exterior with purple marking at the base, creamy white flushed purplish, creamy yellow, bright rose-pink, pink, precocious, open cup-shaped, fragrant, fleshy, filaments purple, anthers brown.

*Note.* We agree with Dandy that there is no clear separation between *Magnolia campbellii* and *Magnolia mollicomata* (see Dandy, 1928a). The species is misidentified as *Magnolia rostrata* by W. W. Smith (1920).

*Magnolia grandiflora* (non. L., 1759) is the name used by Griffith (1847) for this species.

20. **Magnolia dawsoniana** Rehder & E. H. Wilson in Sarg., Pl. Wilson 1: 397. 1913. TYPE: *E. H. Wilson 1241* (holotype, A; isotypes, BM, K, US).

Deciduous tree to 20 m high and 50 cm diam.; twigs yellowish green, turning reddish brown later, glabrous to sparsely pubescent at 1–3 nodes or internodes below the peduncles, lenticellate. Stipules appressed-pubescent, adnate to very base of the petiole, stipular scars 3–4 mm long. Leaves coriaceous, dark green, glossy, glabrous above, glaucous, usually pubescent with slightly curly, colorless hairs at the junctions between the midrib and nerves and along the veins beneath, obovate, sometimes broadly obovate-elliptic, 7.5–14(–17) × 4.5–8 cm; apex rounded to acute, rarely emarginate, base cuneate to subrounded, usually oblique; midrib impressed above, prominent and becoming brown when dry beneath, nerves conspicuously elevated beneath, in 8–10 pairs, reticulation coarsely netted, prominent, on both sides. Petiole glabrous to minutely pubescent, slender, usually reddish, 1.5–3 cm long. Peduncles glabrous or ± pubescent, 1.5–2 × 0.4–0.7 cm, pedicles 7–12 × 3–4 mm; bracts 2, sparsely yellowish pubescent. Flowers precocious, fragrant, usually horizontal, nodding later; tepals 9–12, white, tinged with pale red outside, subequal, oblong-spathulate to obovate-oblong, 7–11 × 2–5 cm; stamens purple-red, 1–1.8 cm long, anthers laterally or sublaterally dehiscent, connective appendage triangular, ca. 1

mm long, filaments 2.5–3 mm long, gynoecium ca. 1.5 cm; scar of perianth and stamens on torus ca. 8 × 6 mm. Fruiting peduncles ca. 2.2 × 1 cm, pedicles 0.7–1 × 0.7–0.8 cm. Fruits cylindric, slightly contorted as carpels partly abortive, ca. 10.5 × 3 cm; ripe carpels obovate, sparsely lenticellate, apically short-beaked. Seeds oblong, ca. 1 cm long.

*Distribution.* CHINA. **Central and southern Sichuan**: Lu Ding Xian, *Qiao H.R. 1010*; Mt. Tachien lu, *Wilson E.H. 1241*. Northern Yunnan.

*Ecology.* In broad-leaved forest. Altitude: 1,600–2,500 m. Flowering April–May; fruiting September.

*Uses.* Bark used for medicinal purposes.

*Magnolia conspicua* Salisb., Parad. Lond. 1: 38, t. 38. 1806. *Yulania conspicua* (Salisb.) Spach, Hist. Nat. Vég. 7: 464. 1839. TYPE: Salisb. t. 38.

*Magnolia yulan* Desf., Hist. Arbr. France 2: 6. 1809. *Michelia yulan* (Desf.) Kostel., Allg. Med.-Pharm. Fl. 5: 1700. 1836. *Gwillimia yulan* (Desf.) C. de Vos, Handb. Boom. Heest. ed. 2: 116. 1887. TYPE: not known.

Deciduous tree to 20 m high and 60 cm diam.; bark dark gray, rough and fissured; young twigs 3–7 mm diam., purple-brown, finely appressed-pubescent, later glabrescent, smooth, sparsely white-lenticellate; terminal winter buds ovoid, densely hairy with long, silky hairs. Stipules sparsely or densely yellowish pubescent, adnate to the base of the petiole, scars 1–4 mm long. Leaves thinly chartaceous, dark green, glabrous to pubescent with straight or slightly undulate hairs along the midrib and nerves or short-scattered-pubescent on the surfaces above, pale green, sparsely to densely pubescent with short or rather long, straight or curly, colorless hairs everywhere or only along the midrib and nerves beneath, obovate to broadly obovate, 8–17.5(–21.5) × 5–10.5(–16) cm; apex rounded to truncate, abruptly short-acuminate, acumen 1–15 mm long, base cuneate or rounded; midrib and nerves visible on both sides, nerves in 7–10 pairs, reticulation coarse, obscured. Petiole appressed-pubescent, glabrescent, 1.3–2.5 cm long. Flowers appearing before the leaves, erect, fragrant, 10–12 cm diam., peduncles 12–20 × 5–7 mm, densely appressed-villous with yellowish hairs, pedicles 4–6 mm long; tepals 9, white, sometimes tinged with purple outside at the base, subsimilar, obovate to spathulate, 6–12 × 2–6 cm; stamens purplish, 10–13 mm long, anthers dehiscing sublaterally, connective appendage narrowly triangular, ca. 1 mm long, filaments 3–4 mm long; gynoecium cylindric, glabrous, 2–2.5 cm long. Fruiting peduncles 12–20 × 6–9 mm. Fruits cylindric, straight or distorted by the abortive carpels, 7.5–15 × 2.5–5 cm; ripe carpels 1–2 cm long, usually white-lenticellate, papilliferous outside, hardly beaked; scars of perianth and stamens along the torus 7–12 × 6–10 mm. Seeds obliquely ovoid to broadly ovoid, ca. 9 × 10 mm.

*Uses.* The straight-grained and fine-textured wood is used for furniture and boards; flower buds for medicinal purposes and the extraction of volatile oil; the tree as an ornamental.

*Collector's notes.* Bark brownish gray peeling off in thick plates; flowers white tinged purple at base; fruits green.

*Notes.* Ueda (1986) gave an account of the complicated synonymy. Formerly, this species was known under the name *Magnolia denudata* Desr., but Dandy (1934) changed the name to the older synonym *Magnolia heptapeta*, based on *Lassonia heptapeta* Buc'hoz. Meyer & McClintock (1987) argued that the names *Magnolia heptapeta* and *Magnolia quinquepeta* should be rejected because their types, artistic impressions of the species, are "entirely without botanical credibility." Ueda (1986), but also Treseder (1978), in his standard work on cultivated Magnolias, accepted both names. The nomenclature specialists I consulted agreed that the names *heptapeta* and *quinquepeta* should be used, "otherwise many other names should be rejected too" (H. P. Nooteboom). *Magnolia precia* Correa ex Vent., nomen nudum (Ventenat, 1806), belongs here.

22. **Magnolia sargentiana** Rehder & E. H. Wilson in Sarg., Pl. Wilson. 1: 398. 1913. TYPE: *E. H. Wilson 914* (holotype, A; isotypes, BM, E, GH, K, US).

*Magnolia conspicua* var. *emarginata* Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 38. 1905. *Magnolia denudata* var. *emarginata* Pamp., Bull. Soc. Tosc. Ortic. 20: 200. 1915. *Magnolia emarginata* (Finet & Gagnep.) Cheng, J. Bot. Soc. China 1, 3: 298. 1934. TYPE: *David s.n.* (holotype, P).

*Magnolia sargentiana* var. *robusta* Rehder & E. H. Wilson in Sarg., Pl. Wilson. 1: 399. 1913. TYPE: *E. H. Wilson 923a* (holotype, A; isotypes, K, US).

Deciduous tree to 20 m high and 25 cm diam.; young twigs 4–7 mm diam., yellow-brown, black-brown to gray-brown, glabrous; terminal winter buds ovoid, densely yellowish villous with silky, long hairs, ca. 2.7 cm long. Stipules sparsely to densely appressed-pubescent, adnate to lower base of the petiole, stipular scars 2–5 mm long. Leaves thin-coriaceous, dull green, glabrous, glossy above; pale green, densely appressed-pubescent with rather long, undulate to crisped, colorless hairs, sometimes seemingly glabrous when covered with minutely scattered hairs below; usually inequilateral, obovate, rarely broadly obovate, sometimes elliptic, 10.5–17.5(–22.5) × 5–10(–12) cm; apex acute to rounded, sometimes emarginate or truncate, base usually oblique, cuneate to broadly cuneate; midrib and nerves conspicuously elevated beneath, nerves in 8–12 pairs, reticulation coarsely netted, visible above. Petiole glabrous, 1.5–3.2(–4.7) cm long. Flowers precocious, slightly fragrant, horizontal or nodding, 15–20 cm diam. when fully open; peduncle 20–23 × 6–7 mm, pedicle 12–15 × 5–6 mm (but absent in *H.T. Tsai 51831*), glabrous to densely yellowish villous; tepals 10–12, subsimilar, purplish red outside and white to pale rose inside, spathulate to obovate, with narrow base, 6.5–9.5 × 2–3 cm; stamens purplish, 14–17 mm long, anthers dehiscing sublaterally, connective appendage triangular, ca. 1 mm long, filaments 3–4 mm long; gynoecium green, cylindric, 8–12 × 3 mm; carpels many. Fruiting peduncles glabrous to hairy, ca. 2–3.5 × 1 cm, pedicles 1.2–2.2 × 0.6–1 cm. Fruits cylindric, 3–20.5 × 1.5—2.5 cm, erect to curved; ripe carpels subglobose, 7–22 mm long, apex short-beaked; torus with scars of perianth and stamens 1.2–1.5 × 1–1.2 cm. Seeds subcordate, 8–12 × 7–10 mm.

*Distribution.* CHINA. **Sichuan**: Wa shan, *Wilson E.H. 914*; Tian Quan, *Tsang H.L. 34828*; near Xizang border, *Pratt A.E. 798*; Mt. Omei, *Chow H.C. 9777*; O-pien hsien, *Liu Y.S. 2191*; Paohsing hsien, *Chu K.L. 3908*. **Yunnan**: between Tsian and Ta Kuan, *Tsai H.T. 50843*; Wen-shan Hsien, *51831*.

*Ecology.* In broad-leaved forest. Altitude: 1,600–2,500 m. Flowering April–May; fruiting September.

*Uses.* Bark for medicinal purposes.

*Note.* *Magnolia sargentiana* var. *robusta* differs from *Magnolia sargentiana* var. *sargentiana* in its larger leaves and bigger flowers and fruits. Except for this difference in size, we could not find any characters to distinguish them. The variety, therefore, is here abolished.

23. **Magnolia sprengeri** Pampanini, Nuovo Giorn. Bot. Ital. 22: 295. 1915. TYPE: *Silvestri 4104* (holotype, FI not seen).

*Magnolia denudata* Desr. var. *purpurascens* Rehder & E. H. Wilson in Sarg., Pl. Wilson 1: 401. 1913. *Magnolia conspicua* var. *purpurascens* sensu Bean, Kew Bull. 1920: 119. 1920. TYPE: *Wilson 373* (lectotype, selected here, A; isolectotypes, E, K, US).

*Magnolia diva* Stapf ex Dandy in Millais, Magnolias 120. 1927. *Magnolia sprengeri* var. *diva* Stapf, Bot. Mag. (Curtis) 153: t. 9116. 1927. TYPE: *E. H. Wilson 21* (lectotype, selected here, K; isolectotypes, A, K, NY).

*Magnolia denudata* Desr. var. *elongata* Rehder & E. H. Wilson in Sarg., Pl. Wilson 1: 402 sub t. 9116. 1913. *Magnolia sprengeri* var. *elongata* (Rehder & E. H. Wilson) Johnstone, Asiatic Magnolias in Cultivation: 87. 1955. TYPE: *E. H. Wilson 345* (holotype, A; isotypes, E, GH, K, US).

Deciduous tree to 20 m high and 18 cm diam.; bark black-gray, falling in small flakes when old; young twigs 3–5 mm diam., yellow to yellow-brown, becoming purple-brown later, glabrous and sparsely lenticellate, old twigs gray-black, fissured; terminal winter buds broadly ovoid, 2.8–3 × 1.8–2.4 cm, densely yellowish villous with straight and silky hairs. Stipules densely pubescent with appressed yellowish white hairs, glabrescent, adnate to the base of the petiole, scars 1–2(–13) mm long. Leaves coriaceous, dark green, glabrous to sparsely pubescent along the midrib and nerves above; pale green, glabrous to appressed-pubescent with fine, short, straight and colorless hairs over the entire surface or covered with long hairs along the midrib only, glabrescent beneath; obovate to narrowly obovate, 7–14.5(–22) × 2.5–7.5(–15) cm; apex rounded, sometimes truncate and short-acuminate with 5–15-mm-long acumen, base cuneate to narrowly cuneate; midrib and nerves conspicuously elevated below, the latter in 6–8 pairs, reticulation coarse, visible on both sides. Petiole slender, glabrous or villous near the base of the blades, 1–3.5 cm long. Peduncles yellowish sericeous with straight hairs, glabrescent, stout, 10–17 × 6–8 mm, pedicles 4–8 × 4–5 mm. Flowers appearing together

with the leaves, saucer-shaped, fragrant, erect, to 20 cm diam. when fully open; tepals 12(–14), subsimilar, spathulate to oblong-obovate, 5–12(–14) × 1.5–4(–6.5) cm, pure white or sometimes with red at the base, rose outside and white inside with flush of red to purple-striate; stamens red, numerous, 1.5–1.7 cm long, anthers sublaterally dehiscing, connective appendage triangular, 1–2 mm long, filaments 5–7 mm long; gynoecium cylindric 2–2.5 × 0.3–0.4 cm, carpels ellipsoid. Fruiting peduncles 10–20 × 7–9 mm, pedicles 4–9 × 5–6 mm. Fruits cylindric and often distorted by the abortive carpels, 6–10 cm long, ripe carpels without beak, 7–15 mm long. Seeds subovoid to subcordiform, 8–12 × 7–9 mm, torus with the scars of perianth and stamens 8–10 × 8–10 mm.

*Distribution.* CHINA. **Guizhou**: Lei Gong Shan, *Li Y.K. 8921*. **Henan**: Lushih, Lao kiun shan, *Hers J 1159*. **Hubei**: Changyang Hsien, *Wilson E.H. 444*; Hsing shan hsien, *373*; Ichang, *Henry A 2522*; Patung hsien, *Chow H.C. 334*. **Hubei-Sichuan (Metasequoia area)**: *Cheng W.C. & C.T. Omei, *Liu Y.S. 1174*. **Yunnan**: Likiang, *Ching R.C. 21681*. Also recorded from Shaanxi and southern Gansu.

*Ecology.* In evergreen broad-leaved or mixed forests. Altitude: 1,200–2,000 m. Flowering March; fruiting June–July.

*Uses.* Flowers and bark used for medicinal purposes; the tree is cultivated as an ornamental.

24. **Magnolia zenii** Cheng, Contr. Biol. Lab. Sci. Soc. China, Bot. Series 8: 291, f. 20. 1933. TYPE: *W. C. Cheng 4233* (holotype, PE).

*Magnolia elliptilimba* Law & Gao, Bull. Bot. Res. (China) 4(4): 190, t. 1. 1984. TYPE: China. Henan: Nanzhao Xian, 12 Mar., 1983, alt. 400–800 m, *Z. Y. Gao 0129* (in Herb. Henan Inst. Biol. not seen).

Deciduous tree to 7 m high; bark gray, smooth; young twigs purple-brown, glabrous, sparsely lenticellate. Terminal winter buds narrowly ovoid, densely sericeous with long hairs. Stipules hairy, adnate to the base of the petiole, scars 3–7 mm long. Leaves chartaceous, dull green, glabrous above; pale green, covered with curly, long hairs along midrib and nerves beneath; obovate, 7–16 × 3–7 cm; apex abruptly short-acuminate, base broadly cuneate to blunt; nerves in 8–12 pairs. Petiole villous, glabrescent, 6–15 mm long. Flowers precocious, cup-shaped, fragrant, 10–12 cm diam., peduncles densely long-hairy, 2–8 mm long; tepals 9–12, subequal, spathulate, 7–8 × 3–4 cm, at first purple-red, becoming white above the middle and purplish toward the base when fully open, the inner tepals 6, narrow; stamens purple, 1.5–1.7 cm long, anthers dehiscing laterally, connective appendage triangular, ca. 1 mm long; filaments ca. 4 mm long; gynoecium cylindric, ca. 2 cm long, carpels ca. 4 mm. Fruits cylindric, 5–20 × 1–2.5 cm; ripe carpels subglobose, papilliferous, apex obtuse.

*Distribution.* CHINA. **Henan**: Nan Zhao Xian, *Gao Z.Y. 126*; Kiangsu, Paochuashan, *Cheng W.C. 4233*.

*Ecology.* In forest. Altitude: 250–300 m. Flowering April–May; fruiting August–September.

*Uses.* Tree cultivated as an ornamental.

*Note.* Only the type specimen of *Magnolia zenii* was available. We have not seen the type of *Magnolia elliptilimba*, but we reduce it to synonymy of *M. zenii* based on the description and the geographic distribution.

**Ib-2. Magnolia** section **Buergeria** (Siebold & Zuccarini) Dandy in Camellias and Magnolias Conf. Report: 73. 1950. *Buergeria* Siebold & Zucc., Abh. Math.-Phys. Cl. Kön. Bayer. Ak. Wiss. 4, 2: 186. 1846. TYPE SPECIES: *Magnolia stellata* (Siebold & Zucc.) Maxim. (*Buergeria stellata* Siebold & Zucc.).

Flowers appearing before the leaves (or with the leaves), pink (inner tepals sometimes tinged with rose or purple). Tepals very unequal, those of the outer whorl calycoid.

KEY TO THE SPECIES OF *MAGNOLIA* SECTION *BUERGERIA*

1. Inner tepals 4–5 cm long; connective appendage of anthers 2–3 mm long; filaments 2.5–3.5 mm; peduncles 7–11 × 4–5 mm. ..... 25. *Magnolia biondii*

Ortic. 20: 200 1915. *Magnolia fargesii* (Finet & Gagnep.) Cheng, J. Bot. Soc. China 1, 3: 296. 1934. TYPE: *Farges 1300* (holotype, P; isotype, K).

*Magnolia aulacosperma* Rehder & E. H. Wilson in Sarg., Pl. Wilson. 1: 396, 408. 1913. TYPE: *E. Wilson 361* (holotype, A; isotypes, K, US).

*Magnolia biondii* f. *purpurascens* Law & Gao, Bull. Bot. Res. (China) 4(4): 192, t. 2. 1984. TYPE: *Gao, Z. Y. 0122* (in Herb. Henan Inst. Biol.).

Deciduous tree to 12 m high and 60 cm diam.; bark pale gray, smooth; twigs slender, glabrous to appressed-pubescent, glabrescent; terminal winter buds ovate, densely yellowish villous. Stipules yellowish to white pubescent with short hairs, adnate to the lower base of the petiole, stipular scars 1–4 mm long. Leaves chartaceous, dull green above, pale green, usually pubescent with long, straight, undulate, crisped and colorless hairs along the midrib and nerves to glabrous beneath, ovate, narrowly obovate-elliptic to oblong-elliptic, rarely oblanceolate, 10–21.7 × 3.5–11 cm; apex acute to acuminate, base cuneate to rounded; nerves in 10–15 pairs. Petiole 1–2 cm long. Peduncles 7–11 × 4–5 mm, densely pubescent with long, yellowish hairs, pedicles very short, ca. 2 mm long. Flowers precocious, 6–8 cm diam., fragrant; tepals 9, the outer 3 nearly linear, 8–11 mm long, the inner tepals 6, white, spathulate, 4–5 × 1.3–2.5 cm, the innermost ones smaller than the others, abaxial faces tinged with purple at the base; stamens 8–10 mm long, connective appendage 2–3 mm long, filaments thick, purple outside, white inside, 2.5–3.5 mm long. Fruits cylindric, ± contorted, 6–14.5 cm long; fruiting peduncles ± pubescent, glabrescent, 1–1.2 × 0.6 cm, pedicles 4–6 mm long; ripe carpels black, globose, compressed laterally, densely papilliferous, scars of perianth and stamens along the torus 9–10 × 6–7 mm.

*Distribution.* CHINA. **Henan**: Yudong Xian, *Pucha Biaoben 23252*; Lushin, Tungho, *Hers J 991*; Sunghsien, Sankuanmiao, *541*; Yungning, Tsi Li Ping, *1343*. **Hubei**: Li-chuan, Tuan-Pao-Shih, *Hwa C.T. 104*; Liang Dung Gonn, *Chun W.Y. 4409*. **Shaanxi**: Nanwutai forest S of Hsingan (Si-an), *Fenzel G. 2893, 2951*. **Sichuan**: Wan-Hsien, Mou-Tao-Chi, Kan-Tsao-Ping, *Hwa C.T. 65*; Tchen Keou Tin, *Farges R.P. 1300*. Also reported from Gansu (W. Qinling) and Shaanxi (Dabashan).

*Ecology.* In forest. Altitude: 400–2,000 m. Flowering March; fruiting September.

*Uses.* Wood used for furniture and general construction work; flower buds for medicine, flowers for volatile oil; tree grown as an ornamental.

*Collector's notes.* Bud silky; flowers white; fruits purplish red tinged.

*Note.* Several new species and varieties of *Magnolia* were recently published in Henan. Their descriptions basically fit in *Magnolia biondii*. Unfortunately, we have not seen their type specimens or other collections; therefore, we have dealt with them under "Dubious Species." Pavolini (1908) misidentified this species as *Magnolia obovata* Thunb.

26. **Magnolia cylindrica** E. H. Wilson, J. Arnold Arbor. 8: 109. 1927. TYPE: *R. C. Ching 2949* (holotype, A; isotypes, E, K, US).

Deciduous tree to 10 m high; bark white-gray, smooth; young twigs purple-brown to dark purple, yellowish appressed-pubescent, sometimes glabrous; terminal winter buds ovate, yellowish sericeous with long hairs. Stipules densely pubescent, adnate to the petiole, stipular scars 2–7(–9) mm long. Leaves chartaceous to subcoriaceous, dark bright green, glabrous above, greenish, appressed-pubescent with fine, short, straight, and colorless hairs beneath, elliptic, narrowly obovate-elliptic, narrowly obovate to obovate, 8–15 × 3–9 cm; apex acute to short-acuminate, base cuneate or narrowly cuneate; nerves fine, prominent below, in 8–11 pairs. Petiole with same indument as young twigs, 7–10(–24) mm long. Peduncles densely yellowish villous, 1–1.2 × 0.4–0.5 cm, pedicles 5–6 × 2–3 mm long; bracts 2, gray-pubescent outside. Flowers precocious; tepals 9, the outer 3 subulate, 2–2.5 × 0.5–1 cm, the inner tepals 6, white, tinged pale rose outside at the base, broadly spathulate to obovate, 6.5–10 × 2.5–4.5 cm, the innermost 3 tepals erect; stamens ca. 7 mm long, anthers laterally dehiscent, connective appendage triangular, ca. 1 mm long, filaments purple, glabrous, ca. 3 mm long; gynoecium green, cylindric, ca. 1.2 cm long. Fruiting peduncles pubescent, 1 1.5 × 0.5–0.6 cm, pedicles 5–10 × 4 mm. Fruits cylindric, 5–7.5 × 1.8–2.5 cm, pendulous.

*Distribution.* CHINA. **Anhui**: Bai Ma Zhai, Lan Ni Ao, Jonzhai, *Yao K. 9006*; Wang Shan, *Ching R.C. 2949*. **Fujian**: near Zhejiang border, *Ching R.C. 2501*. Also reported from northern Jiangxi and western Zhejiang.

*Ecology.* In forest. Altitude: 300–800 m. Flowering May–June; fruiting August–September.

27. **Magnolia kobus** DC., nom. cons. prop., Syst. Nat. 1: 456. 1817. *Magnolia glauca* var. α Thunb., Fl. Jap.: 236, 378, 1784b. *Magnolia tomentosa* Thunb., Trans. Linn. Soc. London.

2: 236. 1794a. *Yulania kobus* (DC.) Spach, Hist. Veg. 7: 467. 1839. TYPE: *Kaempfer* (lectotype, selected by Rehder (1930), BM).

*Magnolia praecocissima* Koidz., Bot. Mag. (Tokyo) 43: 386. 1929. *Buergeria obovata* Siebold. & Zucc. (non *Magnolia obovata* Thunb. 1794), Abh. Math.-Phys. Cl. Königl. Bayer. Akad. Wiss. 4, 2: 187. 1845. TYPE: *Von Siebold, left half of L-908-126-1027* (lectotype, selected by Koidzumi (1929), L.).

This specimen has disappeared in the Leiden Herbarium. Ueda (1985) provided a photo of it, and as long as the specimen has not been found, that is the only trace of a type.

Deciduous tree to 20 m high, often branching near the base; bark gray, rough, fissured; young twigs 1.5–3 mm diam., green, soon turning purple-brown, glabrous or somewhat puberulent; terminal buds ovate, yellow-sericeous with long hairs. Stipules adnate to the base of the petiole, stipular scars 3–7(–10) mm long. Leaves dark green, white pubescent at the base of midrib above, gray-green, white pubescent along the nerves and at junctions with the nerves beneath, obovate-elliptic, ca. 8–17 × 3.5–9.5(–11) cm; apex abruptly acuminate, base narrowly cuneate, slightly decurrent; midrib and nerves impressed when dry above; nerves in 8–12 pairs, margin slightly undulate. Petiole white villous, ca. 1–2.6 cm. Flowers appearing before the leaves, white, fragrant; peduncles 7–10 × 2–2.5 mm, glabrous to hairy on nodes, pedicles 1.4–4 mm long; bracts 2–3, pubescent outside; flower buds narrowly ovate, flowers ca. 9–10 cm diam. when fully open, tepals 9, outer tepals 3, greenish or white, triangular-linear, 5–15 × 2–3 mm, inner tepals white, sometimes flushed with red at the base, spathulate, ca. 5–7(–9) × 1.5–3 cm; stamens ca. 8–10 mm long, anthers dehiscing latrorsely or sublatrorsely, filaments red, ca. 2 mm; connective appendage triangular, ca. 0.5 mm long; gynoecium green, cylindric, ca. 1–1.5 cm long. Fruiting peduncles 8–10 × 3–6 mm, pedicles 6–9 × 3–4 mm. Fruits cylindric, 3.5–11 cm, often contorted by sterile carpels; carpels nearly oblong, white lenticellate. Scars of perianth and stamens 5–6 × 3–5 mm. Seeds subglobose, 10–9 × 9–8 mm.

*Distribution.* Native of Japan and southern Korea, cultivated in Qingdao, Nanjing, and Hangzhou.

*Uses.* Wood used for general construction work and furniture, tree grown as an ornamental.

*Note.* The Kaempfer collection of *Magnolia* named "kobus," from which Kaempfer t. 42 (1791) is drawn, forms the main part of the protologue of Thunberg's (1784b) *Magnolia glauca* var. α. *Magnolia tomentosa* Thunb. (1794a) is based on *Magnolia glauca* Thunb. var. α, with citation of Kaempfer t. 42. So far there is no doubt about the identity of *Magnolia tomentosa*, especially because Thunberg visited London and studied Kaempfer's collections and drawings. But Thunberg (1794b) published a list of specimens kept in UPS, which includes *Magnolia tomentosa*; this name is, in his handwriting, written on sheet number 12887. This specimen, however, appears to be *Magnolia stellata*. If Ueda's (1986) interpretation, that Thunberg himself selected number 12887 as the type of *Magnolia tomentosa*, is correct, *Magnolia tomentosa* becomes the legitimate name for *Magnolia stellata*. The latter name is then superfluous. Thunberg (1805) also published a drawing of sheet number 12887, with the name *Magnolia tomentosa* but without a description. This has commonly been cited as *Magnolia tomentosa* Thunb. (1805), non Thunb. (1794a).

De Candolle (1817), when describing *Magnolia kobus*, cited Banks ic. Kaempfer t. 42 first in the protologue, and then *Magnolia glauca* Thunb. var. α. He cited *Magnolia tomentosa* Thunb. with a question mark. De Candolle also cited *Magnolia gracilis* Salisb. Salisbury (1806) described *Magnolia gracilis* with an excellent figure based on a collection that was sent to De Candolle and is kept in G-DC. This collection appears to be *Magnolia quinquepeta*. However, because Salisbury cited *Magnolia tomentosa* without excluding its type, *Magnolia gracilis* is a superfluous name of *Magnolia tomentosa*. De Candolle, possibly not knowing what *Magnolia tomentosa* was, gave a new name to *Magnolia gracilis* Salisb.: *Magnolia kobus* DC. Because De Candolle cited *Magnolia tomentosa* with a question mark, it could be assumed that he excluded the type of that species, and that *Magnolia kobus* DC. is a superfluous name of *Magnolia quinquepeta* (Buc'hoz) Dandy (1934), based on *Lassonia quinquepeta* Buc'hoz (1779). This was Ueda's (1985, 1986) opinion, and Koidzumi's (1929). Koidzumi assumed that the type of *Magnolia gracilis* Salisb. was also the type of *Magnolia kobus* DC. He therefore adopted a nomen novum, *Magnolia praecossima*, for the species up to then known as *Magnolia kobus*. His name was based on a synonym, *Buergeria obovata* Siebold. & Zucc. (non *Magnolia obovata* Thunb., 1794a). However, it is also possible to exclude *Magnolia gracilis* Salisb. from *Magnolia kobus* DC. Then the latter is typified with the type of *Magnolia tomentosa* Thunb.

In that case there are two possibilities. If *Magnolia tomentosa* Thunb. is lectotypified with *Thunberg 12887*, *Magnolia kobus* DC. is a superfluous name for *Magnolia tomentosa* Thunb. and is the species hitherto known as *Magnolia stellata* (Siebold & Zucc.) Maxim. (1872), based on *Buergeria stellata* Siebold & Zucc. (1845). As pointed out above, *Magnolia stellata* is then a superfluous name for *Magnolia tomentosa* Thunb. If *Magnolia tomentosa* Thunb. is lectotypified with the collection of Kaempfer, as done by Rehder (1930), *Magnolia kobus* DC. is a superfluous name for *Magnolia tomentosa* Thunb. This is rejected by Ueda (1986), who stated that Rehder's lectotypification was contrary to the rules because he would have selected it mechanically. Because Rehder gave ample justification for his choice, we reject that he chose mechanically. We accept *Magnolia kobus* DC. as the name for this species, and we propose both *Magnolia kobus* and *Magnolia stellata* be conserved.

28. **Magnolia stellata** (Siebold & Zucc.) Maxim., nom. cons. propos., Bull. Acad. Sci. St.-Petersburg 17: 419. 1872. *Magnolia kobus* DC. f. *stellata* (Siebold & Zucc.) Blackb., Popul. Gard. 5, 3: 68. 1954. *Magnolia kobus* var. *stellata* Blackb., Amatores. Herb. 17: 2. 1955. *Buergeria stellata* Siebold & Zucc., Abh. Math.-Phys. Cl. Königl. Bayer. Akad. Wiss. 4, 2: 186, t. IIa. 1845. *Talauma stellata* (Siebold & Zucc.) Miq., Ann. Mus. Bot. Lugduno-Batavum 2: 257. 1866. TYPE: *Von Siebold L-908-126-701, -750* (L not seen).

The type was photographed at L for Ueda's (1985) publication. The specimen had not yet been incorporated in the family at the time the Rijksherbarium moved to another building. The type has never been seen again.

*Magnolia halleana* Parsons ex Robinson, Gard 13: 572, f. opp. 572. 1878. TYPE: probably the figure.

*Magnolia stellata* var. *keiskei* Makino, Bot. Mag. (Tokyo) 26: 82. 1912. *Magnolia keiskei* (Makino) Ihrig, Arb. Bull. Univ. Wash. 11, 2: 33. 1948. TYPE = plate cited by Makino.

*Magnolia stellata* var. *rosea* Arnott ex Veitch ex Hu, Man. Econ. Pl. 1: 383. 1955. *Magnolia rosea* (Veitch) Ihrig, Arb. Bull. Univ. Wash. 11,2: 34. 1948. *Magnolia kobus* DC. f. *rosea* (Veitch) Blackburn, Popul. Gard. 5, 3: 73. 1954.

Deciduous large shrub or treelet to 5 m high; young twigs slender, 2–3 mm diam., brown-purple to black-purple, sometimes gray-black, densely appressed-pubescent with long, gray or yellowish hairs, glabrescent, smooth, old twigs brown, glabrous, glabrescent. Stipules densely gray pubescent with silky hairs, adnate to the petiole, stipular scars as long as the petiole, 3–14 mm. Leaves thinly chartaceous, dark bright green, glabrous above; pale green, glabrous below, narrowly obovate to obovate, occasionally ovate, 7–11 × 2–5.6 cm; apex obtuse to acute, base cuneate to attenuate, usually decurrent along the petiole, rarely rounded; margin sparsely pubescent; midrib and nerves finely pubescent above, densely villous, glabrescent beneath; nerves fine, visible below, in 10–14 pairs, reticulation coarse, hardly visible on both sides. Petiole covered with same indumentum as the stipules, glabrescent later, 3–14 mm long. Flowers appearing before and after the leaves, white or rose, fragrant, to 10 cm diam.; peduncles densely gray villous, 2–6 × 2–3 mm, pedicle 0.2–4 × 3 mm; tepals 12–18, very unequal, usually narrowly obovate to spathulate, apically obtuse, rarely acute, basally broad, 3.2–6.5 × 0.7–1.7 cm; stamens 6–11 mm long, anthers dehiscing latrorse or sublatrorse, connective appendage triangular, ca. 1 mm long, filaments 2–5 mm long; gynoecium cylindric, 7–10 × 2–3 mm; carpels many. Fruiting peduncles densely hairy, 3–6 × 3–4 mm. Fruits cylindric or irregularly shaped abortive carpels, 2–4.5 × 1–1.5 cm; ripe carpels subglobose, 7–12 mm long, with short beaks at the apex; scars of perianth and stamens along the torus 2–6 × 3–5 mm.

*Distribution.* Native to Japan, cultivated in Nanjing.

*Uses.* Tree grown as an ornamental.

*Note.* Ueda (1985, 1986) gave an account as to why the common star Magnolia, *Magnolia stellata*, should be legitimately named *Magnolia tomentosa*. However, because of the economic importance of the species it will be proposed as nomen conservandum. See also the notes under *M. kobus*.

**Ib-3. Magnolia** section **Tulipastrum** (Spach) Dandy, in Camellias and Magnolias, Conf. Report: 74. 1950. *Tulipastrum* Spach, Hist. Natur. Veget., Phanerog. 7: 481. 1839. TYPE SPECIES: *Magnolia acuminata* L.

Flowers appearing together or after the leaves, pink, purple, or red. Tepals very unequal (those of the outer whorl calycoid).

29. **Magnolia quinquepeta** (Buc'hoz) Dandy, J. Bot. 72: 103. 1934. *Lassonia quinquepeta* Buc'hoz, Pl. Nouv. Découv. 2: f. 2 of t. 19. 1779. TYPE: f. 2 of t. 19 (Buc'hoz, 1779).

*Magnolia gracilis* Salisb., Parad. Lond. 2: 87, t. 87, nom. illeg. 1807. *Magnolia liliflora* var. *gracilis* (Salisb.) Rehder in L. H. Bailey, Stand. Cycl. Hort. 4: 1968. 1916. TYPE: *Salisbury s.n.* (G-DC).

*Buergeria obovata* Siebold & Zucc., Abh. Math.-Phys. Cl. Königl. Bayer, Akad. Wiss. 4,2: 187. 1845. *Talauma ?sieboldii* Miq. in Ann. Mus. Bot. Lugduno-Batavum 2, 9: 257, 1866. *Talauma obovata* (Siebold & Zucc.) Benth. & Hook. f. ex Hance, J. Bot. 20: 2. 1882 (non Korthals, 1851). TYPE: *Von Siebold right half of L-908-126-1027* (L).

Deciduous shrub to 3.5 m high; bark gray-brown; young twigs 2–4 mm diam., dark purple, glabrous or sometimes hairy on a few nodes near the peduncles, smooth, sparsely lenticellate, old twigs gray-purple and longitudinally fissured; terminal winter buds ovoid, 12–14 × 5–6 mm, yellowish sericeous. Stipules densely yellowish to yellowish white pubescent, adnate to the entire petiole, scars 3–15 mm long. Leaves membraneous to chartaceous, dark green, glabrous, sparsely pubescent over the surfaces or only along the midrib above, pale green, glabrous to pubescent with long, undulate to rarely crisped, colorless hairs along the midrib and the nerves below, broadly elliptic to obovate, 6–15(–26) × 3–7(–10) cm; apex acute to acuminate with short or long acumen, base cuneate to attenuate, usually decurrent along the petiole; midrib and nerves prominent beneath, nerves in 8–10 pairs. Petiole pubescent, glabrescent, ca. 3–15 mm long. Flowers appearing with and after the leaves, slightly fragrant; peduncles glabrous or densely villous with silky, yellowish hairs, glabrescent, 5–20 × 6–8 mm, pedicles 10–12 × 5–7 mm, sometimes absent; bracts densely yellowish sericeous, 11 cm long; tepals 9, the outer 3 subulate, occasionally ovate, greenish to purplish, 10–27 × 4–8 mm, the inner tepals 6, spathulate to obovate, purplish outside and white inside, 5.5–9 × 2.5–4.5 cm; stamens purple-red, 8–10 mm long, anthers dehiscing laterally, connective appendage triangular, filaments purple, ca. 2 mm long; gynoecium cylindric, purplish, 1.2–1.4 × 0.4 cm, carpels many. Fruiting peduncles 10–20 × 3–6 mm, pedicles 3–8 × 3–4 mm long. Fruits cylindric, erect to curved as the carpels partly abortive, 3–6.5 × 1–2 cm; ripe carpels ellipsoid to subglobose, 8–15 mm long, gray-lenticellate outside, short-beaked; torus with the scars of perianth and stamens 8–12 × 5–7 mm. Seeds subcordate, ca. 10 × 7 mm.

*Distribution.* CHINA. **Hubei**: Sichuan, Jiang Jin, *Chen S.J. et al. 840055*; Chengtu, *Fang W.P. 13256*; Kun Hsien, *Wang F.T. 20793, Chiao C.Y. & C.S. Fan 444.* **Yunnan**: N end Lichiang valley, 27°5′N, *Forrest G. 2174*; Shweli–Salwin divide, 25°48′N, 98°48′E, *24700*; Tien chin pu valley, 25°30′N, *5539.* Widely cultivated.

*Ecology.* Flowering March–April; Fruiting August–September.

*Uses.* Flower buds and bark used for medicinal purposes, the tree as an ornamental.

*Note.* Ueda (1985) explained the complicated synonymy. The species was formerly known as *Magnolia lili(i)flora.* The name *Magnolia obovata* Thunb. has also been used for this species for a long time.

See also the note under *Magnolia heptapeta.*

*Magnolia hirsuta* Thunb. (1794b, 1824), based on *Thunberg 12884*, is a nomen nudum.

**Ic. Magnolia** subgenus **Talauma** (Juss.) Pierre, Fl. For. Cochinch. 1: sub t. 1. 1880. TYPE SPECIES: *Magnolia plumierii* Schwartz.

Evergreen tree. Stipular scars up to the apex of the petiole. Anthers introrse. Fruits with connate carpels, the apical parts of the carpels falling off leaving the seeds exposed, hanging from the thread-like funiculus.

**Ic-1. Magnolia** section **Blumiana** Blume, Fl. Java Magnol.: 32. 1829.

Leaves evenly distributed; midrib prominent above, at least toward base. Flowers bisexual; tepals subequal; connective produced into a short or long appendage, triangular. Gynoecium not stipitate. Fruits with connate carpels. When mature the apical parts of the carpels circumscissile and falling, dehiscing along the dorsal suture or not, the basal parts remaining adnate to the torus, or apical parts falling in irregular masses.

30. **Magnolia candollii** (Blume) H. Keng var. **obovata** (Korth.) Nooteboom, Blumea 32: 374. 1987. *Talauma obovata* Korth., Ned. Kruidk. Arch. 2, Versl.: 98. 1851. TYPE: Sumatra Gunung Pamatton, *Korthals s.n.* (lectotype, selected here, L sheet no. 925.250-739; isolectotype, BO).

*Talauma hodgsoni* Hook. f. & Thomson, Fl. Ind. 74. 1855. TYPE: Sikkim, 2,000–5,000 ft., *J. D. Hook s.n.* (holotype, K; isotype, L).
*Talauma oblanceolata* Ridley, Fl. Malay Penins. 5: 286. 1925. TYPE: *H. N. Ridlley 15590* (K. SING).
*Talauma betongensis* Craib, Kew Bull. 1925: 7. 1925. *Magnolia betongensis* (Craib) H. Keng, Gard. Bull. Sing. 31: 129. 1978. TYPE: *Kerr 7449* (holotype, K; isotype, BM).
*Talauma sclerophylla* Dandy, J. Bot. 66: 47. 1928. TYPE: *Haviland 3148* (holotype, BM; isotype, K).
*Talauma levissima* Dandy, Kew Bull. 1928: 191. 1928. TYPE: *H. N. Ridley 9047* (holotype, K; isotype, SING).

Tree to 25 m high; young twigs whitish, stout, ca. 1 cm diam., glabrous. Stipules adnate to the petioles, stipular scars from up to about halfway the length of the petioles to nearly as long as the petioles. Leaves coriaceous, glabrous, obovate or sometimes elliptic, 17–50 × 8–22 cm; apex rounded to slightly acuminate, base cuneate, usually attenuate; nerves in 9–25 pairs, curved upward and meeting in an intramarginal vein, reticulation rather coarse, sometimes obscure. Petiole 2.5–7 cm long. Peduncles glabrous, 3–12 × 0.5–1.3 cm, with 2–18 nodes, pedicles absent or very short. Tepals 9, thick fleshy, the outer 3 greenish outside, sometimes reflexed in mature flowers, 1.5–5(–6.5) × 1–2 cm, the inner tepals 6, creamy white, erect, shorter than to as long as the outer tepals; stamens 1.2–3 cm long, connective appendage triangular to subulate, 1–3 mm long, filaments 1–3 mm long; gynoecium ellipsoid, 1–2 cm long, carpels 10–100, pubescent, the styles long, becoming woody spines to 15 mm in fruits but sometimes caducous; scars of perianth and stamens on torus ca. 5 × 8 mm. Fruits ellipsoid, 5–15 × 4–7.5 cm.

*Distribution.* Tibet, Sikkim, Nepal, Assam (Khasia), Burma, Thailand, and Malesia. In CHINA. **Southern Yunnan:** *D.T. Tao 413.*

*Ecology.* In evergreen broad-leaved forest. Altitude: 800–1,500 m. Flowering May–June; fruiting August–September.

*Notes.* Without fruits this species is hard to distinguish from *Magnolia henryi* Dunn. The latter species has, as typical in subgenus *Magnolia*, follicles that dehisce dorsally. In subgenus *Talauma* the apical parts of the carpels fall off entirely, leaving the axis with the carpellar scars and red seeds hanging from a funiculus. *Magnolia henryi* is therefore intermediate between the two subgenera. *Talauma luchuensis* Law (manuscript), from Yunnan (*D.T. Tao 413*, KUN), is *Magnolia candollii* var. *obovata*, with the developing fruits abnormally precocious.

*Magnolia candollii* var. *obovata* was erroneously identified as *Manglietia glauca* (non Blume, 1823) by Ridley (1922) for the collection of L. M. Bell & Haniff and by Ridley (1913) and Merrill (1921a) as *Talauma candollei* (non Blume, 1823).

## Hybrids and Cultivated Species of Sections Not Native to China

31. **Magnolia ×soulangiana** Hamel, Ann. Soc. Hort. Paris 1: 90. 1827. *Magnolia yulan* var. *soulangiana* (Hamel) Lindl., Bot. Reg. 14: t. 1164. 1828. TYPE: We do not know whether a lectotype has ever been designated.

Deciduous small tree or large shrub to 6–10 m high; young twigs purple-brown or dark purple, 3–4 mm diam., sparsely to densely pubescent, or hairy only at the leaf axils, soon glabrescent; terminal winter buds ovoid, densely brownish villous with somewhat shiny hairs. Stipules densely pubescent with appressed, long, straight, and brownish hairs, adnate to the petiole, scars 4–15 mm long. Leaves membraneous to chartaceous, dark bright green, covered with scattered hairs everywhere or along midrib and nerves above, greenish, pubescent with long, straight, undulate to curly, colorless hairs along midrib, nerves and reticulation beneath, obovate, 6–17.5(–22) × 4–9(–13) cm; apex usually abruptly short-acuminate, acumen 3–20 mm long, base obtuse, cuneate to attenuate; nerves conspicuous below, in 7–10 pairs, reticulation coarsely netted, obscure on both surfaces. Petiole pubescent, 1–1.5 cm long. Flowers appearing before and after the leaves; peduncles densely pubescent with yellow to yellowish white hairs, 12–14 × 4–6 mm, pedicles 5–8 × 3–4 mm; tepals 9, white flushed with pink or purple outside, white or pink inside, spatulate to obovate, the outer 3 subequal to the inner 6 tepals, sometimes about half the length of the inner ones, 5–12.5(–15) × 2–5.5(–9) cm; stamens purple, 1–1.2(–1.4) cm long, anthers dehiscing laterally, connective appendage triangular, ca. 1 mm long, filaments 3–4 mm long; gynoecium green, glabrous to hairy, cylindric, 1.5–2.2 × 0.3–0.4 cm. Fruits cylindric, ca. 5–10 × 3 cm; ripe carpels ovoid to subglobose, white-lenticellate, 1–1.5 cm long, without beaks; torus with scars of perianth and stamens ca. 8 × 8 mm. Seeds broadly ovoid or obovoid, slightly compressed, ca. 1.2 cm long.

*Note.* Hybrid from *Magnolia heptapeta* and *Magnolia quinquepeta*, cultivated in gardens as an ornamental.

**Magnolia** (subgenus *Magnolia*) section **Theorhodon** Spach, Hist. Natur. Veget. Phanerog. 7: 470. 1839.

Stipules free from the petiole, leaves evergreen. Flowers neither precocious nor with a much reduced outer whorl of tepals, tepals subsimilar in texture. Fruit ellipsoid to oblong. Not native to China.

32. **Magnolia grandiflora** L., Syst. Nat. ed. 10 (2): 1082. 1759. TYPE: ?

Evergreen tree up to 30 m high in its original habitat; bark brownish or gray; young twigs stout, 6–7 mm diam., dull brown, densely yellowish sericeous, eventually glabrous. Stipules covered with the same indument as the young twigs, free from the petiole. Leaves thick coriaceous, dark green, glossy above, green, densely hairy with short to long, undulate to curly, colorless or brown hairs, gradually glabrescent beneath, elliptic, ovate to obovate, 10–20 × 4–10 cm; apex acute to short-acuminate, base cuneate to broadly cuneate; midrib and nerves visible on the undersides, nerves in 8–10 pairs, reticulation coarsely netted, prominent above, obscured below. Petiole 1.5–4 cm long, without stipular scars. Flowers erect, heavily scented, 15–20 cm diam., peduncles 3–4 × 0.8–0.9 cm, densely yellowish sericeous; pedicles very short, ca. 1 mm long; tepals 8–12, subsimilar, white, broadly obovate, broadly elliptic to orbicular, basally short-clawed, concave, thick fleshy, 8–10 × 5–8 cm; stamens purplish, ca. 2 cm long, anthers introrsely dehiscing, connective appendage triangular, ca. 2 mm long, filaments flat, 1–2 mm long; gynoecium ellipsoid, densely yellowish tomentose; carpels ovate, 1–1.5 cm, styles recurved. Fruiting peduncles 3–4 × 0.8–0.9 cm, pedicles ca. 1 mm long. Fruits ovoid-cylindric, 5–10 × 4–5 cm, densely brown or yellow tomentose; ripe carpels apically long-beaked, scars of perianth and stamens along torus 1.7–2 × 1 cm. Seeds ellipsoid to ovoid, compressed laterally, ca. 1.4 × 0.6 cm.

*Distribution.* Native of southeastern United States, cultivated in southern China.

*Uses.* Wood yellow-white, heavy and hard, used for interior finish; leaves, young shoots, and flowers extracted for volatile oil; the tree is a spectacular ornamental.

**II. Manglietia** Blume, Verh. Bat. Gen. 9: 149. 1823. *Magnolia* sect. *Manglietia* (Blume) Baillon, Adansonia 7: 66. 1866. TYPE SPECIES: *Manglietia glauca* Blume.

*Paramanglietia* Hu & Cheng, Acta Phytotax. Sin. 1, 2: 255. 1951. TYPE SPECIES: *Paramanglietia aromatica* (Dandy) Hu & Cheng.

*Manglietiastrum* Law, Acta Phytotax. Sin. 11: 72, t. 2. 1979. TYPE SPECIES: *Manglietiastrum sinicum* Law.

*Tree.* Stipules adnate to or free from petiole. Flowers terminal, solitary, bisexual; tepals 9–13, 3-merous, subequal; anthers introrse, connective produced into a short or long appendage. Gynoecium sessile, but a gynophore present in section *Manglietiastrum*. Follicles free, crowded, dehiscent along the dorsal and sometimes also the ventral suture.

*Distribution.* About 25 species in tropical and subtropical Asia from the eastern Himalayas eastward to southern China and Malesia (not in the Moluccas and New Guinea). Eighteen species in China.

*Note.* *Manglietia* is still treated as a separate genus mainly because the number of ovules is 4–12(–16), while in *Magnolia* it is 2(–4). Leaf and wood anatomical characters point to the fact that *Manglietia* consists of a group of closely related species, although the similarity with *Magnolia* is great. However, all genera of Magnoliaceae as recognized by Nooteboom (1985) are quite similar in anatomical characters.

Many species of *Manglietia* have a hypodermis of 1–2 subepidermal layers beneath the upper epidermis, some also adjacent to the lower epidermis; few species have this hypodermis adjacent only to the lower epidermis. Species of *Magnolia* mostly lack a hypodermis. *Manglietia* consists entirely of evergreen species, thus the anatomy must be compared with the anatomy of evergreen species of *Magnolia*. The species of *Manglietia* usually do not have helical thickenings and usually have scalariform perforations and large vessel-ray pits throughout the rays; this pitting is present only in the marginal ray cells of the evergreen species of *Magnolia*. Scalariform perforations do occur in some deciduous species of *Magnolia*, and helical thickenings are found in a few species of *Manglietia*.

Regarding *Manglietia sinica* [*Manglietiastrum sinicum* Law, *Magnolia sinica* (Law) Noot.; Nooteboom (1985) at that time was not able to study any collections], we conclude that the number of ovules, as well as the sometimes well-developed hypodermis, and the scalariform and unilateral compound vessel-ray pitting throughout the rays, warrant regarding it as a species of *Manglietia*, not of *Magnolia*. Moreover, oil cells are usually absent in the rays, as in *Manglietia*. However, the discontinuous helical thickenings in the vessels point to *Magnolia*, although this character is found in a few other species of *Manglietia*.

KEY TO THE SPECIES OF *MANGLIETIA*
(primarily based on flower characters)

1. Twigs glabrous. ..... 2
1. Twigs hairy at least when young. ..... 12
2(1). Gynoecium stipitate; stipules free. ..... 18. *Manglietia sinica*

2. Gynoecium not stipitate; stipules adnate to petiole. ..... 3
3(2). Leaves glaucous beneath. ..... 4
3. Leaves not glaucous beneath. ..... 6
4(3). Twigs 4–5 mm thick; leaf base narrowly cuneate, reticulation rather obscure. ..... 2. *Manglietia conifera*
4. Twigs 6–10 mm thick; leaf base cuneate, reticulation distinct. ..... 5
5(4). Peduncle 15 mm long; stipules pubescent; leaves obovate, 5–7 cm broad, apex short-acuminate; gynoecium hairy; fruits ovoid, 6 cm long, follicles hairy. ..... 13. *Manglietia microtricha*
5. Peduncle 30–34 mm long; stipules glabrous; leaves narrowly obovate, 10.5–13 cm broad, apex acuminate; gynoecium glabrous; fruits ovoid-oblong, 10–16 cm long, follicles glabrous. ..... 8. *Manglietia grandis*
6(3). Peduncle 5–7 mm thick. ..... 7
6. Peduncle 2–4 mm thick. ..... 9
7(6). Leaves 11–16 cm broad, reticulation distinct; stipular scars on petiole 16–45 mm long; peduncle hairy; flower purple or red, outer tepals 12–14 cm long; gynoecium 27 mm high, carpels 70–80; fruits 9.5 cm long. ..... 11. *Manglietia lucida*
7. Leaves 3.5–10 cm broad, reticulation rather obscure; stipular scars on petiole 1–7 mm long; peduncle glabrous; flower (greenish) white, outer tepals 5.5–8(–20) cm long; gynoecium 16–22 mm high, carpels 12–30 or 38–46; fruits 5–7 cm long. ..... 8
8(7). Pedicle 4 mm; stipules (rufous) villous; leaf base cuneate; apex short-acuminate; petiole not dilated at base; outer tepals oblong; connective appendage of anthers semiorbicular, 1 mm long, filaments 1 mm long; gynoecium ovoid; fruiting peduncles 3–5.5 cm long, fruits ellipsoid. ..... 15. *Manglietia pachyphylla*
8. Pedicle 6–8 mm; stipules pubescent; leaf base attenuate-cuneate, apex acuminate; petiole dilated at base; outer tepals obovate-elliptic; connective appendage of anthers triangular, 1.8 mm long, filaments 2 mm long; gynoecium broadly ellipsoid; fruiting peduncles 9–11 mm long, fruits ovoid or ovoid-globose. ..... 5b. *Manglietia fordiana* var. *calcarea*
9(6). Carpels 45–86. ..... 10
9. Carpels (12–)20–36. ..... 11
10(9). Gynoecium glabrous, tree to 25 m high; stipules glabrous or pubescent; reticulation of leaf distinct; outer tepals thin-coriaceous, stamens 13–16 mm long, connective appendage triangular with a sharp pointed tip, filaments 2–5 mm long; gynoecium ovoid or narrowly ovoid, 17–28 mm high; fruiting peduncles 5–10 mm thick, fruits ovoid-oblong or cylindric, 6.5–11 cm long; scars of perianth and stamens along torus under fruit 14–20 mm long. ..... 10. *Manglietia insignis*
10. Gynoecium hairy, tree to 8 m high; stipules sparsely hairy; reticulation of leaf rather obscure; outer tepals thick-fleshy, stamens 10 mm long, connective appendage triangular, filaments 1 mm long; gynoecium ellipsoid, 14–15 mm high; fruiting peduncles 3–4 mm thick, fruits ovoid-ellipsoid, 3.5 cm long; scars of perianth and stamens along torus under fruit 7–9 mm long. ..... 4. *Manglietia duclouxii*
11(9). Outer tepals 5.5–7 cm long, inner tepals 4–4.8 cm long; connective appendage of anthers triangular, 1.8 mm long; leaf base cuneate, reticulation coarse. ..... 5a. *Manglietia fordiana* var. *fordiana*
11. Outer tepals 3.5 cm long, inner tepals 2.8 cm long; connective appendage of anthers semiorbicular, 1–1.5 mm long; leaf base narrowly cuneate, reticulation fine. ..... 2. *Manglietia conifera*
12(1). Leaves glaucous beneath. ..... 13
12. Leaves not glaucous beneath. ..... 15
13(12). Peduncle 10 mm long; apex of leaf short-acuminate, petiole dilated at base; outer tepals 2–2.2 cm long, thick-fleshy; connective appendage of anthers triangular. ..... 3. *Manglietia dandyi*
13. Peduncle 15–90 mm long; apex of leaf acuminate or acute, petiole not dilated at base; outer tepals 3.5–7.5 cm long, thin-coriaceous; connective appendage of anthers triangular with a sharp pointed tip, or semiorbicular. ..... 14
14(13). Stipules glabrous; reticulation of leaf distinct, coarse, base cuneate; pedicle present; inner tepals obovate or elliptic; connective appendage of anthers triangular with a sharp pointed tip, 4 mm long; scars of bracts 2 or 3. ..... 7. *Manglietia glauca* var. *sumatrana*
14. Stipules pubescent; reticulation of leaf rather obscure, fine, base narrowly cuneate; pedicle absent; inner tepals spathulate; connective appendage of anthers semiorbicular, 1–1.5 mm long; scars of bracts 0 or 1. ..... 2. *Manglietia conifera*
15(12). Carpels 20–39. ..... 16
15. Carpels 44–88. ..... 19
16(15). Outer tepals 3.5 cm long; flower (greenish) yellow or yellowish, inner tepals 2.8 cm long. ..... 2. *Manglietia conifera*
16. Outer tepals 5.5–8 cm long; flower (greenish) white, inner tepals 4–8 cm long. ..... 17
17(17). Connective appendage semiorbicular; inner tepals 9; gynoecium ellipsoid; fruits subglobose; scars of perianth and stamens along torus under fruit 7–10 mm long. ..... 1. *Manglietia aromatica*
17. Connective appendage triangular or very long, narrowly triangular; inner tepals 6 or 7; gynoecium ovoid; fruits ovoid; scars of perianth and stamens along torus under fruit 13–22 mm long. ..... 18
18(18). Connective appendage very long, narrowly triangular; reticulation of leaves distinct, petiole dilated at base; filaments 1 mm long. ..... 5c. *Manglietia fordiana* var. *forrestii*
18. Connective appendage triangular; reticulation of leaves rather obscure, petiole not dilated at base; filaments 1.5–2 mm long. ..... 5a. *Manglietia fordiana* var. *fordiana*

19(15). Leaves glabrous. ..... 20
19. Leaves hairy beneath at least when young. 22
20(19). Peduncle 30–37 mm long. ..... 9. *Manglietia hookeri*
20. Peduncle 10–15 mm long. ..... 21
21(20). Leaves 11–16 cm broad, obovate, reticulation coarse; peduncle stout, 6 mm thick; outer tepals 12–14 cm long, thick-fleshy; fruiting peduncles 4.5 cm long, fruits ovoid. ..... 11. *Manglietia lucida*
21. Leaves 4–8 cm broad, elliptic or narrowly obovate, reticulation fine; peduncle slender, 4 mm thick; outer tepals 5–7 cm long, thin-coriaceous; fruiting peduncles 1.2–2.5 cm long, fruits ovoid-oblong or cylindric. ..... 10. *Manglietia insignis*
22(19). Peduncle 10.1–13 mm thick. ..... 12. *Manglietia megaphylla*
22. Peduncle 4–10 mm thick. ..... 23
23(22). Peduncle 4.1–10 mm thick. ..... 24
23. Peduncle 4 mm thick. ..... 28
24(23). Twigs in innovations 5.1–12 mm thick. ..... 25
24. Twigs in innovations 2–5 mm thick. ..... 26
25(24). Pedicle absent; twigs pubescent, stipules pubescent; leaves minutely (scattered) hairy beneath, apex short-acuminate. ..... 6. *Manglietia garrettii*
25. Pedicle present; twigs villous, stipules (rufous) villous; young leaves with longer hairs beneath, apex acuminate or acute. ..... 12. *Manglietia megaphylla*
26(24). Gynoecium hairy; hairs white; follicles hairy. ..... 17. *Manglietia ventii*
26. Gynoecium glabrous; hairs brown or red, follicles glabrous. ..... 27
27(26). Gynoecium 13–15 mm high; twigs villous, 4–5 mm diam., stipules (rufous) villous; young leaves with longer hairs beneath, reticulation rather obscure, petiole not dilated at base; flower creamy white, outer tepals coriaceous, 3.7–5.7 × 2–2.5 cm, the inner petals 9–12 cm long; connective appendage short pointed or semiorbicular, 1–1.5 mm long, fruiting peduncles slender, fruits ovoid. ..... 14. *Manglietia moto*
27. Gynoecium 30 mm high; twigs pubescent, 5–8 mm diam., stipules pubescent; leaves minutely (scattered) hairy beneath, reticulation distinct, petiole dilated at base; flower purple or red, outer tepals thick-fleshy, 6–6.5 × 3 cm, the inner ones slightly smaller; connective appendage triangular, 3 mm long; fruiting peduncles stout, fruits ovoid-oblong. ..... 6. *Manglietia garrettii*
28(23). Peduncle (22–)31–90 mm long. ..... 29
28. Peduncle 10–30 mm long. ..... 30
29(28). Pedicle absent; twigs villous, stipules (rufous) villous; young leaves with longer hairs beneath; inner tepals 9–12 cm, outer tepals 3.7–5.7 cm long. ..... 14. *Manglietia moto*
29. Pedicle present; twigs pubescent, stipules pubescent; leaves minutely (scattered) hairy beneath; inner tepals 2.7–4.5 cm, outer tepals 4–4.5 cm long. ..... 5d. *Manglietia fordiana* var. *kwangtungensis*
30(28). Gynoecium hairy; pedicle absent; follicles hairy. ..... 17. *Manglietia ventii*
30. Gynoecium glabrous; pedicle present; follicles glabrous. ..... 31
31(30). Peduncle 10–15 mm long, pedicle 3–5 mm; reticulation of leaf distinct; outer tepals thin-coriaceous; connective appendage of anthers triangular with a sharp pointed tip, filaments 2–5 mm long; gynoecium 17–28 mm high; fruits ovoid-oblong or cylindric, 6.5–11 cm long; scars of perianth and stamens along torus under fruit 14–20 mm long. ..... 10. *Manglietia insignis*
31. Peduncle 22–30 mm long, pedicle 1–2 mm; reticulation of leaf rather obscure; outer tepals coriaceous; connective appendage of anthers semiorbicular, filaments 1 mm long; gynoecium 11–15 mm high; fruits ovoid, 2.5–3.5 cm long; scars of perianth and stamens along torus under fruit 9 mm long. ..... 5d. *Manglietia fordiana* var. *kwangtungensis*

## Key to the Species of *Manglietia*
(based primarily on fruit characters)

1. Stipules free; gynoecium stipitate. ..... 18. *Manglietia sinica*
1. Stipules adnate to petiole; gynoecium not stipitate. ..... 2
2(1). Follicles hairy. ..... 3
2. Follicles glabrous. ..... 7
3(2). Pedicle present; leaves narrowly elliptic or narrowly obovate. ..... 4
3. Pedicle absent; leaves elliptic or obovate. 5
4(3). Tree ca. 15 m high; twigs yellowish villous when young, 4–5 mm diam.; stipules pubescent; reticulation of leaf distinct; stipular scars 9–11 mm long; peduncle hairy; flower (greenish) white; outer tepals ovate or oblong; stamens 12–20 mm long; gynoecium 17–25 mm high. 16. *Manglietia szechuanica*
4. Treelet ca. 8 m high; twigs glabrous, 3 mm diam.; stipules sparsely hairy; reticulation of leaf rather obscure; stipular scars 2–3 mm long; peduncle glabrous; flower purple or red; outer tepals obovate; stamens 10 mm long; gynoecium 14–15 mm high. ..... 4. *Manglietia duclouxii*
5(3). Young twigs densely tomentellous, 2–3.5 mm thick; leaves not glaucous beneath. ..... 17. *Manglietia ventii*
5. Young twigs glabrous or rather long-hairy, 6–10 mm thick; leaves glaucous beneath. 6
6(5). Twigs glabrous; leaves glabrous, reticulation distinct, fine; petiole glabrous; peduncle glabrous, 15 mm long. ..... 13. *Manglietia microtricha*
6. Young twigs with rather long, undulate to curly, spreading rufous hairs; leaves pubescent beneath at least when young, reticulation rather obscure, coarse; petiole hairy; peduncle hairy, 10 mm long. ..... 3. *Manglietia dandyi*
7(2). Pedicle absent. ..... 8
7. Pedicle present. ..... 15
8(7). Fruiting peduncles 11–14 mm thick. ..... 9
8. Fruiting peduncles 2–9 mm thick. ..... 10
9(8). Twigs and stipules glabrous; leaves glaucous beneath, narrowly obovate, 10.5–13 cm

broad; petiole not dilated at base; fruits oblong-ovoid, 10–16 × 6–10 cm; scars of perianth and stamens along torus under fruit 15–17 mm long; peduncle 30–34 mm long, 13–14 mm thick; flower pink; carpels 95–110; scars of bracts 0. ..... 8. *Manglietia grandis*

9. Young twigs densely appressed-pubescent; stipules pubescent; leaves not glaucous beneath, obovate or narrowly ovate, 6–9.5 cm broad; petiole dilated at base; fruits subglobose to ovoid, 8–8.5 × 5.2 cm; scars of perianth and stamens along torus under fruit 7 mm long; peduncle 12–20 mm long, 4–5 mm thick; flower white; carpels 29–39; scars of bracts 1 or 2. ..... 1. *Manglietia aromatica*

10(8). Carpels 48–88. ..... 11

10. Carpels (12–)20–36. ..... 12

11(10). Young leaves scattered hairy with long, dark brown hairs beneath, 11–19 × 5–7 cm; twigs and stipules brown to rufous villous; apex acuminate or mucronate; reticulation rather obscure; petiole not dilated at base; fruits ovoid; flower (greenish) white or (greenish) yellow or yellowish; outer tepals coriaceous; connective appendage short-pointed or semiorbicular, 1–1.5 mm long; gynoecium 13–15 mm high. ..... 14. *Manglietia moto*

11. Leaves minutely brownish hairy beneath, 18–34.5 × 8–12 cm; twigs and stipules pubescent; apex short-acuminate; reticulation distinct; petiole dilated at base; fruits oblong; flower purple or red; outer tepals thick-fleshy; connective appendage triangular, 3 mm long; gynoecium 30 mm high. ..... 6. *Manglietia garrettii*

12(10). Fruiting peduncles 4.1–6 mm thick. ..... 13

12. Fruiting peduncles 2–4 mm thick. ..... 14

13(12). Leaves not glaucous, glabrous or minutely scattered hairy beneath; petiole not dilated at base, stipular scar 2–6 mm long; peduncle 4 mm thick; outer tepals 5.5–7 cm long, thin-coriaceous; inner tepals 4–4.8 cm long; connective appendage 1.8 mm long; filaments 1.5–2 mm long; scars of bracts 1. ..... 5a. *Manglietia fordiana* var. *fordiana*

13. Leaves glaucous, densely pubescent beneath when young; petiole dilated at base, stipular scar 6–10 mm long; peduncle 5 mm thick; outer tepals 2 2.2 cm long, thick-fleshy; inner tepals 1.8–2 cm long; connective appendage 1 mm long; filaments 1 mm long; scars of bracts 2. ..... 3. *Manglietia dandyi*

14(12). Twigs 4–10 mm diam., usually glabrous, sometimes pubescent at the annular scars; reticulation of leaf coarse, base cuneate; flower (greenish) white; outer tepals 5.5–7 cm long; inner tepals 4–4.8 cm long; connective appendage triangular, 1.8 mm long. ..... 5a. *Manglietia fordiana* var. *fordiana*

14. Twigs 4–5 mm diam., usually ferrugineous pubescent when young; reticulation of leaf fine, base narrowly cuneate; flower (greenish) yellow or yellowish; outer tepals 3.5 cm long; inner tepals 2.8 cm long; connective appendage semiorbicular, 1–1.5 mm long. ..... 2. *Manglietia conifera*

15(7). Fruits ovoid-globose, 9.5 × 8–10 cm or 7–9.5 × 6–8.5 cm. ..... 16

15. Fruits ovoid, ovoid-oblong, cylindric, ellipsoid, or oblong, 2.5–8 × 2.5–5.5 cm. ..... 18

16(15). Twigs glabrous to minutely hairy; fruiting peduncles 4.5 cm long; fruits 9.5 × 8–10 cm; stipules pubescent; leaves and petiole glabrous. ..... 11. *Manglietia lucida*

16. Twigs densely and longer hairy when young. 17

17(16). Leaves 23–40 × 9.4–17 cm; fruiting peduncles 10–30 × 10–13 mm; stipules (rufous) villous; leaves scattered villous with long undulate to curly dark brown hairs beneath at least when young; petiole hairy. ..... 12. *Manglietia megaphylla*

17. Leaves 21–32 × 6.5–10 cm; fruits 7–9.5 × 6–6.5 cm broad; peduncle 30–37 × 7–10 mm; pedicle 7–13 mm. ..... 9. *Manglietia hookeri*

18(15). Leaves glaucous beneath; fruit ovoid to ovoid-oblong, 3.5–8 × 2.5–5.5 cm; scars of bracts 2 or 3. ..... 7. *Manglietia glauca* var. *sumatrana*

18. Leaves not glaucous beneath; scars of bracts 0 or 1. ..... 19

19(18). Scars of perianth and stamens along torus under fruit 7–9 mm long. ..... 20

19. Scars of perianth and stamens along torus under fruit 12–22 mm long. ..... 21

20(19). Twigs hairy at least when young; fruit ovoid or irregular, 2.5–3.5 × 2.5 cm; tree of ca. 15 m high; stipules pubescent; petiole hairy; fruiting peduncles 3–3.5 cm long, 5 mm thick; peduncle hairy, 22–31 mm long; flower (greenish) white; outer tepals coriaceous; connective appendage semiorbicular, 1 mm long; gynoecium glabrous, ovoid; styles 1–1.5 mm long. ..... 5d. *Manglietia fordiana* var. *kwangtungensis*

20. Twigs glabrous; fruits ovoid-ellipsoid, ca. 3.5 cm long; treelet ca. 8 m high; stipules sparsely hairy; petiole and peduncle glabrous; fruiting peduncles 1.3–1.5 cm long, 3–4 mm thick; peduncle 13–15 mm long; flower purple or red; outer tepals thick-fleshy; connective appendage triangular, 2–3 mm long; gynoecium hairy, styles 3–4 mm long. ..... 4. *Manglietia duclouxii*

21(19). Fruits ovoid-oblong, cylindric, or ellipsoid, 5–7 × 4.5 or 6.5–11 × 3–4 cm; peduncle 10–20 mm long; pedicle 3–5 mm; connective appendage triangular with a sharp pointed tip or semiorbicular; twigs 3–8 or ca. 10 mm diam. ..... 22

21. Fruits ovoid-globose or irregular, 2.5–6 × 2–5 cm; connective appendage triangular or very long, narrowly triangular; twigs 3–8 mm diam. ..... 23

22(21). Fruits ellipsoid, 5–7 × 4.5 cm; stipules (rufous) villous; apex of leaf short-acuminate, reticulation rather obscure; peduncle stout, 7 mm thick; outer tepals coriaceous;

connective appendage semiorbicular; filaments 1 mm long. ..... 15. *Manglietia pachyphylla*

22. Young twigs glabrous or pubescent at the nodes, 3–8 mm diam.; fruits ovoid-oblong to ovoid-cylindric, sometimes irregular, 6.5–11 × 3–4 cm; stipules glabrous or pubescent; apex of leaf acuminate or mucronate, reticulation distinct; peduncle slender, 4 mm thick; outer tepals thin-coriaceous; connective appendage triangular with a sharp pointed tip; filaments 2–5 mm long. ..... 10. *Manglietia insignis*

23(21). Young twigs densely brown pubescent, 3–6 mm diam.; fruits ovoid, 4–5.5 × 3.5–5 cm; reticulation of leaf distinct; connective appendage very long, narrowly triangular; filaments 1 mm long. ..... 5c. *Manglietia fordiana* var. *forrestii*

23. Fruits ovoid to ovoid-globose or irregular, 2.5–6 × 2–5 cm; reticulation of leaf rather obscure; connective appendage triangular; filaments 1.5–2 mm long. ..... 24

24(23). Twigs glabrous, 5–7 mm diam.; base of leaf attenuate-cuneate; petiole dilated at base; peduncle 5–6 mm thick; pedicle 6–8 mm; gynoecium broadly ellipsoid, 16–20 mm high; scars of bracts 0. ..... 5b. *Manglietia fordiana* var. *calcarea*

24. Young twigs glabrous or pubescent at the nodes, 4–8 mm diam.; base of leaf cuneate; petiole not dilated at base; peduncle 4 mm thick; pedicle 0–1 mm; gynoecium ovoid, 13–15 mm high; scars of bracts 1. ..... 5a. *Manglietia fordiana* var. *fordiana*

## II-1. **Manglietia** section **Manglietia**

Gynoecium sessile. Stipules ± adnate to petiole, at least in China.

1. **Manglietia aromatica** Dandy, J. Bot. 69: 231. 1931. *Paramanglietia aromatica* (Dandy) Hu & Cheng, Acta Phytotax. Sin. I: 255. 1951. TYPE: *R. C. Ching 7421* (holotype, BM; isotypes, NY, PE). Figure 2.

Tree to 20 m high and 50 cm diam., bark gray; young twigs at first densely appressed-pubescent with short, straight, gray or brownish hairs, soon glabrescent, stout, 7–10 mm diam., black-brown, later gray-brown; terminal buds ovoid, densely hairy, 2–2.4 cm long; stipules densely appressed-pubescent with rather long, straight, yellowish hairs, adnate to the petiole. Leaves glabrous, thinly coriaceous to coriaceous, (narrowly) obovate, 17–22.5 × 6–9.4 cm; apex mucronate or acuminate, base cuneate; nerves in 9–16 pairs; midrib impressed above; reticulation coarse, prominent. Petiole glabrous, 2.7–3.5 cm long, conspicuously dilated toward the base, stipular scars 5–12 mm long. Peduncles glabrous, ca. 12 × 4–5 mm, pedicles absent. Flowers white, tepals 12, subequal, obovate to narrowly obovate, 6–8 × 2.5 cm, 3-merous; stamens 1–1.2 cm long, filaments 1–2 mm long, connective appendage semiorbicular; gynoecium ellipsoid, ca. 16 × 10 mm; scars of perianth and stamens on the torus 7–10 × 6–10 mm. Fruiting peduncle 13–20 × 11 mm. Fruits subglobose to ovoid, ca. 8–8.5 × 5.2 cm; torus with scars of perianth and stamens 0.7–2 × 1 cm; carpels 29–39, with thick and ligneous wall, free when ripe, their dorsal faces 10–25 × 0.8–1.9 cm, adaxial parts 1–2 cm long, dehiscing along the dorsal and ventral suture; fruiting peduncles stout, 1.3–1.9 × 0.6–1.2 cm. Seeds broadly ellipsoid, 10–12 × 7–8 mm.

*Distribution.* China and northern Vietnam. In CHINA. **Guangxi**: Bako Shan, Poseh, near Yunnan border, *Ching R.C. 7421*; Lingle, *Ling Le Exped. 32928*; Donglin, *Chang C.C. 11432*. **Guizhou**: *Huang D.F. 1651*. **Southeastern Yunnan**: Guangnan, *Wang C.W. 87854*; Shichou District, *Law Y.W. 4074*, *Wu C.A. 62- 37*; Mar-li-po, Hwang-jin-in, *Feng K.M. 13009*; Si-chour-hsien, Faa-doou, *11990*.

*Ecology.* In mixed forest. Altitude 1,300–1,900 m. Trees in the natural forest (Jingping of Yunnan) reach a height of 20.4 m and a diameter of 40 cm by the age of 54 years. Flowering May–June; fruiting September–October.

2. **Manglietia conifera** Dandy, J. Bot. 68: 205. 1930. TYPE: *Fleury in Chevalier 37817* (holotype, P; isotype, L). Figure 3.

*Manglietia chingii* Dandy, J. Bot. 69: 232. 1931. TYPE: *R. C. Ching 8390* (holotype, BM; isotypes, A, K, NY, PE).

*Manglietia tenuipes* Dandy, J. Bot. 69: 232. 1931. TYPE: *R. C. Ching 7117* (holotype, BM; isotype, NY).

*Manglietia glaucifolia* Law, Guihaia 4(4): 263. 1986. TYPE: China. Leishan, Guizhou: alt. 1,580 m, *C. P. Chien et al. 50689* (holotype, PE not seen).

*Manglietia ovoidea* Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 108. 1988. TYPE: *B. L. Chen Gs 86182* (holotype, SYS).

Tree to 28 m high and 55 cm diam., twigs black-brown and covered with many annular stipular scars, 4–5 mm diam., usually densely ferrugineously pubescent in innovations, soon glabrescent. Stipules pubescent, adnate to the base of the petiole. Leaves thinly coriaceous to coriaceous, dark glossy green, glabrous above, pale green to ± glaucous, glabrous, or sometimes appressed-brown-hairy when young, soon glabrescent, usually the

FIGURE 2. *Manglietia aromatica* Dandy.—1. Branch with deflorated flower.—2. Flower.—3. Flower, outer tepals removed.—4. Fruit. Based on *SYS 161520 = Chen Bao Liang 86 S 109*. Drawing by Xie Qing Jian.

hairs microscopically small and the leaves seemingly glabrous beneath; elliptic to (narrowly) obovate, 12.3–19.6 × 4.3–6.4 cm; apex acute to (shortly) acuminate, base narrowly cuneate; midrib sulcate above, elevated below; nerves in 12–14(–17) pairs, meeting in a looped intramarginal vein; reticulation fine, inconspicuous on both sides. Petiole pubescent, glabrescent, sulcate above, 1.2–

FIGURE 3. *Manglietia conifera* Dandy.—1. Fruiting branch.—2. Fruit. Based on *SYS 161743* = *Chen Bao Liang GS 86-182*. Drawing by Xie Qing Jian.

1.5 cm, stipular scars on petiole 3–7 mm long. Peduncle variable in length, 1.5–9 × 0.2–0.4 cm, erect or recurved, glabrous to ± pubescent, pedicle absent, bract single, spathaceous, pubescent, directly under the perianth. Tepals 9–11, the outer tepals 3, yellowish green to green, obovate, thinly coriaceous, ca. 3.5 × 2.4 cm, inner tepals 6–8, spathulate, fleshy, outside glabrous, yellowish with a flush of purple at the base, ca. 2.8 × 1.4 cm; stamens numerous with purple base, 9–11 mm, including 1–1.5-mm-long blunt connective appendage; gynoecium ovoid, ca. 1.5 cm, carpels 20–28, glabrous, slightly connate when young, styles glabrous, 1–2.5 mm long; ovules 3–11 in each carpel. Ripe fruits ovoid to globose, 3.2–5.4 × 2.8–4.2 cm, the surface of the torus foveolate because of the dense scars of the fallen stamens, deeply depressed, scars of perianth and stamens ca. 5–16 × 4–7 mm along the torus; fruiting peduncle 1.5–9 × 0.2–0.4 cm, the dorsal face of the carpels 16–22 × 7–9 mm, elliptic, opening along the dorsal suture only or both along dorsal and ventral suture. Seeds flat, subcordate, 7–9 × 6–8 mm.

*Distribution.* China and northern Vietnam. In CHINA. **Guangdong**: Luoding, *Wang P.S. 614*; Ruyuan, *Ko S.P. 52921*; Sunyi Tai to Fat Youk Chong Ping, *Ko S.P. 51777*; Kung Ping Shan, and Vicinity Taan Faan, Fang Cheng Dist., *Tsang W.T. 26813*. **Guangxi**: Na Pa, Sup Man Ta Shan, *Liang H.Y. 69538*; Yeo Mar Shan, *Ching R.C. 7117*; Me Kon, Seh Feng, Dar Shan, S Nanning, *Ching R.C. 8390*; Damiaoshan, *Chun S.H. 14206*. **Yunnan**: Maguang, *Chen B.L. 87 F 195*; Mengze, *Xu Y.C. 595*.

*Ecology.* Locally fairly common, in mixed evergreen forests, on sandshale hills. Altitude: 500–1,700 m. Flowering May–June; fruiting September–October.

*Uses.* Wood used for general construction work and furniture, bark used for medicine. Also grown as an ornamental.

*Note.* The specimens examined are uniform in all characters, but the variation in length of the peduncles is considerable. There are, however, intermediate forms.

We were not able to see the type of *Manglietia glaucifolia* Law. Fortunately, Law's original description gives enough information to enable us to recognize it. Consideration of the diagnostic characters and the geographic distribution leads to the conclusion that *Manglietia glaucifolia* belongs to *Manglietia conifera*.

3. **Manglietia dandyi** (Gagnep.) Dandy in Praglowski, World Pollen Spore Fl., 3 (Magnoliaceae): 5. 1974. *Magnolia dandyi* Gagnep., Notulae Syst. 8: 63. 1939. TYPE: *Poilane 20714* (holotype, P). Figure 4.

Tree to 15 m high, ca. 18 cm diam.; bark gray, quite rough; the indument with long, undulate to curly, spreading, rufous hairs; young twigs 6–7 mm diam., at first densely pubescent, finally glabrescent, old ones gray to brown-gray, ± pubescent to glabrous. Stipules densely pubescent, adnate to the petiole, scars 6–10 mm long. Leaves membraneous to thinly coriaceous, dark green, slightly pubescent, especially along the midrib above, glaucous, at first densely pubescent, sooner glabrescent beneath, obovate, elliptic to obovate-elliptic, 16–24 × 5–8.5 cm; apex short-acuminate, acumen 5–10 mm long, base cuneate to obtuse; midrib slightly impressed above, nerves obscure above, conspicuous below, in 8–13 pairs, reticulation laxly netted, not prominent on both sides. Petiole densely pubescent, dilatate toward the base, 1.2–2.3 cm long. Peduncle pubescent, ca. 1 × 0.5 cm, pedicle absent; bracts 2, densely pubescent outside. Flower bud ovoid; tepals 9–11, subequal, white to yellowish, the outer 3 fleshy, obovate-oblong, pubescent outside at the base, 2–2.2 × 1.5–1.7 cm, the inner tepals 6–8, obovate, glabrous, often abruptly constricted near the base, 1.8–2 × 0.9–1.6 cm; stamens numerous, sparsely pubescent outside, 5.5–7 mm long, connective appendage triangular, ca. 1 mm long, filaments ca. 1 mm long; gynoecium ovoid, 10–13 mm long, carpels 24–30, glabrous to pubescent, ovules 2–10; scars of perianth and stamens along torus ca. 6 mm long in flower. Fruiting peduncles 2–4.5 × 0.5 cm. Fruits ovoid to cylindric, 6–7.5 × 1.8–2.5 cm, entirely connate when young; mature carpels glabrous or ± pubescent, dorsal faces 1–1.6 cm long in upper and 2–3 cm long in lower carpels, dehiscing along the dorsal suture; scars of perianth and stamens ca. 1.3 × 0.5 cm. Seeds orange-red, 1–2 in each carpel.

*Distribution.* China, Laos, and Vietnam. In CHINA. **Guangdong** Huashuishan, *Zheng P. 22*; Ruyuan, *Chen B.L. 80115*; Ying-teh District, *Tse H. 695*; Huangtung, Yaoshan, *Sin S.S. 9966*; Lok Chong, *Tso C.L. 20508*; Lung T'au Mountain, near Iu, *C.C.C. To Kang Peng cs 12179*; Pan Ling Tsze, *Chun W.Y. 5860*. **Guangxi**: Cangwu Xian, *Chun S.H. 10140*; He Xian, *Chen L.C. 500183*. **Yunnan**: Marlipo, Sze-tai-po, *Feng K.M. 13960*; Menglun, *Chang H.T. 6342*, Si-chour-hsien, Faa-doou, *Feng K.M. 11771*; Wenshan, *Gao T.X. 5*; Xichou, *Zhu D.Q. 5*.

*Ecology.* In evergreen broad-leaved forest. Altitude: 1,450–2,000 m. Flowering April; fruiting September–October.

FIGURE 4. *Manglietia dandyi* (Gagnep.) Dandy.—1. Fruiting branch (*Feng 13960*, P).—2. Partly deflorated flower.—3. Stamen.—4. Outer petal.—5. Inner petal (*Poilane 20714*, P). Drawing by Joop Wessendorp, Rijksherbarium, Leiden.

*Collector's note.* Fruits orange-red, usually yellow-greenish tinged with a little red when mature and becoming brown when dry.

*Notes.* C. Y. Wu & W. T. Wang (1957) misidentified this species as *Manglietia rufibarbata* non Dandy (1928). The latter species is from Vietnam and has not been recorded for China. See also under *Manglietia moto*.

The species has some noteworthy characters. (1) The base of the lowest carpels is sometimes decurrent along the torus, so a short gynophore seemingly occurs. (2) Sometimes there are three ovules in the lowest carpels and two above the middle carpels, instead of more than four ovules as normal in *Manglietia*. (3) The carpels are from glabrous to hairy throughout the area of its dis-

tribution. The mature fruits as seen in the field often become greenish yellow instead of purple as is common in fruits of Magnoliaceae.

4. **Manglietia duclouxii** Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 33, t. 5A. 1905. *Magnolia duclouxii* (Finet & Gagnep.) Hu in Hu & Chun, Icon. Pl. Sin. 2: 18, t. 68S. 1929. TYPE: *Ducloux 2133* (lectotype, selected here, P).

Tree of ca. 8 m, young twigs slender, ca. 3 mm diam., glabrous, yellow-brown, gray-black later. Stipules sparsely hairy. Leaves thinly coriaceous to coriaceous, glabrous, dark green above, pale green, glabrous or scattered appressed-pubescent with fine, rather short, straight, brown hairs, with long colorless hairs along the margin and the midrib beneath, narrowly obovate to elliptic, 10.2–16 × 3–4 cm; apex acuminate, base cuneate; nerves fine in 9–11 pairs; reticulation netted, inconspicuous. Petiole glabrous, lengthwise grooved above, 1–1.2 cm long, with a stipular scar 2–3 mm long. Peduncle glabrous, 1.3–1.5 × 0.3–0.4 cm, bract 1, pedicle 2–3 mm long. Tepals 9, usually outer ones larger than inner ones, fleshy, purple or red, obovate to broadly obovate, 2.8–3.5 × 1.5–2.3 cm; stamens ca. 10 × 2 mm, including 2–3-mm-long connective appendage and 1-mm-long filaments; gynoecium ellipsoid, 1.4–1.5 × 0.7–0.8 cm, carpels 45–55, narrowly elliptic, ferrugineous-hairy, ca. 7–8 mm; styles glabrous, ca. 3–4 mm long; ovules ca. 5 in each carpel. Fruits ovoid-ellipsoid, ca. 3.5 cm long (not seen). Scars of perianth and stamens 7–9 × 3–4 mm.

*Distribution.* Vietnam and China. In CHINA. **Guangxi**: Longgui, *Li Y.K. 430*. **Sichuan**: Gu Lin Xian, *Qiao H.R. 1114*; Gulin, *Gulin Yiyao Gongsi 846*. **Yunnan**: Long ky, *Maire E.E. s.n.*; Malipo Xian, *KUN 76298*; Wenshan, *Feng K.M. 22369*.

*Ecology.* In evergreen forest. Altitude: 700–1,800 m. Flowering May–June; fruiting September–October.

*Note.* *Manglietia duclouxii* is easily recognized by its slender twigs, thin, small leaves, which are usually covered with minute, short, and rather long hairs beneath, and the pubescent gynoecium.

5. **Manglietia fordiana** Oliver in Hook., Icon. Pl. 10: t. 1953. 1891. *Magnolia fordiana* (Oliver) Hu, J. Arnold Arbor. 5: 228. 1924. TYPE: *C. Ford 90* (holotype, K).

*Paramanglietia microcarpa* Chang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 53. 1961. TYPE: *S. K. Lau 4246* (holotype, SYS; isotype, A).

*Manglietia hainanensis* Dandy, J. Bot. 68: 204. 1930. TYPE: *Tsang & Fung 656 in Herb. Lingn. Univ. 18190* (holotype, BM; isotypes, A, K, MO, NY).

*Manglietia yuyuanensis* Law, Bull. Bot. Res. (China) 5, 3: 125. 1985. TYPE: China. Zhejiang: Changhua Xian, alt. 1,000 m, *X. Y. Hoo 23326* (IBSC not seen).

5a **Manglietia fordiana** var. **fordiana**.

Tree to 30 m high and 1.5 m diam.; young twigs 4–8(–10) mm diam., yellow-brown to dark brown, usually glabrous, sometimes pubescent only along the annular scars of the stipules. Stipules usually ± pubescent with ferrugineous hairs, adnate to the base of petiole. Leaves thinly coriaceous to coriaceous, both sides glabrous or minutely scattered-pubescent beneath, narrowly obovate, obovate-elliptic to narrowly elliptic, 8–16(–20) × 2.5–5.4(–7) cm; apex mucronate to acuminate, base cuneate, sometimes slightly decurrent into the petiole; midrib impressed above, elevated and glabrous or hairy below, nerves in 8–12(–17) pairs, reticulation coarse, hardly visible. Petiole glabrous or pubescent, sulcate on the upper side, 1.4–4.2 cm long, stipular scar glabrous or pubescent, 2–6 mm long. Peduncles glabrous or ferrugineous-pubescent, 8–13 × 4 mm, pedicles absent or to 1 cm long; bracts 1–2. Tepals 9, the outer 3 slightly larger than the inner ones, the tepals concave, thinly coriaceous, obovate-elliptic, greenish outside, hardly pubescent outside at the base, 5.5–7 × 2.5–4 cm, the inner tepals pure white, fleshy, spathulate to broadly obovate, with cuneate to short-clawed base, 4–4.8 × 1.5–2.2 cm; stamens numerous, 9–12 mm long, connective appendage short triangular, ca. 1.8 mm long, filaments glabrous, 1.5–2 mm long; gynoecium ovoid to subglobose, glabrous and smooth, 1.3–1.5 × 1–1.2 cm, carpels (12–)24–36, styles glabrous, 0.5–1 mm long. Fruits ovoid or sometimes irregular-shaped because the carpels are partly abortive, 2.5–6 × 2–3.5(–5) cm; fruiting peduncle 1–2.5 × 0.4–0.6 cm, pedicle 1–5(–9) mm long; ripe carpels sometimes only 4–10, torus with scars of perianth and stamens 1.3–1.7 × 0.4–0.5 cm. Seeds flat-ovate, ellipsoid or irregularly shaped, 6–10 × 4–7 mm.

*Distribution.* China and Vietnam. In CHINA. **Anhui**: Wangshan, *Cheng W.C. 4030*. **Fujian**: *Chung H.H. 2940*. **Guangdong**: Loh Fian mountain, *Funkhouser W.L. C.C.C. 9082 a*; Lok Chong, *Tso C.L. 21005*; Luh Fau Mountain, *Merrill E.D. 10904*; Ruyuan, *Chen*

*B.L. 315*; Sunyi Dist., *Wang C. 31135*; Tsengshing District, Naam Kwan Shan, *Tsang W.T. 20440*. **Guangxi**: Cangwu Xian, *Chun S.H. 10035*; He Xian, *Li Y.K. 401535*; Lungnan Xian, *Lau S.K. 4850*; Pingnan, *Wang C. 39230*. **Hainan**: Bak Sa, *Lau S.K. 25956*; Dai Land Dungta, *Chun N.K. & C.L. Tso 43956*; Dung Ka to Wen Fa Shi, *Chun N.K. & C.L. Tso 43687*; Fan ya to Yik Tsok Mau, *McClure F.A. C.C.C. 9652*; Jianfong, *Chang H.T. 6095*. **Zhejiang**: King Yuan, *Ching R.C. 2472*. HONG KONG. **Tai Mo Shan:** *Chan K.Y. 1033*; Ma On Shan, *Hu S.Y. 10169 A*. Also in Yunnan, Guizhou, Jiangzi, Hunan.

*Ecology.* In subtropical evergreen broad-leaved forest; usually the trees grow on granite and sandshale. It was reported that this tree was easily cultivated and grew fast. It had attained a height of 18 m and a diameter of ca. 23 cm after 28 years at Xinyi Xian in Guangdong Province. Altitude: 500–1,300 m. Flowering April–May; fruiting August–October.

*Uses.* Because of the nicely structured and medium-hard wood, the timber is used for house building, veneer, furniture, and musical instruments. The local people in Guangxi treat dry cough and constipation with the bark. The tree is also cultivated as an ornamental.

*Collector's note.* The bark is brownish gray, smooth; branches are dark gray; leaves are glossy dark green above and pale green below; the flower buds are solitary, terminal, ovoid, flowers are creamy white, fragrant, anthers red; young fruits are purplish; seed coat is orange.

*Note.* *Manglietia hainanensis* is conspecific with *Manglietia fordiana*. It differs from the latter only in the length of the pedicle and the texture of the leaves. Although the pedicle usually is absent in *Manglietia hainanensis*, it sometimes occurs and then varies in length from 0 to 5 mm, occcasionally to 7–9 mm (*H. Y. Liang 62608*) throughout its geographical range. The leaves of *Manglietia hainanensis* are generally thinner than those of *Manglietia fordiana*. This difference is not a reliable character, however, because the leaves of *Manglietia fordiana* show a continuous variation in texture. Thus, there is no character left to distinguish *Manglietia hainanensis* from *Manglietia fordiana*. Regarding *Manglietia yuyuanensis*, there is no doubt that it is conspecific with *Manglietia fordiana*, despite its glabrous leaves. The degree of hairiness varies in *Manglietia fordiana*, too. *Manglietia yuyuanensis* represents an extreme, glabrous form. *Manglietia fordiana* and all synonyms mentioned above possess a leaf hypodermis with sinuous anticlinal walls and ± subglobose to ovoid sclereids, not known in other species of *Manglietia* in China. *Manglietia globosa* and *Paramanglietia microcarpa* are easily recognizable as *Manglietia fordiana*.

5b. **Manglietia fordiana** var. **calcarea** (X. H. Song) B. L. Chen & Nooteboom, stat. nov. *Manglietia calcarea* X. H. Song, J. Nanjing Inst. Forest. 4: 46. 1984. TYPE: China. Guizhou: Mogan, Libo Xian, alt. 670 m, *X. H. Song & F. Gao 640* (NF not seen).

Tree to 14 m high and 35 cm diam.; young twigs 5–7 mm diam.; plant entirely glabrous except for the stipules. Stipules densely pubescent with straight, appressed, brown hairs, adnate to the very base of the petiole, scars 4–5 mm long. Leaves coriaceous, rigid, dark green above, obovate-elliptic to narrowly obovate, 14.5–20 × 3.5–7 cm; apex rounded with an acumen 6–10(–14) mm long, base attenuate-cuneate; midrib impressed above, elevated beneath, nerves obscure above, visible to hardly prominent below, in 14–17 pairs. Petiole 2.8–3.8 cm long, dilatate toward the base. Peduncle 5–8(–20) × 5–6 mm, pedicle 6–8 mm long. Tepals 9, white, the outer 3 obovate-elliptic, ca. 6.2 × 2.5 cm, apex rounded, the inner tepals spathulate, 4.5–5.5(–6) cm long; stamens many, 1.2 cm long, connective appendage triangular, ca. 1.8 mm long, filaments ca. 2 mm long; gynoecium broadly ellipsoid, ca. 1.6–2 × 1 cm, carpels 12–16(–30), ovules ca. 7; torus with the scars of perianth and stamens 8–14 × 5–6 mm. Fruiting peduncle ca. 9–11 × 6 mm. Fruit ovoid to ovoid-globose, ca. 6 × 5 cm, ripe carpels ligneous, dorsal face elliptic, dehiscing along the dorsal venture; scars of perianth and stamens 1.2–1.3 × 0.7–0.8 cm. Seeds oblong, 8–10 × 5–6 mm, 2–5 in each carpel.

*Distribution.* CHINA. **Guizhou**: Pinfa, *Cavalerie J. 3182*; Yunnan-sen District, *Cavalerie J. 2263*.

*Ecology.* In margin of forest, growing on limestone. Altitude: 600–800 m. Flowering April–May; fruiting August–September.

*Uses.* Good timber, beautiful flowers; the tree also cultivated as an ornamental.

*Note.* This variety is characterized by both twigs and leaves being glabrous, the gynoecium broadly ellipsoid, and the carpels narrowly elliptic.

5c. **Manglietia fordiana** var. **forrestii** (W. W. Smith ex Dandy) B. L. Chen & Noot., stat. nov. *Manglietia forrestii* W. W. Smith ex Dandy, Notes Roy. Bot. Gard. Edinburgh 16:

126. 1928. TYPE: *G. Forrest 26705 A* (holotype, E; isotypes, A, K, NY).

*Manglietia globosa* Chang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 53. 1961. TYPE: *R. C. Ching 8394* (holotype, SYS; isotype, NY).

Tree to 18 m high, 46 cm diam.; stipules, young twigs, petiole, peduncles, and outer tepals outside at the base densely brown-pubescent with short to long, straight, appressed hairs; young twigs brownish, 3–6 mm diam., old ones dull brown, gray pubescent with straight to curly hairs; leaves and midrib scattered-pubescent with short, straight hairs beneath. Stipules adnate to the base of the petiole. Leaves coriaceous, bright green, glabrous above, pale green below, usually obovate, rarely narrowly obovate, 13–24.5 × 5.4–9.6 cm; apex mucronate to abruptly acuminate, acumen 5–17 mm long, base cuneate; nerves fine, in 9–14 pairs; reticulation distinct beneath, fine or coarse. Petiole sulcate on upper face, dilated toward the base, 1.5–2.6 cm long, stipular scars 2–8 mm long. Peduncles stout, 1.4–2.6 × 0.4–1 cm, pedicles 2–5 mm long. Flowers pure white, fragrant; tepals 9(–10), outer 3 thinly coriaceous, obovate to oblong-obovate, brown-pubescent outside at the base, 6.3–7 × 3.4–4.8 cm, the inner tepals 6, fleshy, spathulate, obovate to ± subcircular, clawed at the base, 4–5.3 × 2–3.5 cm; stamens 1–1.5 cm long, connective appendage obtuse, filaments ca. 1 mm long; gynoecium ovoid, smooth, 1.2–2.2 × 1–1.4 cm, carpels 26–28, styles 1–2 mm long. Fruiting peduncles, 1.7–2.6 × 0.6–1 cm, pedicles 2–8 mm long. Fruits ovoid, 4–5.5 × 3.5–5 cm, dorsal faces of carpels 1.5–2 cm long in the upper to 3.5–4 cm long in the lower carpels, carpels densely papilliferous, with short beak, dehiscing along dorsal and ventral suture; torus with scars of perianth and stamens 1.3–2.2 × 0.5–0.9 cm.

*Distribution.* China and Annam. In CHINA. **Southwestern Guangxi**: Chu Fang Shan, 30 Li S W of Shan Fang, *Wang C.W. 39301, Ching R.C. 5910.* **Southern Yunnan**: Cangyuan, *Li S.P. Mu 199*; hills NW of Tengyueh, *Forrest G. 27300*; Nan-Chiao, *Wang C.W. 73474*; Szemeo, *Forrest G. 11988*; Pingpien, *Feng K.M. 5193*; Si-chour-hsien, Ting-mann, *12254.*

*Ecology.* In mixed broad-leaved or deciduous forests. Altitude: 540–2,400 m. Flowering June; fruiting September–October.

*Collector's notes.* Widely branched; flowers green-white or pure soft white, fleshy, fragrant, anthers purple; fruits creamy reddish.

*Uses.* The timber is used for doors, windows, and furniture.

*Note.* This variety differs from variety *fordiana* in young twigs, stipules, undersides of the leaves, petioles, peduncles, and the outer tepals outside at the base being brown pubescent; the leaves are larger, to 24.5 cm long and 9.6 cm wide.

5d. **Manglietia fordiana** var. **kwangtungensis** (Merr.) B. L. Chen & Nooteboom, stat. nov. *Manglietia kwangtungensis* (Merr.) Dandy, Kew Bull. 1927: 264. 1927. *Magnolia kwangtungensis* Merr., J. Arnold Arbor. 8: 5. 1927. TYPE: *K. P. To, W. T. Tsang & U. K. Tsang 345 in C. C. C. 12344* (holotype; A; isotypes, BM, E, MO, SYS, UC).

Tree 15 m high; young twigs, stipules, midrib beneath, petiole and peduncles densely pubescent with short to long, straight to undulate, rufous hairs; young twigs 4–5 mm diam. Leaves dark green glossy above, pale green, scattered appressed-pubescent with short, straight, rufous hairs below, coriaceous, (narrowly) obovate, 14.4–19 × 3.2–6.4 cm; apex (shortly) acuminate, base narrowly cuneate to cuneate; nerves fine in 9–13 pairs, reticulation inconspicuous on both sides. Petiole sulcate above, 1.3–2.2 cm long, stipular scars 3–5 mm long. Peduncles 2.2–3.1 × 0.4 cm, with only one bract scar near the base of perianth, pedicle 1–2 mm long. Tepals 9, the outer 3 obovate-oblong, coriaceous, greenish with a flush of purple, ± brown hairy outside at base, 4–4.5 × 2–2.5 cm, the inner tepals 6, white, spathulate to obovate, short-clawed at base, thick, fleshy, 2.7–4.5 × 0.9–2.3 cm; stamens 0.7–1.5 cm long, connective appendage blunt, ca. 1 mm long, filaments glabrous, ca. 1 mm long; gynoecium broadly ovoid, 1.1–1.5 × 0.9–1.1 cm, carpels 44–49, styles 1–1.5 mm long, scars of perianth and stamens along the torus 0.9–1.2 × 0.4 cm. Fruits ovoid to irregularly shaped because partly abortive, 2.5–3.5 × 2.5 cm; fruiting peduncles 3–3.5 × 0.5 cm, pedicles ca. 5 mm long; ripe carpels 7–10 mm long.

*Distribution.* CHINA. **Guangdong**: Ruyuan, Yingde, *C.C.C. 12344.* **Guangxi**: Damiaoshan, *Chen T.C. 617.*

*Ecology.* In mixed forest. Altitude: 700–1,000 m. Flowering May–June.

*Note.* Because of its rufous or red-brown indumentum, it is not too difficult to distinguish *Manglietia fordiana* var. *kwangtungensis* from varieties *fordiana* and *forrestii.* In addition, variety

*kwangtungensis* shows smaller flowers and many more carpels.

The collection *C.C.C. 12179*, cited under *Magnolia kwangtungensis* Merr. (1927), belongs to *Manglietia dandyi* (Gagnep.) Dandy.

6. **Manglietia garrettii** Craib, Kew Bull. 1922: 166. 1922. TYPE: *Garrett 114* (holotype, UT; isotypes, BM, K).

Tree to 20 m high and 1.2 m diam. Young twigs, stipules, petioles and peduncles densely brown pubescent with short to long, straight to slightly undulate hairs. Twigs brown, stout, 5–8 mm diam. Stipules adnate to the petioles, scars 1.8–2.5 cm long. Leaves densely coated with minute (even with hand lens hardly visible), brownish hairs beneath, coriaceous, (narrowly) elliptic to obovate, 18–34.5 × 8–12 cm; apex short-acuminate, base cuneate or rounded; nerves in 12–21 pairs, prominently elevated beneath, reticulation prominent on both sides, coarse; petiole 3–5 cm long, thickened toward the base. Peduncle 1.5–4 cm × 6–9 mm, pedicle absent. Flower buds elongate, 6–6.5 × 2.2–2.5 cm. Tepals 9, purple or violet-red, thick and succulent, 3 outer ones 6–6.5 × 3 cm, 6 inner ones slightly smaller; stamens 1.1–1.5 cm long, connective appendage triangular, ca. 3 mm long; gynoecium glabrous, ovoid to narrowly ovoid, ca. 3 × 2 cm, carpels 66–88; styles glabrous, 2–3 mm long. Fruits broadly ovoid-oblong, 4–9 × 3.5–6 cm; dorsal faces of ripe carpels 1–2 cm long in upper and 2.5–3.2 cm long in lower carpels, short-beaked. Scars of perianth and stamens 10–12 × 9 mm. Seeds ellipsoid, obovoid, and irregularly shaped, 9–14 × 5–8 mm.

*Distribution.* China (southern Yunnan), Thailand, and Vietnam.

7. **Manglietia glauca** Blume var. **sumatrana** (Miq.) Dandy, Kew Bull. 1928: 188. 1928. *Manglietia sumatrana* Miq., Fl. Ned. Ind. Suppl.: 367. 1861. TYPE: *Tijsmann 468* (holotype, L; isotype, BO).

*Manglietia pilosa* P. Parm., Bull. Sci. France Belgique 27: 217, 292. 1895. *Manglietia singalanensis* Agostini, Atti Com. Accad. Fisiocrit. Siena 9 (7): 22. 1926. TYPE: *Beccari PS 334* (holotype, FI; isotype, L).

Tree to 26 m high and 80–100 cm diam.; bark gray-brown; twigs green, 5–6 mm diam., appressed short-hairy. Stipules glabrous or with some hairs on the apex, adnate to the very base of the petiole. Leaves appressed-puberulent, with short to long, straight, colorless to brownish hairs, glaucous beneath, thinly coriaceous, obovate to narrowly obovate or narrowly elliptic, 10–35 × 3.5–12 cm; apex acuminate, acumen 3–15 mm long, base cuneate; nerves in 10–16 pairs, prominent below, reticulations laxly netted, visible on both sides. Petiole covered with the same indumentum as twigs, lengthwise shallowly grooved, 1.5–3 cm long, stipular scars never over ⅓ of the length of the petiole. Peduncles minutely pubescent only at the nodes, 1.5–4 cm long, pedicles 2–8 mm long. Flowers white, the outer 3 tepals thinly coriaceous, obovate-elliptic, greenish outside, 5–7.5 × 2–3 cm, the inner 6 tepals smaller than the outer ones; stamens numerous, 0.6–1.3 cm long, connective appendage very acute, ca. 4 mm long, filaments ca. 3 mm long; gynoecium ovoid to orbicular, ca. 15 × 7 mm, carpels 20–50. Fruits ovoid to ovoid-oblong, 3.5–8 × 2.5–5.5 cm; the carpels opening ventrally and then dorsally, after staying closed toward the basal side of the dorsal suture. Seeds flat-orbicular to ellipsoidal, often irregularly shaped, 5–8 × 4–5 mm.

*Distribution.* Native of Indonesia (western Sumatra), cultivated in Guangdong, Guangsi, and Fujien.

*Ecology.* In forests. Altitude 600–1,300 m (in Indonesia). Flowering February–April; fruiting September–October (in China).

*Uses.* Cultivated as an ornamental tree.

*Note.* Y. W. Law in W. C. Cheng (1983) and L. G. Lin (1985) treated this variety as *Manglietia glauca* Blume.

8. **Manglietia grandis** Hu & Cheng, Acta Phytotax. Sin. 1: 158. 1951. TYPE: *C. W. Wang 87020* (holotype, PE). Figure 5.

Tree 12 m high and 35 cm diam.; plant glabrous except the sometimes puberulent undersides of leaves; young twigs stout, 8–10 mm diam., usually covered with a waxy substance, so seemingly gray; stipules adnate to the base of the petioles. Leaves glabrous, glossy above, glaucous, glabrous or minutely scattered-puberulent, ± papilliferous beneath, coriaceous, narrowly obovate, 20–35.5 × 10.5–13 cm; apex acuminate, base cuneate; nerves 17–26 pairs, reticulation visible when dry. Petiole 2.6–4 cm long, stipular scars 5–8 mm long. Flower pink. Fruiting peduncle 3–3.4 × 1.3–1.4 cm, pedicle absent. Fruit oblong-ovoid, 10–16 × 6–10 cm; carpels 97–106, 3–4 cm, dehiscing along the dorsal and the ventral suture, beaks sharp and slightly recurved, 3–4 mm long. Scars of perianth and stamens along the torus 1.5–1.7 cm long.

FIGURE 5. *Manglietia grandis* Hu & Cheng.—1. Branch with flower bud.—2. Bud with bracts.—3. Fruit, one follicle enlarged. Based on *SYS 161411* = *Chen Bao Liang 86 S 297*. Drawing by Xie Qing Jian.

*Distribution.* CHINA. **Southeastern Yunnan**: Mar Li Po, *Wang C.W. 87020*.

*Ecology.* In subtropical forests, on sandy soil and limestone. Altitude: 800–1,800 m.

*Uses.* Wood straight-grained, fine-textured, very good for house building and furniture because of its durability.

*Note.* *Manglietia grandis* differs from other species by its much larger leaves, numerous car-

pels, and bigger fruits; the fruits are the largest in Chinese Manglietias so far as we know. We have not seen the mature flowers and therefore cannot describe them in detail.

9. **Manglietia hookeri** Cubitt & W. W. Smith, Records Bot. Surv. India 4: 273. 1913. *Magnolia hookeri* (Cubitt & W. W. Smith) Raju & Nayar, Indian J. Bot. 3, 2: 170. 1980. SYNTYPES: Silum and other stations in the Bhamo division of Upper Burma: *Cubitt 302A, 327* (CAL not seen), *Rodgers 314* (CAL).

Tree to 25 m high, 90 cm diam.; young twigs, stipules, petiole, and peduncles covered with an indument of straight, white, silver, to brownish appressed hairs. Twigs brown, stout, (4–)8–12 mm diam. Stipules adnate to the base of the petiole. Leaves glabrous on both sides, coriaceous, narrowly obovate (or elliptic), 21–32 × 6.5–10 cm; apex acuminate, base cuneate, ± decurrent along the petiole; nerves in 12–19 pairs, reticulation prominent when dry. Petiole conspicuously sulcate above, 2–3.5 cm long, stipular scar obvious, nearly to the base of the blade, usually 1.2–2 cm long. Peduncles stout, 1.5–3.7 × 0.5–0.7 cm, pedicles 0.7–1.3 cm long. Flowers white, ca. 10 cm diam.; tepals 9–12, the outer 3 thinly coriaceous, obovate, 7–10 × 3.5–4 cm, creamy above the middle, becoming greenish toward the base, the inner tepals 6–9, thick, fleshy, spathulate to obovate, 7–8.5 × 3–3.5 cm, narrowly and short-clawed at base; stamens 1.7–2.2 mm long, connective appendage triangular with a sharp-pointed tip, 1–2 mm long, filaments 3–5 mm long. Gynoecium ovoid to broad-ellipsoid, 1.8–2.3 × 1.3–1.5 cm; carpels 50–64, reddish brown when dry, styles black-brown, 4–7 mm long. Scars of fallen perianth and stamens 1.6–2 × 0.6–0.7 cm. Fruiting peduncles 1.7–4 × 0.7–1 cm, pedicles 0.9–1.5 cm long. Fruits ovoid to subglobose, 7–9.5 × 6–6.5 cm; dorsal face of the ripe carpels from 1–1.3 cm long in the upper to 2.3–3 cm long in the lower carpels, short-beaked, smooth, dehiscing dorsally. Seeds ovate, elliptic-ovoid, elliptic to irregularly shaped, 8–13 × 5–7 mm.

*Distribution.* China and Upper Burma. In CHINA. **Guizhou**: Wangmo Xian, *Zhang Z.S. 1395*. **Southwestern Yunnan**: Shweli-Salwin divide, *Forrest G. 15952*; Chen-Kang Hsien, *Wang C.W. 72797*; Hills 3 days S of Tengyueh, 24°40′N, 98°30′E, *Forrest G. 27364*; Jingdong, *Li M.K. 3515*; Menghai, *Li Y.H. 4068*; Tungkwong valley, 25°5′N, *Forrest G. 7725*; Shuning, *Yu T.T. 16559*; Tengchong, *Li W.Z. 8271*.

*Ecology.* In mixed forests. Altitude: 1,000–3,000 m. Flowering April–May; fruiting October.

*Collector's note.* The flower buds green, flowers white, purple-white, deep pink fleshy; fruit follicles conelike, green or black.

10. **Manglietia insignis** (Wall.) Blume, Fl. Javae: Magnol. 22. 1828. *Magnolia insignis* Wall., Tent. Fl. Nepal.: 3, t. 1. 1824. TYPE: *Wallich 973* (holotype, K; isotypes, BM, GH).

*Magnolia shanpaensis* Hu, Acta Phytotax. Sin. 1: 157. 1951. TYPE: *H. T. Tsai 56560*, p.p. (holotype, PE; isotype, A).

*Manglietia yunnanensis* Hu, Acta Phytotax. Sin. 1: 159. 1951. TYPE: *H. T. Tsai 56560*, p.p. (holotype, PE).

*Manglietia patungensis* Hu, Acta Phytotax. Sin. 1: 335. 1951. TYPE: *H. C. Chow 484* (holotype, PE; isotypes, A, E, NY).

*Manglietia maguanica* Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 109. 1988. TYPE *B. L. Chen & Y. H. Su 86 S 053* (holotype, SYS).

*Manglietia tenuifolia* Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 110. 1988. TYPE *B. L. Chen & Li 86 S 195* (holotype, SYS).

Tree to 25 m high and 50 cm diam.; young twigs glabrous or ferrugineous to yellowish pubescent at the node, usually 3–8 mm diam. Stipules glabrous, sometimes pubescent, adnate to the base of the petiole, 19–27 mm long. Leaves thinly coriaceous to coriaceous, shining green above, pale green, glabrous to minutely pubescent beneath, narrowly obovate to elliptic, 14.5–26.5(–30) × 4.3–7.8 cm; apex acuminate to mucronate, acumen 5–15 mm long; base cuneate, ± attenuate along the petiole; nerves fine, in 10–22 pairs, reticulation densely netted, prominent on both surfaces. Petiole sulcate above, 1.7–3.5 cm long, stipular scars glabrous or sometimes scattered-hairy, 4–10(–13) mm long. Peduncles glabrous to pubescent only near the scar of the fallen bract, 1–1.5 × 0.4 cm, pedicles 3–5 mm long. Flowers fragrant, tepals 9–12, the outer 3 obovate-oblong, 5–7 × 2–2.5 cm, thinly coriaceous, brown-greenish, sometimes white-hairy outside at the base, reflexed later, the inner 6–9 white to purple, spathulate to narrowly obovate, short-clawed at base, 5–6.5 × 1.3–2.5 cm; stamens 1.3–1.6 cm long, connective appendage triangular with a sharply pointed tip, 1–2 mm long, filaments glabrous, 2–5 mm long; gynoecium ovoid to ovoid-cylindric, 1.7–2.8 × 1–1.2 cm, carpels 50–86, glabrous, styles glabrous, 2–4 mm long. Fruiting peduncles 1.2–2.5 × 0.5–1 cm, pedicles 0.5–1.1 cm long. Fruits ovoid-oblong, sometimes irregularly shaped because part of carpels abortive, 6.5–11 × 3–4 cm, the scars of perianth and stamens along the torus 1.4–2 × 0.6–0.7 cm; ripe carpels 0.7–1.2

cm long in the upper and 1–2 cm long in the lower carpels, dehiscing along the dorsal suture, obviously papilliferous, apex short-beaked.

*Distribution.* Nepal, northeastern India, China, northern Burma, northern Vietnam. In CHINA. **Guangxi**: Damiaoshan, *Chun S.H. 15857*; He Xian, *Chen Z.Z. 52125*; Lingui, *51153*; Longsheng, *51134*; Quan Xian, *Tsoong C.H. 81657*. **Guizhou**: Kaili Xian, *Qiannan Exped. 2081*; In silva frondosa collis ad vic. Kenichunpo, eastern and western Salwin and Irraway divide, *Rock J.F. 21991*; Tsarong, *Forrest G. 18964*; Shweli-Salwin divide, N of Ho-tou, *26738*. **Yunnan**: K'raikha-Salween divide, *Forrest G. 18371*; Salween-Mekong divide, *14402*; Shangpa Hsien, *Tsai H.T. 56560*; Shunning Hila, Wumulung, *Yu T.T. 16727*; Tengyueh valley 25°N, *Forrest G. 8678*; Wen shan Hsien, *Tsai H.T. 51702*; Salwin-Kui chiang divide, 28°24′N, 98°24′E, *Forrest G. 20844*; Chen-Kang Hsien, *Wang C.W. 72322*.

*Ecology.* In mixed forests, usually growing on yellow loam. Altitude: 600–2,000 m. Flowering May–June; fruiting August–September.

*Uses.* Wood used for furniture, tree grown as an ornamental because of its beautiful flowers.

*Collector's notes.* Bark gray, smooth; flowers greenish shaded purplish outside, white, ivory white, yellow-white to deep purple inside, fleshy, fragrant; leaves green above, pale green below, bruised leaves spicy-fragrant; fruit follicles conelike, green when young, orange-green, reddish yellow, red later.

*Note. Manglietia insignis* is a very widespread species. It therefore displays many variations in shape and size of the leaves as well as size and color of the flowers throughout the area of distribution.

11. **Manglietia lucida** B. L. Chen & S. C. Yang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 3: 94. 1988. TYPE: *B. L. Chen & C. N. Mai 87 T 002* (holotype, SYS). Figure 6.

Tree to 18 m high and 65 cm diam.; young twigs stout, 8–10 mm diam., grayish, smooth, often longitudinally wrinkled when dry, glabrous to minutely hairy. Stipules ferrugineous-pubescent, adnate to the base of the petiole, 3–4(–11.5) cm long. Leaves coriaceous, glabrous on both sides, with slightly recurved margins, obovate, approximately three times as long as broad, dark green and glossy above, often pale green below, 27–44 × 11–16 cm; apex acuminate, acumen 10–25 mm long; base cuneate, decurrent with two ridges into the petiole; midrib lengthwise sulcate above, rather elevated below; nerves in 13–19 pairs, curved upward and meeting in an intramarginal vein; all lesser veins forming a coarse reticulation on rather dull upper faces; petiole glabrous, often conspicuously thickened toward its base, 3.6–6 cm long, stipular scars 16–45 mm long. Peduncle pubescent as stipules, ca. 1.4 cm long and 6 mm thick, pedicle with same indumentum, 5–6 mm long; spathaceous bract only one, rather thick coriaceous, broadly obovate, at the base of pedicle, its outside face pubescent, 83 × 69 mm. Tepals 9(–11), purple, the outer 3 narrowly obovate, fleshy, 12–14 × 5.8–6 cm, the inner 6–8 in two rows, shorter and narrower than the outer tepals. Stamens numerous. Gynoecium ovoid, ca. 2.7 × 1.8 cm, carpels 70–80, glabrous, nearly entirely connate when young. Fruits ovoid-globose, 9.5 × 8–10 cm, torus with scars of perianth and stamens ca. 3 × 2 cm; fruiting peduncle ca. 4.5 × 1 cm, pedicle ca. 2.5 × 1 cm, ripe carpels ligneous, 20–35 × 8–10 mm, abaxial part 10–15 mm long, dehiscing along the dorsal suture at first and later also along the ventral suture. Seeds ca. 3 in each carpel.

*Distribution.* CHINA: **Southeastern Yunnan**: Maguan, *B. L. Chen & C. N. Mai 87 T 002*.

*Ecology.* In secondary forest. Altitude: 550–670 m. Flowering March–May; fruiting September–October.

*Note. Manglietia lucida* is apparently most closely allied to *Manglietia garrettii* and *Manglietia grandis*. It differs from the former by the obovate leaves, glabrous leaves and petioles, and bigger flowers, and from the latter by the pubescent stipules and peduncles, as well as by its smaller fruits.

12. **Manglietia megaphylla** Hu & Cheng, Acta Phytotax. Sin. 1: 159. 1951. TYPE: China. Yunnan: Faadou, Sichour Hsien, 1,100 m, *C. W. Wang 85156* (holotype, PE not seen). Figure 7.

Tree to 25 m high and 85 cm diam.; buds, young twigs, stipules, petiole, midrib and nerves below, and peduncles densely villous with rather long, undulate to curly, dark brown or rufous hairs; twigs stout, 8–12 mm diam., black-brown. Stipules adnate to the base of the petiole. Leaves thinly coriaceous, dark green, glabrous above, pale green, scattered-villous with long, undulate to curly, dark brown hairs below, obovate, 23–40 × 9.4–17 cm; apex acute to abruptly short-acuminate, base cuneate; nerves visible beneath, in 20–22 pairs; reticulation coarsely netted, prominent on both sur-

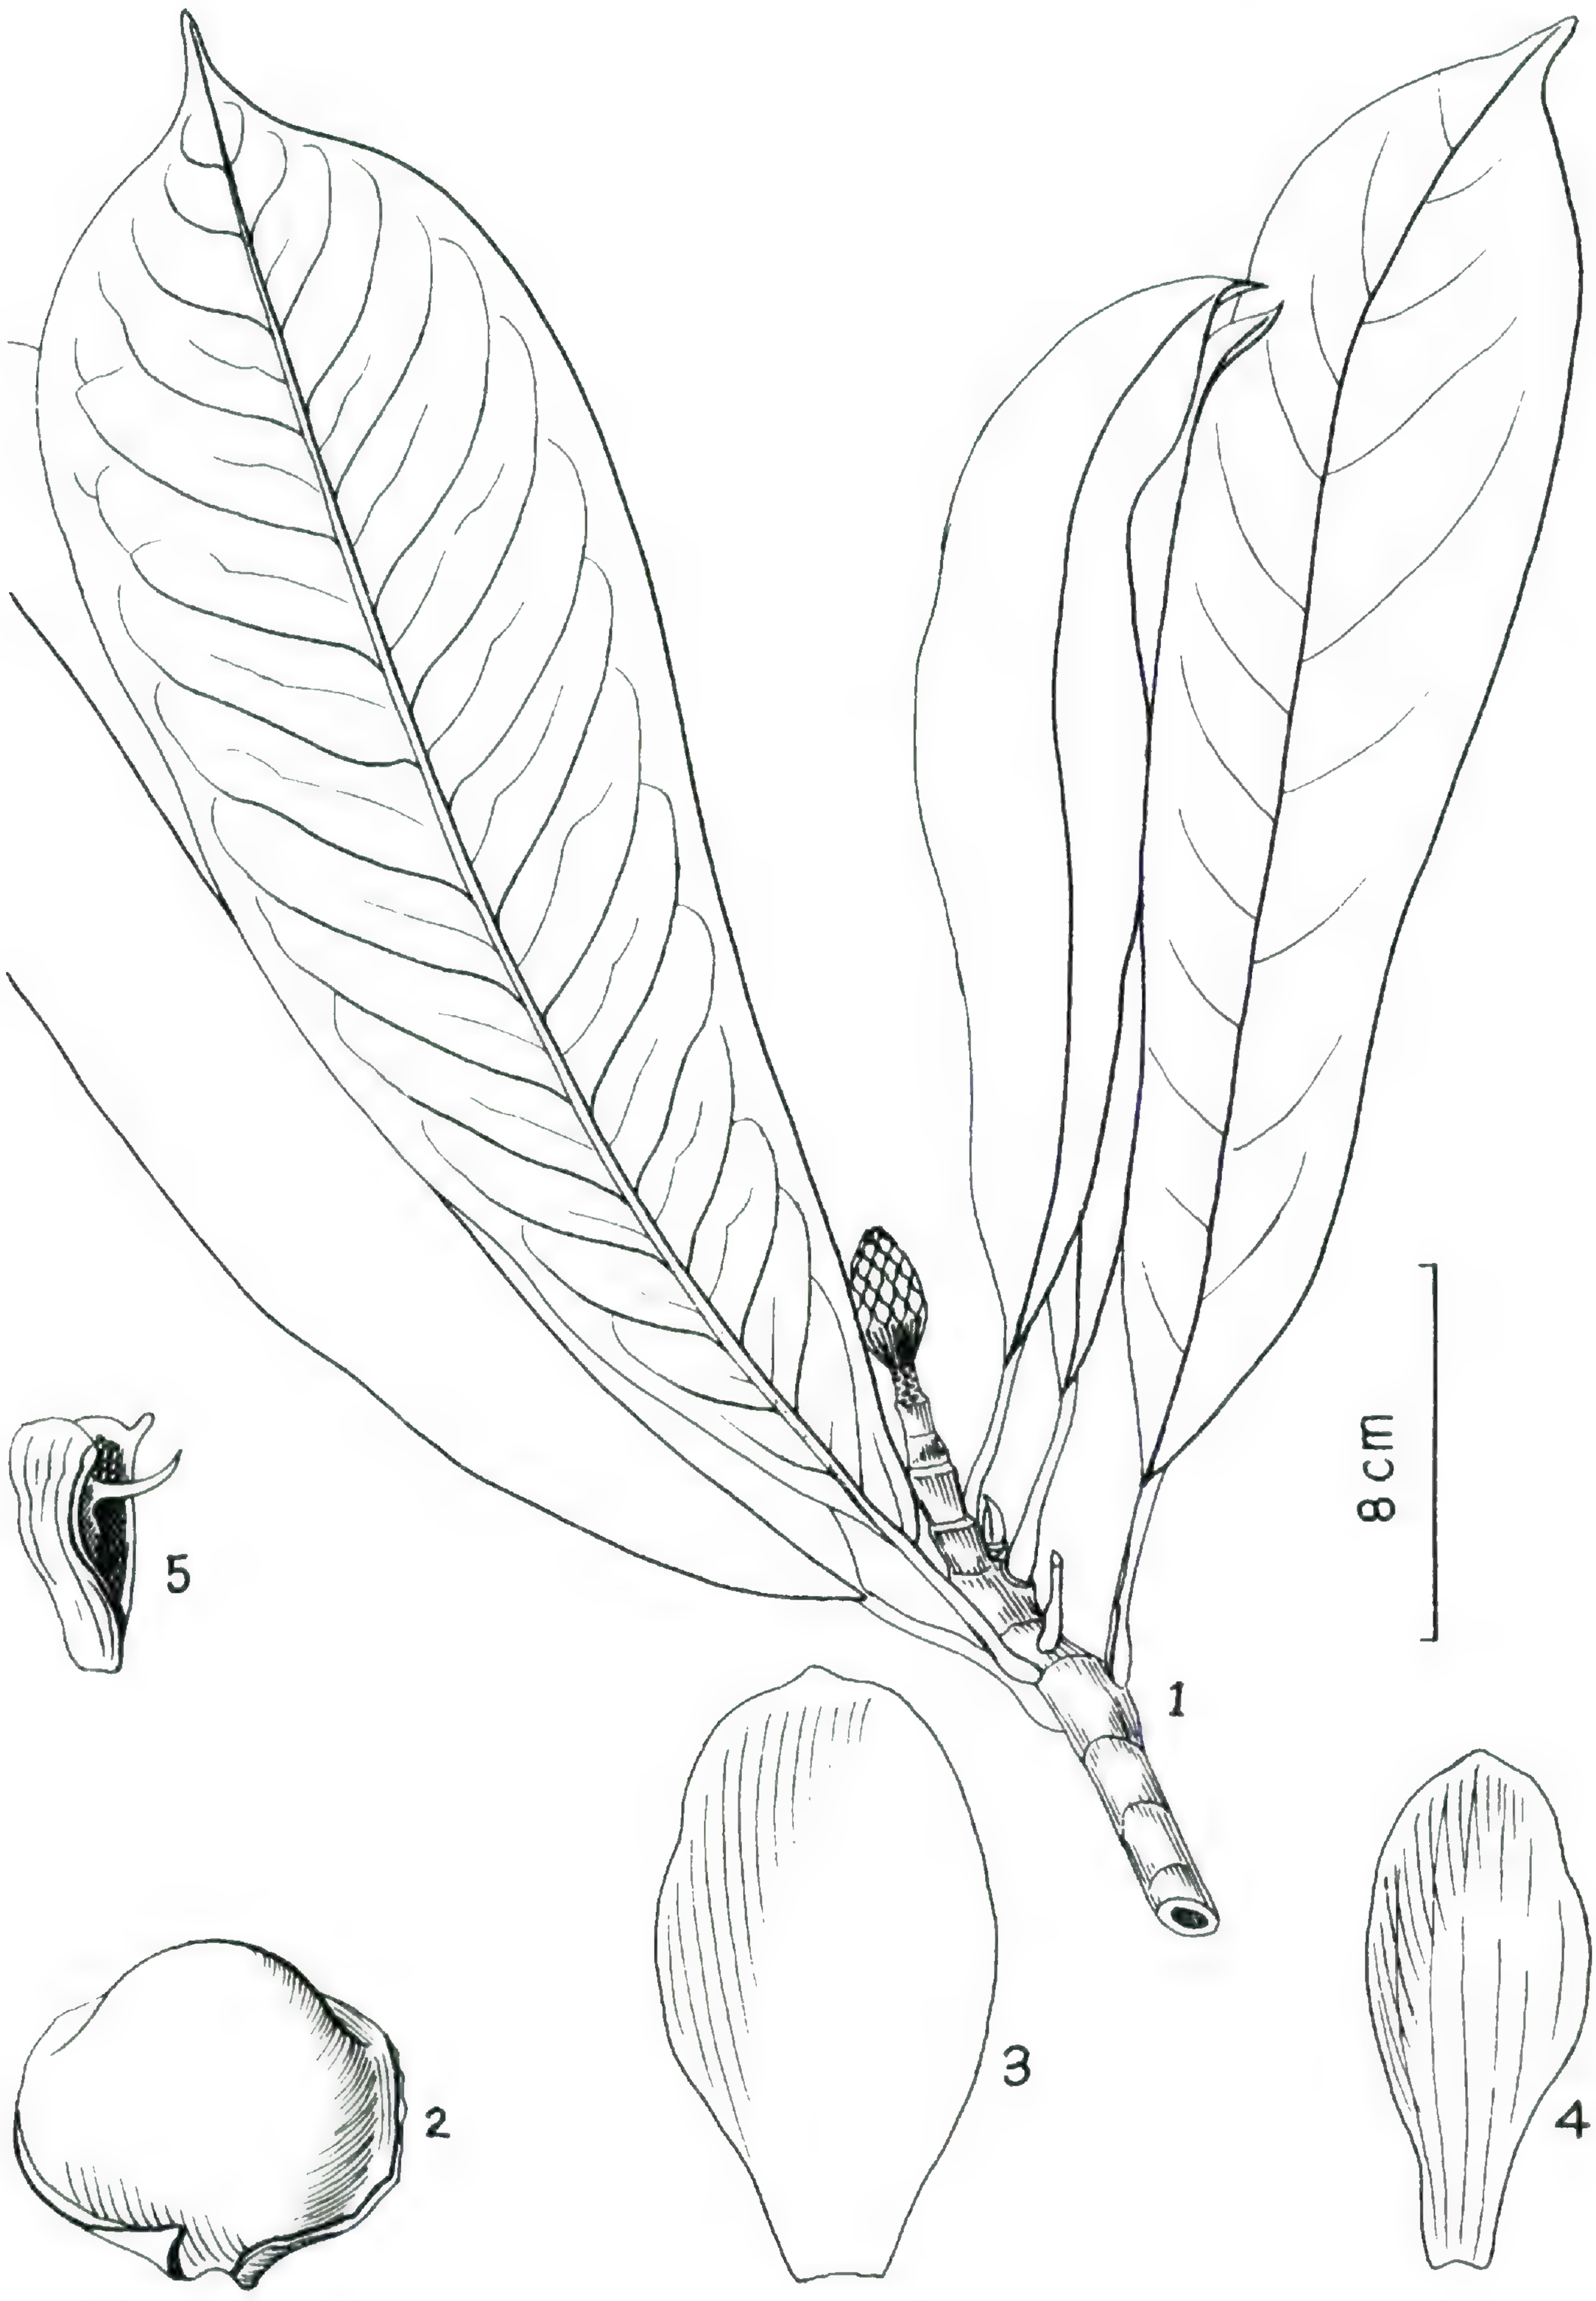

FIGURE 6. *Manglietia lucida* B. L. Chen & S. C. Yang.—1. Fruiting branch.—2. Bract.—3. Outer tepal.—4. Inner tepal.—5. Follicle. Based on *SYS 161496 = Chen Bao Liang 87 T 002*. Drawing by Xie Qing Jian.

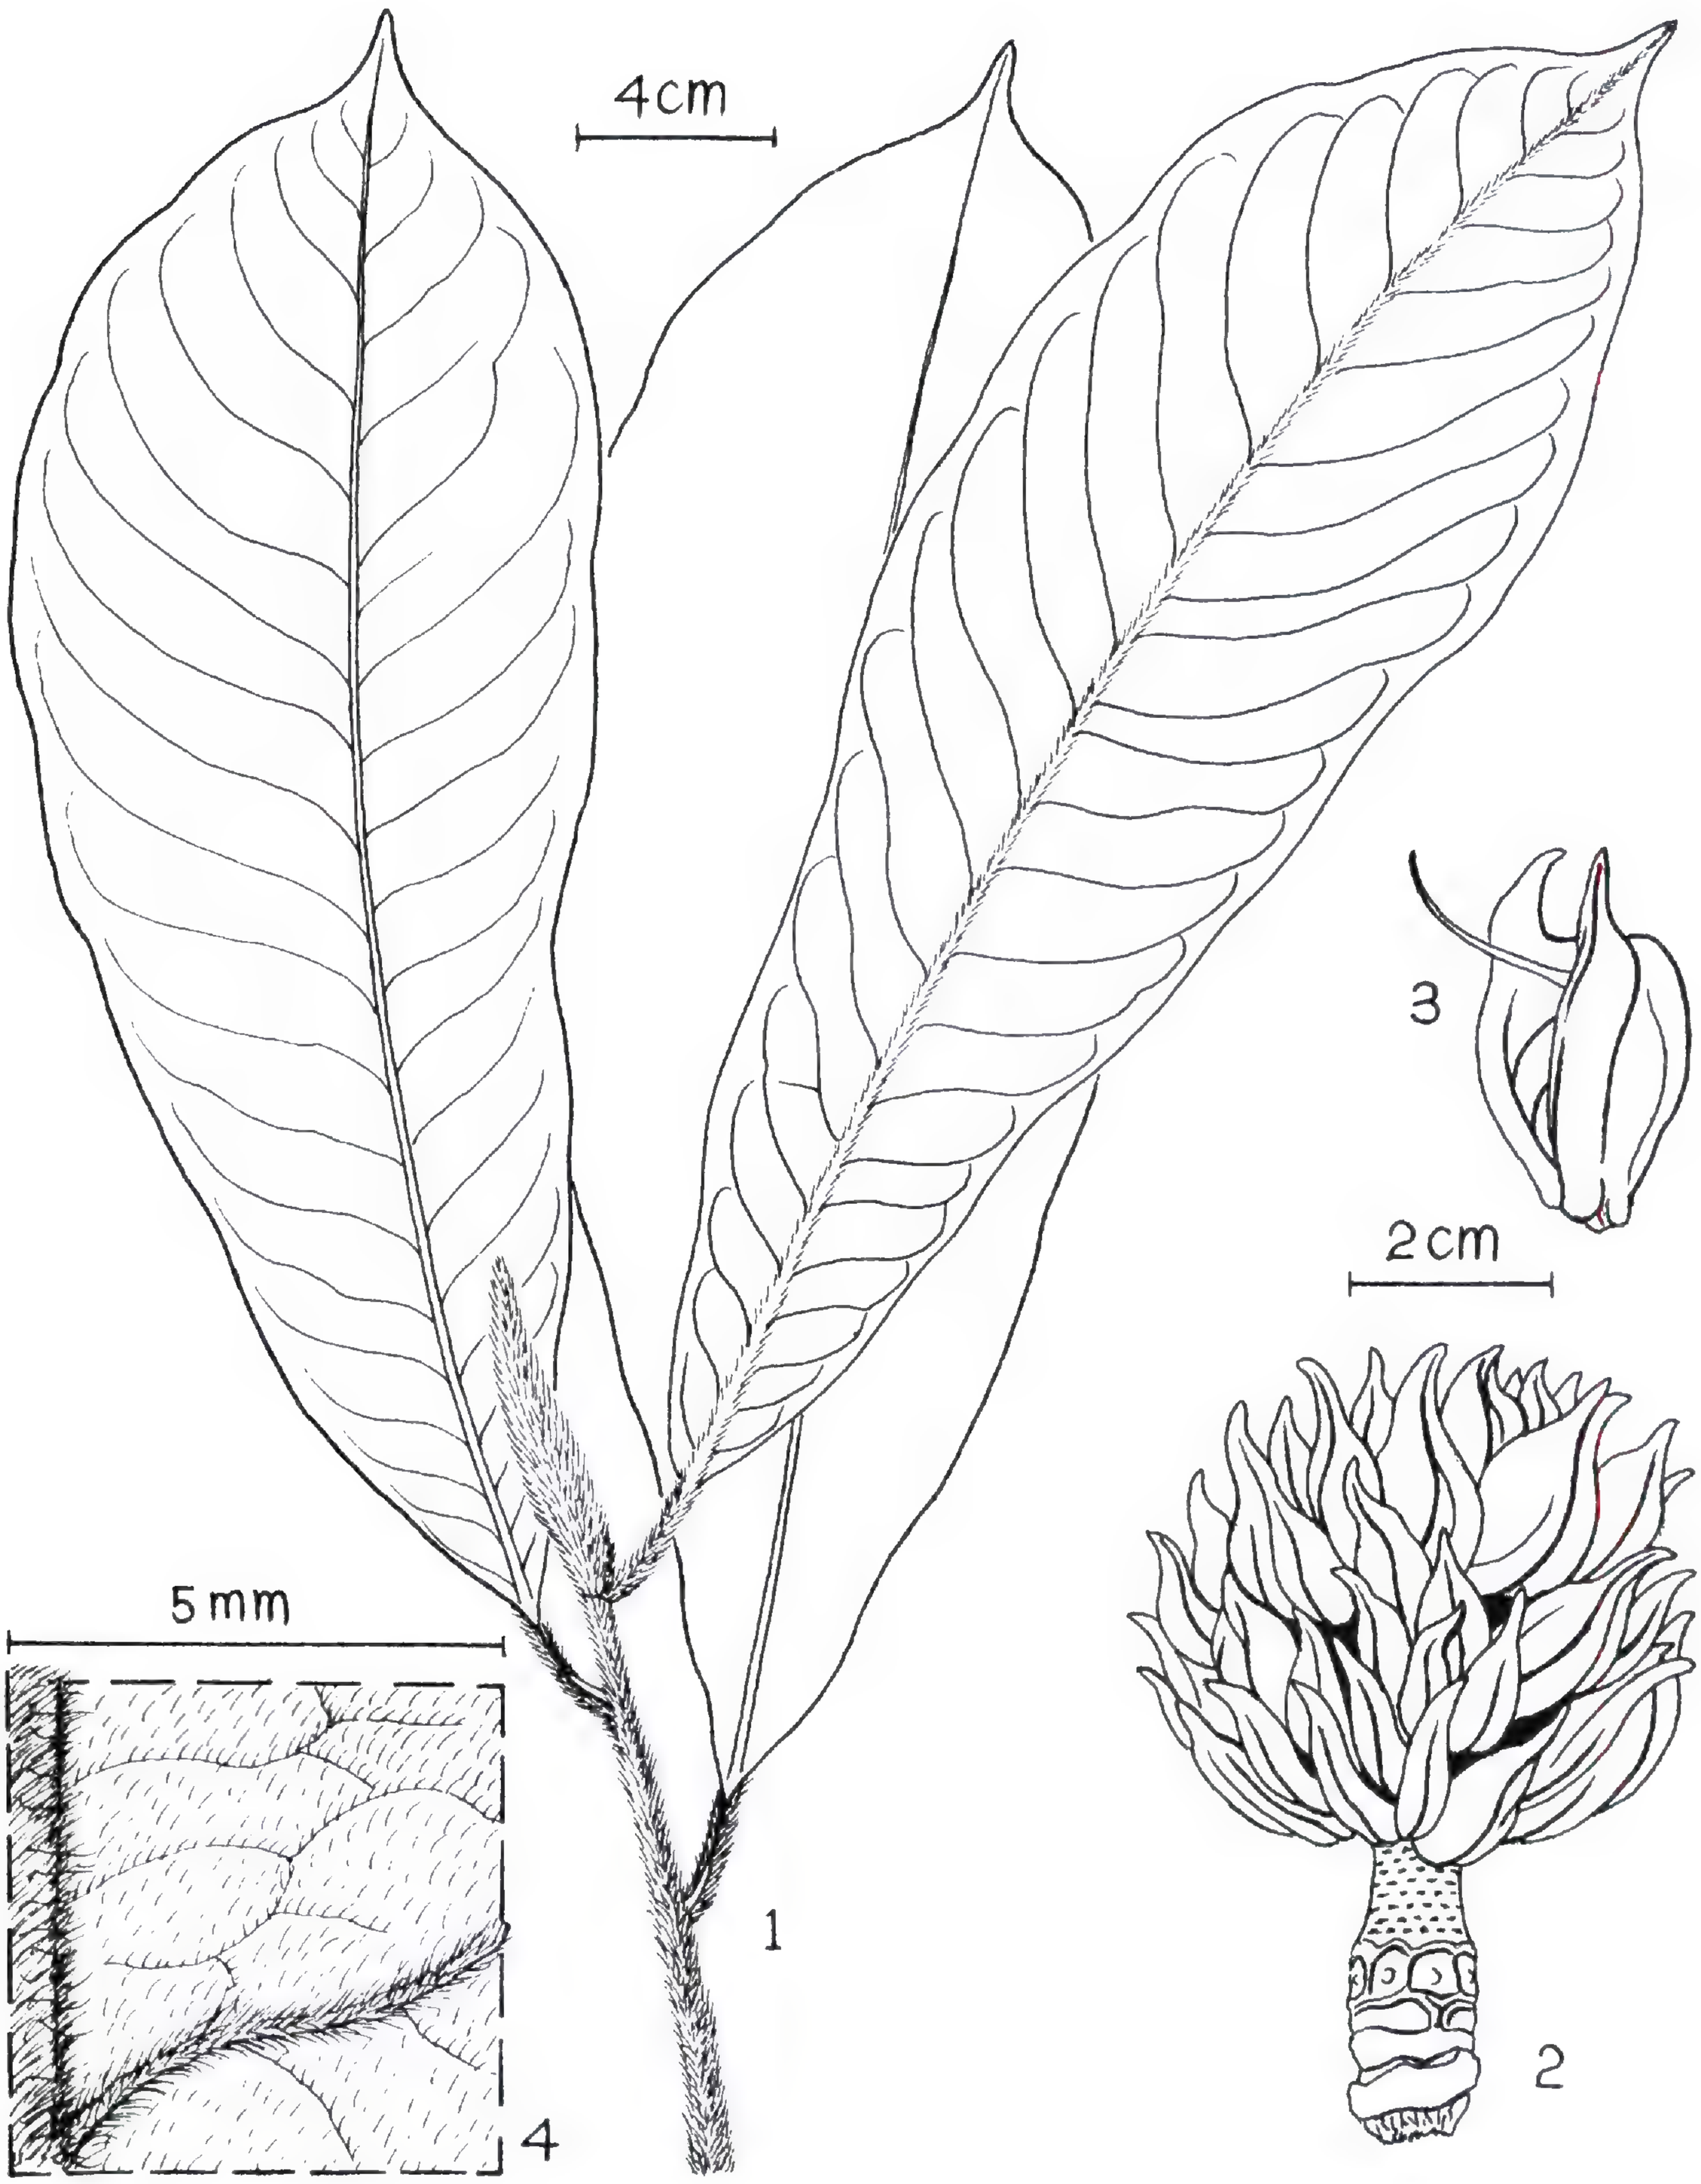

FIGURE 7. *Manglietia megaphylla* Hu & Cheng.—1. Branch with flower bud.—2. Fruit.—3. Follicle.—4. Undersurface of leaf. Based on *SYS 161435* = *Chen Bao Liang 87 T 102*. Drawing by Xie Qing Jian.

faces. Petiole usually dilatate toward the base, 1.5–3.7 cm long, stipular scars 0.7–3 cm long. Flowers not seen. Fruits ovoid to globose or oblong, ca. 7–9 × 6.5–8.5 cm; carpels 57–65, 2.5–3 cm long, apex with sharp beak 4–7 mm long, slightly recurved, dehiscing along the dorsal and the ventral suture; fruiting peduncles stout, ca. 1–3 × 1–1.3 cm. Pedicle 6 mm.

*Distribution.* CHINA. **Guangxi**: Donglin, *Chang C.C. 11438.* **Yunnan**: Maguang, *Chen B.L. GS 9 5*; Si-chour-hsien, Faa Doou, *Feng K.M. 11808.*

*Ecology.* In evergreen broad-leaved forests. Altitude: 800–1,500 m. Flowering April; fruiting September–October.

*Uses.* Wood straight-grained, coarse-textured and durable, moderately light and soft, commonly used for construction work, furniture, and plywood.

*Collector's note.* Fruit pale green, globose.

*Note.* In *Manglietia megaphylla* the distinguishing characters are the rufous indumentum with dense and long hairs, large leaves, and ovoid to oblong-ovoid fruits.

13. **Manglietia microtricha** Law, Bull. Bot. Res. (China) 5(3): 125, t. 4. 1985. TYPE: *Tibet Complex Exped. 74-1847* (holotype, PE not seen).

Tree to 30–40 m high, 40–60 cm diam.; young twigs stout, 6–10 mm diam. Stipules appressed brown pubescent, adnate to the base of the petiole, scars 6–13 mm long. Leaves coriaceous, green, glabrous above, glaucous beneath, obovate, 13–16 × 5–7 cm; apex short-acuminate, base cuneate; nerves in 15–17 pairs, reticulation fine, densely netted, prominent on both sides when dried. Petiole 2–2.5 cm long. Flower not seen. Fruiting peduncle ca. 1.5 cm long. Fruit ovoid, ca. 6 cm long, the dorsal face of the ripe carpel narrowly ellipsoid, appressed brown pubescent, with a ca. 3-mm-long beak at the apex. Seeds brownish, 1.5–2 cm long.

*Distribution.* CHINA. **Xizang** (Moyuo).

*Ecology.* In evergreen broad-leaved forest. Altitiude: 2,000 m. Fruiting September–October.

*Note.* No collections of this species were available; thus, based on Law's original description, *Manglietia microtricha* seems closely related to *Manglietia szechuanica.*

14. **Manglietia moto** Dandy, Notes Roy. Bot. Gard. Edinburgh 16: 128. 1928. TYPE: *K. P. To, W. T. Tsang & U.K. Tsang 180 in C. C. C. 12179* (holotype, A; isotypes, MO, SYS, UC).

Tree to 20 m high, 60 cm diam.; buds, young twigs, stipules, petiole, midrib below, bracts and peduncles densely villous with rather long crispy to curly dark brown to rufous hairs; young twigs 4–5 mm diam. Leaves green, glossy above, scattered-hairy with long, undulate to curly dark brown hairs beneath, glabrescent later, coriaceous, (narrowly) obovate, 11–19 × 5–7 cm; apex mucronate to acuminate, base cuneate to broadly cuneate, nerves in 9–19 pairs, reticulation obscure on both sides; petiole lengthwise narrowly sulcate above, 1.5–3.7 cm long, stipular scars narrowly triangular, 0.4–1.5(–3) cm long. Peduncles 4.3–9 cm × 4–6 mm, pedicle absent. Flowers fragrant; tepals 9, creamy white, the outer 3 coriaceous, oblong to ovate-oblong, ± hairy outside at the base, 3.7–5.7 × 2–2.5 cm, the inner 6 thick and fleshy, spathulate to obovate, slightly concave, the innermost ones usually becoming short-clawed toward the base, 9–12 × 1–1.8 cm; stamens numerous, 1.1–1.4 cm long, connective appendage semirounded or sometimes with a short, sharp tip, 1–1.5 mm long, filaments glabrous, ca. 1 mm long; gynoecium broadly ovoid, 1.3–1.5 × 1–1.2 cm, number of carpels 48–71; styles ca. 2 mm long; scars of the fallen perianth and stamens 9–12 × 4–7 mm. Fruiting peduncles ca. 11 × 0.5–0.6 cm. Fruits ovoid, 5–7 × 3.5–6 cm; carpels papilliferous on the dorsal face, apex with a ca. 2–3-mm-long beak. Seeds ovoid to elliptic, 6–9 × 4–6 mm, 6–9 in each carpel.

*Distribution.* CHINA. **Guangdong**: Wat Shui Shan, North river region, *Chun W.Y. 7353*; Yuyuen distr., *Ko S.P. 53514*; also reported form Ruyuan, Yaoshan, Yingteh, Lokchong, and Huanshuishan. Western, central, and northern Guangxi (He Xian, Cangwu Xi). Southern Hunan.

*Ecology.* In mixed forests. Altitude: 400–900 m. Flowering May–June; fruiting August–September.

*Uses.* Wood fine-textured, soft, used for general construction work and furniture.

*Collector's note.* Bark dull gray, flowers creamy white.

*Notes.* See Dandy (1928a). *Manglietia moto* is a notable species and is easily distinguished by its rufous indument and long peduncles.

*Manglietia rufibarbata*, which was originally collected from Vietnam, has not been recorded in China so far as we know. In our opinion, it closely resembles *Manglietia moto* in all characters, except for its stout peduncles and the fruits with rufous hairs. Because we have not seen sufficient material of *Manglietia rufibarbata*, we still maintain it here.

The type was identified as *Magnolia kwangtungensis* Merr. by Merrill (1927a) = *Manglietia fordiana* Oliver var. *kwangtungensis.*

15. **Manglietia pachyphylla** Chang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 53.

1961. TYPE: *P. S. Wang & H. H. Chiu 241* (holotype, SYS). Figure 8.

*Manglietia crassipes* Law, Bull. Bot. Res. (China) 2: 133. 1982. TYPE: China. Guangxi: Jinxiu Xian, 1,300 m, *Q. H. Lu 4319* (holotype, IBK not seen).

Tree 16 m high and 30 cm diam.; bark gray-black; twigs dull black, stout, ca. 1 cm diam., glabrous, covered with a waxy substance; stipules brown-villous, adnate to very base of the petiole. Leaves coriaceous, thick, rigid when dry, glabrous, dark glossy green above, pale green, minutely pubescent beneath, (narrowly) obovate or elliptic, 13–32 × 5–10 cm; apex blunt, short-acuminate; base cuneate; nerves in 8–14 pairs, faint on both surfaces, reticulation obscure. Petiole stout, sulcate above, 3–5 cm long, stipular scars 1–7 mm long. Peduncles minutely pubescent, ca. 1.7–2 × 0.7 cm, pedicle ca. 4 mm long; bract only one, broadly ovate, coriaceous, glabrous, ca. 4.8 × 7 cm. Flowers fragrant, tepals 9, white, the outer 3 oblong, coriaceous, 5.5–8 × 3.2–3.5 cm, the inner 6 obovate or broadly obovate, attenuate toward the base, convex, thick and fleshy, 3.2–4.3 × 2.5–3 cm, the innermost tepals usually short-clawed basally; stamens 0.7–1.2 cm long, connective appendage with rounded apex, ca. 1 mm long, filaments glabrous, ca. 1 mm long; gynoecium ovoid, ca. 2.2 × 1.8 cm; styles glabrous, ca. 1 mm long; the torus with scars of perianth and stamens ca. 1.5 × 0.7 cm. Fruiting peduncles 3–5.5 × 1–1.2 cm. Fruits ellipsoid, 5–7 × 4.5 cm; ripe carpels 38–46, ca. 1.5–2.5 mm long, short-beaked. Seeds 3–4 in each carpels, flat globose, 5–6 mm diam.

*Distribution.* CHINA. **Guangdong**: Conghus Xian, *Guang 242*; Tsung-hwa District, Sam Kok Shan, *Wang P.S. & Chiu, H.S. 241, Tsang W.T. 25175*. **Guizhou**: Anlong Xian, *Huangshan Exped. 3049*. Also reported from Guangxi (Dayaoshan and Jinxiu Shan).

*Ecology.* In evergreen broad-leaved forests. Altitude: 800–1,500 m. Flowering May; fruiting August–September.

*Uses.* The timber is used for general construction work, furniture and plywood; the tree is grown also as an ornamental plant because of its handsome crown.

*Notes.* The type specimen of *Manglietia crassipes* has not been seen. However, according to the published description and the collections examined, it is clear that *Manglietia crassipes* is conspecific with *Manglietia pachyphylla*.

16. **Manglietia szechuanica** Hu, Bull. Fan. Mem. Inst. Biol. (Peiping) 10: 117. 1940. TYPE: *T. T. Yu 3105* (holotype, PE; isotype, A).

Tree 15 m high and 30 cm diam.; young twigs green, 4–5 mm diam., at first yellowish villous, soon glabrescent or only hairy at the nodes; stipules pubescent, adnate to the base of the petiole. Leaves glabrous above, pale green, appressed-pubescent with short, straight, brown hairs on the surface and with rather long, straight, colorless to yellowish hairs along midrib and margins beneath, coriaceous, narrowly obovate, 13–20 × 4–7.3 cm; apex mucronate to acuminate, acumen 15–17 mm long; base narrowly cuneate to cuneate; midrib impressed above, elevated below, white villous with brown pigment, nerves fine in 8–19 pairs, reticulation coarse. Petiole white villous or later glabrescent, 1.5–2.5 cm long, stipular scars 9–11 mm long. Peduncles villous, glabrescent, 1–1.6 × 0.4–0.5 cm, pedicles 3–4 mm long. Flowers white; tepals 9, the outer 3 ovate-oblong, greenish with a flush of purple, sparsely villous, 4–5.5 × 2–2.8 cm, the inner 6 oblong to obovate, short-clawed at base, 4.5–6 × 1.5–3 cm; stamens 1.2–2 cm long, connective appendage triangular; gynoecium ovoid-ellipsoid, 1.7–2.5 × 1.5–3 cm, carpels 42–58, the lower narrowly ellipsoid, yellowish pubescent, 8–10 mm long. Styles glabrous, 4–6 mm long. Scars of perianth and stamens 7–10 × 5 mm.

*Distribution.* CHINA. **Northern Yunnan**: Suijiang, *Sun B., S. 341*. **Southern and central Sichuan**: Omei Xian, *Chow H.C. 11944*; Pingshan, *Yu T.T. 3105*.

*Ecology.* Altitude: 1,400–1,800 m.

*Collector's note.* Flowers pink or purple-red, scented. Bark grayish brown, smooth; leaves dark green above, yellowish brown with long hairs beneath.

17. **Manglietia ventii** Tiêp, Feddes Repert. 91, 9–10: 560. 1980. TYPE: China. Yunnan: Dinbian Hsien, alt. 880 m, 9 Aug. 1953, *P. I. Mao 2842* (LE not seen).

Tree to 30 m high. Young twigs 2–3.5 mm diam., black-gray, densely appressed-tomentellous with short, straight, glistening, yellowish hairs, old ones ± gray-pubescent to glabrescent. Stipules yellowish appressed-tomentellous, adnate to the base of the petiole, scars 1–2 cm long. Leaves usually crowded at the end of the twigs, chartaceous to thinly coriaceous, elliptic, broadly elliptic, obovate-elliptic to obovate, sometimes unequal; glabrous above, appressed-tomentose with short, straight, glistening, yellowish to silver hairs beneath, 9–18

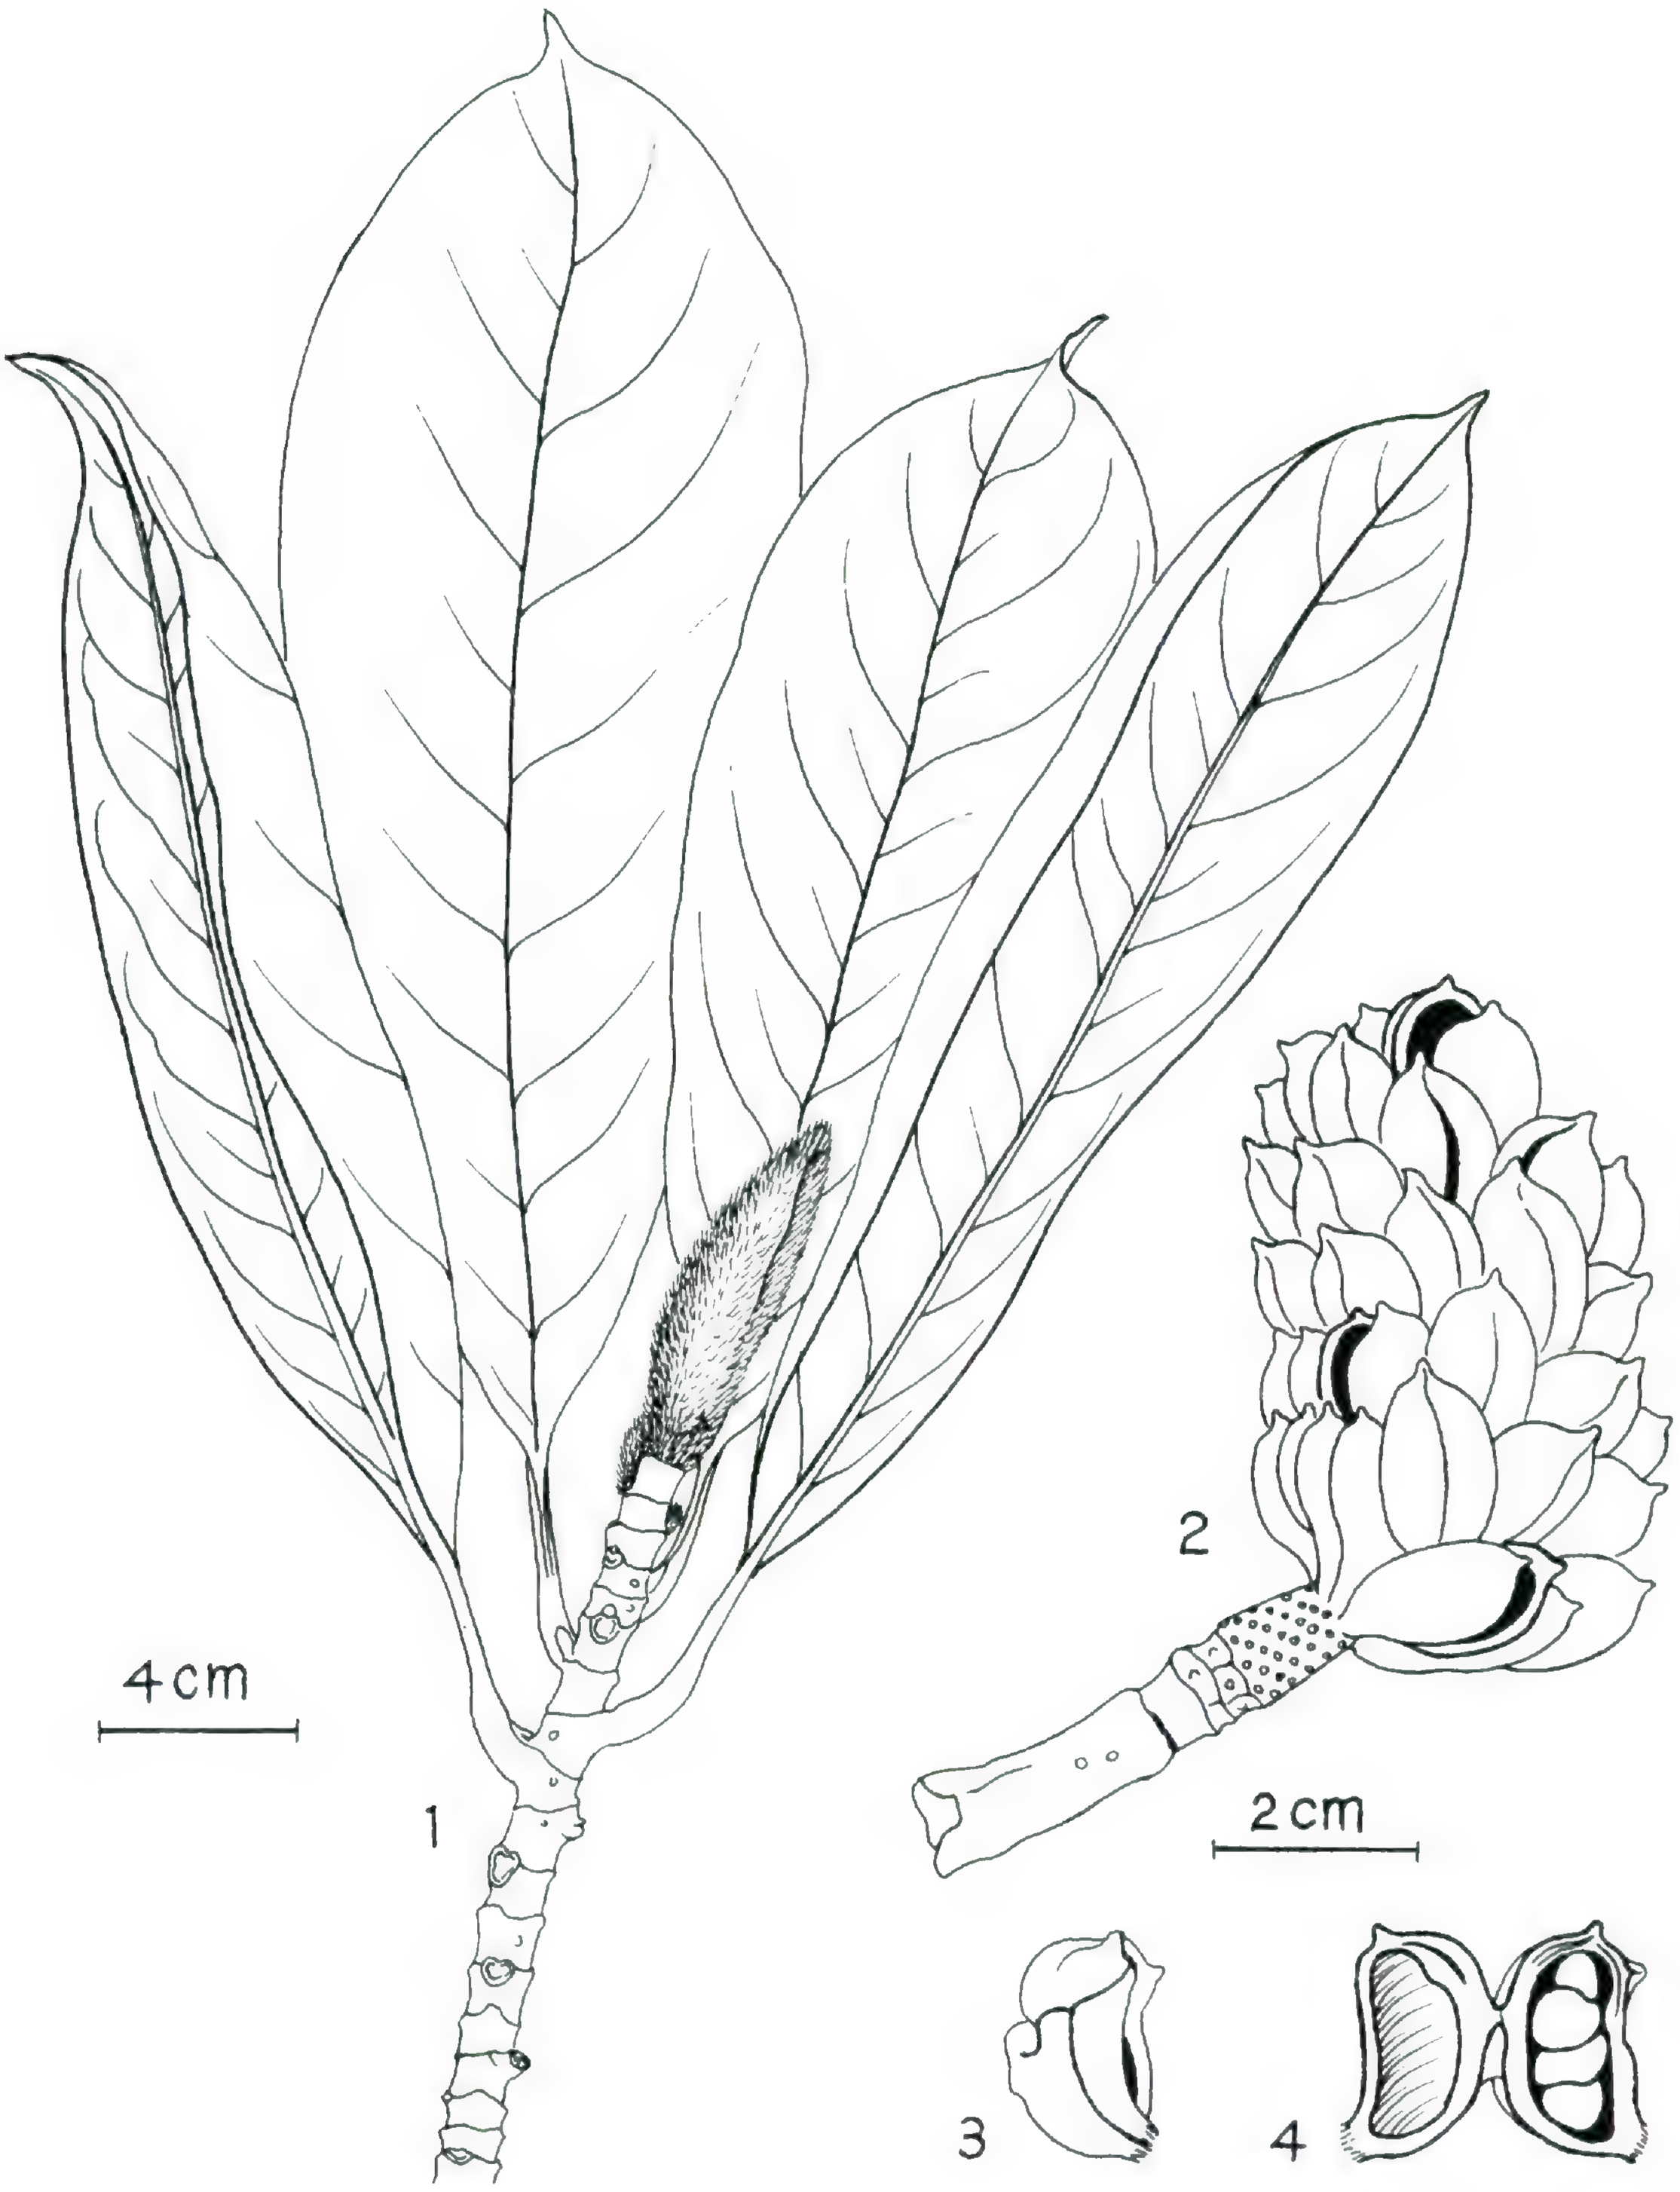

FIGURE 8. *Manglietia pachyphylla* Chang.—1. Branch with flower bud.—2. Fruit.—3. Follicle.—4. Open follicle with seeds. Based on *SYS 121334, Anonymous 241.* Drawing by Xie Qing Jian.

× 2.2–6.5 cm; apex short-acuminate to acuminate, acumen 3–17 mm long, base cuneate to obtuse; midrib impressed above, elevated below, densely pubescent to glabrescent, nerves fine, in 12–16 pairs, obscure above, visible beneath, reticulation lax, faint on both sides. Petiole slender, tomentellous, with same hairs as the young twigs, glabrescent, 2.6  3 cm long. Flower not seen. Fruit-

ing peduncle yellowish appressed-tomentose, 1–1.5 × 0.4–0.6 cm, with a bract scar, pedicle absent. Fruit ovoid to long-globose, 3.5–7 × 2.5–4.5 cm; ripe carpels ca. 64, long-ovoid, the lowest carpels decurrent along the torus, ± yellowish pubescent, especially toward the base of the lowest carpels, beak rather long, erect or recurved, dehiscing along the dorsal suture, 2–2.2 cm long; torus with 6–9 × 7 mm scars of perianth and stamens; scars of the fallen tepals ca. 10. Seeds subcordate to ovoid, ± impressed, 1–3 in each carpel, 7–7.5 × 5–6 mm.

*Distribution.* China and Vietnam. In CHINA. **Southeastern Yunnan**: Ping-pien Hsien, *Tsai H.T. 61619.*

*Ecology.* Altitude: 880 m.

**II-2. Manglietia** section **Manglietiastrum** (Law) Nooteboom, *Manglietiastrum* Law, Acta Phytotax. Sin. 11: 72, t. 2. 1979. *Magnolia* sect. *Manglietiastrum* (Law) Noot., Blumea 31: 91. 1985. TYPE SPECIES: *Manglietiastrum sinicum* Law.

Stipules free from petiole. Young leaves spreading in bud. Gynophore present.

18. **Manglietia sinica** (Law) B. L. Chen & Nooteboom, comb. nov. *Manglietiastrum sinicum* Law, Acta Phytotax. Sin. 17: 73, t. 2, 3. 1979. *Magnolia sinica* (Law Yuh-wu) Noot., Blumea 31, 1: 91, photo. 3. 1985. TYPE: China. Yunnan: Xichou, 1,550 m, *Law & Wang 6-75* (IBSC, v. spont.).

Tree to 40 m high and 1.2 m diam.; bark gray, longitudinally fine-fissured; trunk somewhat buttressed at the base; plant entirely glabrous; twigs dark green when young, faint brown when old; stipules free from the petiole. Leaves coriaceous, dark shining green above, pale green beneath, narrowly obovate, 15–26(–30) × 5–8(–9.5) cm; apex short-acuminate, with ca. 5-mm-long acute tip, base cuneate; margin slightly revolute; nerves in 13–16 pairs, reticulation coarse, prominent on both surfaces when dry. Petiole smooth above, slightly thickened at base, 1.5–2 cm long. Tepals 9, 3-merous, in 3 whorls; stamens ca. 65, connective appendage long-pointed; carpels 13–16. Fruits green at first, slightly flushed, obscure brown when dry, ovate, oblong-ovoid to obovoid, 5–8.5 × 3.5–6.5 cm; carpels thick woody, narrowly oblong-elliptic to obovoid-elliptic, 2.5–4 × 1.5–2.5 cm, opening along the ventral suture and splitting at the apex, dorsal faces conspicuously lenticellate; gynophore ca. 1 × 1.3 cm. Seeds 1–3 in each carpel, elliptic, compressed laterally, 1–1.3 cm wide, ca. 7 mm thick.

*Distribution.* CHINA. **Southeastern Yunnan**: Xichou, *Chen B.L. 87 F 180.*

*Ecology.* In evergreen broad-leaved rainforest. Altitude: 1,300–1,500 m. Flowering April; fruiting September–October.

*Note.* *Manglietia sinica*, a magnificent tree, is confined to a small area in southeastern Yunnan. One of the authors has investigated it several times in the field. The species possesses the chief diagnostic characters of *Manglietia*, e.g., habit of tree, the terminal flowers with 9 tepals, and more than 2 ovules in each carpel. Therefore, we prefer to include it in *Manglietia*. On the other hanad, there occur some remarkable characters in this species, such as the petioles without stipular scars and the gynoecium with a short gynophore. These features easily distinguish it from the other species in this genus and warrant its status as a section. The sections in *Magnolia* are based on the same kind of characters.

**III. Kmeria** (Pierre) Dandy, Kew Bull. 1927: 262. 1927. *Magnolia* subg. *Kmeria* Pierre, Fl. Forest. Cochinch. 1: sub t. 1. 1880. TYPE SPECIES: *Kmeria duperreana* (Pierre) Dandy.

*Tree.* Stipules adnate to the petiole. Flowers terminal, solitary, unisexual; tepals 6–7, 3-merous, subequal; anthers dehiscing introrsely, the connective produced into a short or moderately elongated appendage. Gynoecium sessile. Carpels comparatively few, concrescent. Ovules 2. Fruiting carpels woody, separating on dehiscence, dehiscing completely along the ventral suture and partly along the dorsal suture, thus finally becoming bifid. Seeds 1–2 in each carpel.

*Distribution.* Two species, southern China to Indochina.

*Note.* This genus is closely related to *Magnolia*. It could also be treated as a section close to section *Gwillimia*. In China the only species that occurs is *Kmeria septentrionalis*.

1. **Kmeria septentrionalis** Dandy, J. Bot. 69: 233. 1931. TYPE: *R. C. Ching 5247* (holotype, BM; isotypes, NY, PE).

Tree to 18 m high; bark gray; twigs green, ± glaucescent when dry, appressed short pubescent. Stipules glabrous or sparsely pubescent, adnate to rather high on the petiole, stipular scars nearly to

its apex. Leaves coriaceous, bright green, glabrous above, greenish, glabrous or sparsely pubescent toward the base when young beneath, elliptic-oblong or obovate-oblong, 8–15 × 3.5–6 cm; apex retuse, base broadly cuneate; midrib prominent below, nerves visible on both sides, in 12–17 pairs, reticulation prominent on both surfaces when dry. Petiole slender, pubescent to glabrescent, 2–3.5 cm long. Brachyblast glabrous, 1.5 cm long. Flower bud (the male flower) subglobose; tepals 6; stamens 1–1.5 cm long, connective appendage triangular, 1–2.5 mm long.

*Distribution.* CHINA. **Northern and central Guangxi**: Huanjiang, *Pang C.F. 28*; southeastern Luchen, *Ching R.C. 5247*. **Yunnan**: Huang Jingin, Mar Li Po, *Wang C.W. & Liu 83157*; Maguan, *Chen B.L. 87 F 173*.

*Ecology.* In evergreen forest. Altitude: 300–500 m. Flowering May–June.

*Collector's notes.* Tree with a large dense crown; bark gray; leaves evergreen; flowers white, fragrant.

*Note.* This species is closely related to *K. duperreana* (Pierre) Dandy. Recently, a new record of *K. duperreana* in Libo of Guizhou was reported, but we have not seen a collection from that locality.

TRIBE MICHELIEAE

**IV. Michelia** L., Sp. Pl.: 536. 1753. *Champaca* Adans., Fam. Pl. 2: 365, 537. 1763. *Sampacca* O. Kuntze, Rev. Gen. Pl. 1: 6. 1891. TYPE SPECIES: *Michelia champaca* L.

*Liriopsis* Spach, Hist. Natur. Veget., Phanerog. 7: 460. 1839, non *Liriopsis* Reichenb. (1828). TYPE SPECIES: *Liriopsis fuscata* (Andr.) Spach.

*Paramichelia* H. H. Hu, Sunyatsenia 4: 142. 1940. TYPE SPECIES: *Paramichelia baillonii* (Pierre) Hu.

*Tsoongiodendron* W. Y. Chun, Acta Phytotax. Sin. 8: 7. 1963. TYPE SPECIES: *Tsoongiodendron odorum* Chun.

Trees or shrubs. Stipules adnate to or free from the petiole. Flowers bisexual, on short brachyblasts in the axils of the leaves, growth monopodial. Tepals 6–21, 3–6-merous, subequal or rarely the outer whorl different. Anthers latrorse or sublatrorse (to introrse), connective produced into a short or elongated appendage. Gynoecium stipitate; carpels many to few (rarely 1), free or connate; ovules 2 to many; follicles free, ± spaced along the torus, dehiscing along the dorsal suture, finally becoming 2-valved, or concrescent, forming a fleshy syncarp, tardily and irregularly dehiscent, or a woody syncarp, the upper parts of the carpels falling away while also dehiscing along the dorsal suture, the basal parts remaining attached to the torus with their suspended seeds.

*Distribution.* About 40 species, in Southeast Asia from India and Sri Lanka eastward to southwestern and southeastern China, northeastward to southern Japan and southeastward into Indonesia (not in Sulawesi and New Guinea).

KEY TO THE SECTIONS OF *MICHELIA*

1. Tepals very dissimilar, those of the outer whorl much shorter and narrower those of the inner whorls; fruit apocarpous; stipules free from petiole. ..... **IV-2.** *Michelia* sect. *Anisochlamys*
1. Tepals of the outer whorl sometimes smaller and thinner than those of the inner whorls, but not very dissimilar; fruits apocarpous or syncarpous; stipules free from or adnate to petiole. ..... 2
2(1). Fruits syncarpous; stipules adnate to petiole. 3
2. Fruits apocarpous; stipules free from or adnate to petiole. ..... 4

3. Tepals 12; fruits 3–9 cm. ..... **IV-6.** *Michelia* sect. *Paramichelia*
4(2). Tepals 6, or occasionally 4, 2-merous; stipules free from petiole. ..... **IV-3.** *Michelia* sect. *Dichlamys*
4. Tepals 6–21, 3–6-merous; stipules free from or adnate to petiole. ..... 5
5(4). Petioles not exceeding 10 mm, stipules adnate to it; shrubs or small trees. ..... **IV-4.** *Michelia* sect. *Micheliopsis*
5. Petioles longer than 10 mm, stipules free or adnate. ..... **IV-1.** *Michelia* sect. *Michelia*

KEY TO THE SPECIES OF *MICHELIA*
(primarily based on floral characters)

1. Tepals 6 or 7. ..... 2
1. Tepals 8–20. ..... 10
2(1). Petiole 2–10 mm. ..... 3
2. Petiole 10–45 mm. ..... 6
3(2). Gynoecium longer than androecium. ..... 4
3. Gynoecium shorter than androecium, often entirely hidden. ..... 5
4(3). Petiole 5–10 mm long, stipular scars nearly to its apex; tepals 22–35 mm long; gynophore 5–8 mm long; gynoecium ovoid to oblong. ..... 33. *Michelia yunnanensis*
4. Petiole 3–5 mm long, stipular scars to halfway; tepals 15–25 mm long; gynophore 1–3 mm long; gynoecium cylindric. ..... 32a. *Michelia figo* var. *figo*
5(3). Stipules adnate to petiole; petiole 2–4 mm; flower purple or red; stamens 10 mm long; gynoecium cylindric. ..... 32b. *Michelia figo* var. *crassipes*
5. Stipules free; petiole 10 mm; flower white; stamens 11–15 mm long; gynoecium ellipsoid. ..... 26. *Michelia angustioblonga*
6(2). Leaves glabrous. ..... 7

6. Leaves hairy beneath at least when young. 8
7(6). Base of leaf broadly cuneate or attenuate-cuneate, nerves in 7–17 pairs; brachyblast pubescent, 7–15 × 3–9 mm; gynophore and carpels glabrous; twigs and stipules pubescent; scars of perianth and stamens along torus under fruit 6–8 mm long. ..... 30. *Michelia martinii*
7. Base of leaf cuneate or rounded, nerves in 9–12 pairs; brachyblast tomentellous or puberulous, 3–11 × 2–4 mm; gynophore and carpels silver gray tomentellous; twigs tomentellous; stipules glabrous, puberulous, or tomentellous; scars of perianth and stamens along torus under fruit 4–5 mm long. ..... 28. *Michelia chapensis*
8(6). Leaves 1.5–2.5 cm broad; shrub to 4 m high; leaf apex obtuse; outer tepals spathulate, 18–20 × 4–5 mm; gynoecium hidden by the stamens; gynophore 3–4 mm long. ..... 26. *Michelia angustioblonga*
8. Leaves 2.8–16.5 cm broad; tree to 15–18 m high; leaf apex short-acuminate, acuminate, or acute; outer tepals obovate, oblong, or elliptic; gynoecium ovoid or cylindric; gynophore 5–10 mm long. ..... 9
9(8). Pedicle present; twigs appressed tomentellous; stipules glabrous or tomentellous; leaves 2.8–4.5 cm broad, reticulation rather obscure; petiole not dilated at base; gynoecium cylindric. ..... 29. *Michelia leveilleana*
9. Pedicle absent; twigs pubescent; stipules pubescent; leaves 4.5–10(–16.5) cm broad, reticulation distinct; petiole dilated at base; gynoecium ovoid. ..... 27. *Michelia balansae*
10(1). Stipules free. ..... 11
10. Stipules adnate to petiole. ..... 25
11(10). Leaves glabrous. ..... 12
11. Leaves hairy beneath at least when young. 17
12(11). Brachyblast 10–40 mm long; outer tepals 5–8 cm long; stamens 13–25 mm long. ..... 13
12. Brachyblast 2.5–6 mm long; outer tepals 1–3 cm long; stamens 2.5–10 mm long. 15
13(12). Leaves glaucous beneath, nerves in 12–14 pairs; stipules silky; petiole hairy; outer tepals 35 mm broad; gynoecium golden puberulous, ca. 20 mm long. ..... 13. *Michelia ingrata*
13. Leaves not glaucous beneath; stipules glabrous or pubescent; petiole glabrous; outer tepals 15–40 mm broad; gynoecium glabrous. ..... 14
14(13). Plant entirely glabrous; reticulation of leaf densely netted, nerves in 7–12 pairs; inner tepals 4.5–5 cm long; gynoecium 10–13 mm high; scars of perianth and stamens along torus under fruit 5–6 mm long. ..... 18. *Michelia maudiae*
14. Plant hairy at least in innovations; stipules pubescent; reticulation laxly netted, nerves in 9–20 pairs; inner tepals 5.5–7 cm long; gynoecium 17–20 mm high; scars of perianth and stamens along torus under fruit 20–22 mm long. ..... 15. *Michelia lacei*
15(12). Twigs glabrous, 1–2 mm diam.; stipules puberulous; midrib of leaf prominent above, at least toward base; tepals very dissimilar, outer tepals small, nearly linear, ca. 1 mm broad; gynophore under fruit 2–3 mm long. ..... 25. *Michelia hypolampra*
15. Twigs hairy at least when young; stipules pubescent or tomentellous; midrib of leaf not prominent above; tepals subsimilar, outer tepals obovate or spathulate; gynophore under fruit 10–17 mm long. ..... 16
16(15). Gynoecium glabrous, cylindric, 10–12 mm long; stipules tomentellous; reticulation distinct; petiole dilated at base; filaments 2.5–3 mm long. ..... 5. *Michelia coriacea*
16. Gynoecium hairy, ovoid, 4–6 mm long; stipules pubescent; reticulation of leaf rather obscure; petiole not dilated at base; filaments 1 mm long. ..... 4. *Michelia compressa*
17(11). Outer tepals 1–3 cm long. ..... 18
17. Outer tepals 3.1–9 cm long. ..... 20
18(17). Pedicle present; leaves 5–10(–16.5) × 3–4(–7) cm, reticulation distinct; brachyblast silver or brown tomentellous, 6–10 mm long; connective appendage linguiform, 2–4 mm long; filaments 1.5–2 mm long; gynophore under fruit 5–8 mm long. ..... 19. *Michelia mediocris*
18. Pedicle absent; leaves 4–26 × 1.5–12.5 cm, reticulation rather obscure; brachyblast 3–6 or 13–25 mm long; connective appendage triangular, 0.5–1 mm long; filaments 1–6 mm long; gynophore under fruit 10–30 mm long. ..... 19
19(18). Gynophore 12–15 mm long; twigs tomentose; stipules silky; brachyblast 13–25 mm long; outer tepals 16–24 mm broad; stamens 17–20 mm long, filaments 4–6 mm long; gynoecium cylindric, 17–20 mm high; number of ovules per carpel 10; follicles hairy. ..... 10. *Michelia foveolata*
19. Gynophore 2–6 mm long; twigs puberulous; stipules pubescent; brachyblast 3–6 mm long; outer tepals 3–10 mm broad; stamens 2.5–7 mm long, filaments 1 mm long; gynoecium ovoid, 4–6 mm high; number of ovules per carpel 2–8; follicles glabrous. ..... 4. *Michelia compressa*
20(17). Leaves glaucous beneath; twigs villous, 5–7 mm diam.; stamens 17–22 mm long, filaments 4–6 mmm; gynoecium golden puberulent. ..... 13. *Michelia ingrata*
20. Leaves not glaucous beneath; twigs pubescent, tomentose, or tomentellous. ..... 21
21(20). Gynophore 10–15 mm long; stipules silky. 22
21. Gynophore 2–5 mm long; stipules pubescent or tomentellous. ..... 23
22(21). Filaments 3 mm long; twigs glabrous or pubescent; leaves minutely scattered hairy beneath, reticulation distinct, laxly netted; gynoecium 3–6 mm high; fruiting brachyblasts 5–7 cm long; follicles glabrous. ..... 17. *Michelia masticata*
22. Filaments 4–6 mm long; twigs tomentose; young leaves tomentose beneath, reticulation rather obscure, densely netted; gynoecium 17–20 mm high; fruiting brachyblasts 1.5–3 cm long; follicles hairy. ..... 10. *Michelia foveolata*
23(21). Leaves 6.5–14 × 4–6.5 cm; connective

appendage linguiform; twigs and stipules tomentellous; tepals 9–12, outer tepals 35–45 × 10–15 mm; gynoecium cylindric. ... 16. *Michelia macclurei*

23. Leaves (10–)12–20(–24) × 3.5–7 or 18–25 × 4–7.5 cm; connective appendage triangular; twigs pubescent or tomentose; stipules pubescent; tepals 9–12 or 13–17, outer tepals 32–36 × 10–12 or 45–70 × 20–25 mm; gynoecium ellipsoid. ... 24

24(23). Pairs of lateral nerves 11–15; twigs pubescent, 2–3 mm diam.; leaves finely appressed pubescent beneath, base cuneate or broadly cuneate; tepals 9–12, 45–70 × 20–25 mm; filaments 2–3 mm long; scars of perianth and stamens along torus under fruit 5–10 mm long. ... 2. *Michelia cavaleriei*

24. Pairs of lateral nerves 16–18; twigs tomentose, ca. 4 mm diam.; young leaves densely appressed tomentellous beneath, base rounded; tepals 13–17, the outer ones 32–45 × 10–12 mm; filaments 4 mm long; scars of perianth and stamens along torus under fruit 12–14 mm long. ... 1. *Michelia aenea*

25(10). Stamens 20–39 mm long. ... 26

25. Stamens 5–15 mm long. ... 27

26(25). Brachyblast 20–22 mm long; tree to 15 m high; twigs in innovations 8–12 mm thick; petiole dilated at base; stipular scars 7–10 mm long; brachyblast 10–12 mm thick; petiole absent; stamens 33–39 mm long, filaments 7–8 mm long; gynoecium shorter than androecium, often entirely hidden, 24 mm high; gynophore 6 mm long. ... 12. *Michelia fulva*

26. Brachyblast 30–35 mm long; treelet to 5–6 m high; twigs in innovations 2–3 mm thick; petiole not dilated at base; stipular scars 3–4 mm long; brachyblast 5–6 mm thick; petiole present; stamens 20–24 mm long, filaments 2–4 mm long; gynoecium longer than androecium, 15 mm high; gynophore 30 mm long. ... 7. *Michelia elliptilimba*

27(25). Outer tepals 10–30 mm broad. ... 28

27. Outer tepals 2.5–10 mm broad. ... 32

28(27). Pedicle present. ... 29

28. Pedicle absent. ... 30

29(28). Petiole hairy, 2.5–3 cm; stipular scars 15 mm long, leaf base cuneate, reticulation rather obscure; outer tepals 3; gynophore 4 mm long. ... 20. *Michelia microtricha*

29. Petiole 0.8–2.5 cm, glabrous; stipular scars 2–6 mm long; leaf base broadly cuneate or rounded; reticulation distinct; outer tepals 4 or 5, gynophore 5–12 mm long. ... 6. *Michelia doltsopa*

30(28). Connective appendage 2–4 mm long, narrowly triangular or linguiform; twigs sparsely minutely puberulous or tomentellous; leaves minutely appressed pubescent beneath, reticulation distinct; gynoecium 6–10 mm high; fruiting brachyblasts 5 mm thick. ... 14. *Michelia kisopa*

30. Connective appendage very short to long triangular, 0.5–3 mm; twigs pubescent or tomentose; young leaves densely or sparsely pubescent beneath, reticulation rather obscure; gynoecium 9–14 mm or 3–5 mm high; fruiting brachyblasts 2–4 mm thick. 31

31(30). Gynoecium ovoid to oblong, 3–5 mm high; petiole 3–5 mm long. ... 33. *Michelia yunnanensis*

31. Gynoecium cylindric, 9–14 mm high; petiole 9–25 mm long. ... 9. *Michelia floribunda*

32(27). Outer tepals 4–6. ... 33

32. Outer tepals 3. ... 34

33(32). Stipular scars 3–5 mm long; leaves elliptic or narrowly elliptic, reticulation rather obscure; brachyblast stout; gynoecium 9–15 mm high; gynophore 6–7 mm long. ... 22. *Michelia velutina*

33. Stipular scars 17–28 mm long; leaves ovate or narrowly ovate, reticulation distinct; brachyblast slender; gynoecium 7–12 mm high; gynophore 3–5 mm long. ... 3. *Michelia champaca*

34(32). Stipular scars 1–5 mm long. ... 35

34. Stipular scars 6–20 mm long. ... 36

35(34). Tepals 9–12; connective appendage ca. 0.5 mm long; stipules pubescent; fruiting brachyblasts 11 mm long and 8 mm thick; fruits 13.5–15.5 cm long; gynophore under fruit 20–25 mm long. ... 23. *Michelia wilsonii*

35. Tepals 12–15; connective appendage 1–3 mm; stipules tomentellous; fruiting brachyblasts 5–8 mm long and 3–4 mm thick; fruits 2.5–6 cm long; gynophore under fruit 10–15 mm long. ... 9. *Michelia floribunda*

36(34). Tepals 9, 15–20 × 5–7.5 mm; stamens 7.5–8.5 mm, connective appendage 0.5 mm; gynoecium ovoid, 3–4 mm, carpels 10–12; stipular scars 6–18 mm. ... 34. *Michelia odora*

36. Tepals 9–20, 19–50 × 6–23 mm; connective appendage 1–4 mm long; gynoecium ovoid or more often cylindric; carpels often more than 12; stipular scars 2–20 mm. ... 37

37(36). Stipular scars 14–20 mm; gynoecium 6–10 mm; tepals 9–15, 22–35 mm × 7–13 mm; connective appendage 2–4 mm. ... 14. *Michelia kisopa*

37. Stipular scars 2–4 mm; gynoecium 9–14 or 6–9 mm; tepals 12–20, 12–20 × 19–35 mm; connective appendage 1–3 mm. 38

38(37). Tepals 6–23 mm broad; gynoecium 9–14 mm; connective appendage 1–3 mm; stipular scars 2–14 mm. ... 9. *Michelia floribunda*

38. Tepals 2.5–7 mm broad; gynoecium 6–9 mm; connective appendage 1–2 mm; stipular scars 6–10 mm. ... 35. *Michelia baillonii*

## Key to the Species of *Michelia*
(primarily based on fruit characters)

1. Fruits with connate carpels, when mature the apical parts of the carpels falling, dehiscing along the dorsal suture or not, the basal parts remaining adnate to the torus, or apical parts falling in irregular masses. 2

1. Fruits consisting of free carpels, which dehisce along the dorsal suture, main nerve often persistent. ..... 3
2(1). Reticulation densely netted; fruits 3–9 cm long and 2.5–4.5 cm broad. ..... 35. *Michelia baillonii*
2. Reticulation laxly netted; fruits 13–16 cm long and 7–9 cm broad. .. 34. *Michelia odora*
3(1). Stipules adnate to the petiole. ..... 4
3. Stipules free. ..... 17
4(3). Stipular scars 11–28 mm long. ..... 5
4. Stipular scars 1–10 mm long. ..... 8
5(4). Pedicle present, at least 3 mm long; leaves elliptic or narrowly obovate, reticulation rather obscure; twigs tomentellous. ..... 20. *Michelia microtricha*
5. Pedicle absent or very short. ..... 6
6(5). Leaves minutely appressed pubescent, glabrescent beneath; twigs puberulous or tomentellous; fruiting brachyblasts 7 × 5 mm; follicles 8–14 × 7–10 mm. ..... 14. *Michelia kisopa*
6. Young leaves tomentose or pubescent beneath; twigs pubescent or tomentose; fruiting brachyblast 5–30 × 3–5 mm; follicles 7–20 × 7–14 mm. ..... 7
7(6). Leaves 1–5 cm broad; reticulation rather obscure; twigs tomentose; stipules tomentellous; fruiting brachyblast 5–8 mm long. ..... 9. *Michelia floribunda*
7. Leaves 3.4–12 cm broad; reticulation distinct; twigs and stipules pubescent; fruiting brachyblast 10–30 mm long. ..... 3. *Michelia champaca*
8(4). Petiole 2–5 mm (*Michelia yunnanensis* with very short petiole is also possible here). 9
8. Petiole 5.1–30 mm. ..... 10
9(8). Shrub to 2–5 m high; flower purple or red; fruiting brachyblast 10–20 × 3–5 mm. ..... 32b. *Michelia figo* var. *crassipes*
9. Shrub or treelet to 15 m high; flower white or yellow; fruiting brachyblast 7–25 × 2–4 mm. ..... 32a. *Michelia figo* var. *figo*
10(8). Pedicle present. ..... 11
10. Pedicle absent. ..... 13
11(10). Treelet to 5 or 6 m high; twigs silky, 2–3 mm diam.; stipules silky; leaves 16–22 × 7.5–10 cm, nerves in 9–14 pairs; petiole 2–2.5 cm; brachyblast 30–35 mm long; outer tepals 3; stamens 20–24 mm long; gynophore 30 mm long. ..... 7. *Michelia elliptilimba*
11. Tree to 15–30 m high; twigs pubescent or tomentellous; stipules pubescent or tomentellous; brachyblast 4–17 mm long; leaves 9–22 × 4–8 or 11–24 × 3.5–6.5(–8.5) cm, nerves 10–28 pairs; petiole 0.8–2.5 cm; outer tepals 4–6; stamens 8–15 mm long; gynophore 5–12 mm long. ..... 12
12(11). Scars of perianth and stamens along torus under fruit 5 mm long; twigs and stipules pubescent; reticulation of leaf rather obscure; petiole hairy. ..... 22. *Michelia velutina*
12. Scars of perianth and stamens along torus under fruit 7–10 mm long; twigs sparsely tomentellous; stipules tomentellous; reticulation distinct; petiole glabrous. ..... 6. *Michelia doltsopa*
13(10). Fruiting brachyblasts 2–4 mm thick. ..... 14
13. Fruiting brachyblasts 5–12 mm thick. ..... 15
14(13). Shrub or small tree 6–12 m; petiole 5–10 mm; stipular scar 3–7 mm; nerves in 7–9 pairs. ..... 33. *Michelia yunnanensis*
14. Tree to 28 m high; petiole 9–25 mm; stipular scar 2–14 mm; nerves in 8–14 pairs. ..... 9. *Michelia floribunda*
15(13). Young twigs 8–12 mm thick; stipules hispid; reticulation of leaf distinct; stipular scars 7–10 mm long; scars of perianth and stamens along torus under fruit 10 mm long. ..... 12. *Michelia fulva*
15. Young twigs 1–3 mm thick; stipules pubescent; reticulation rather obscure; stipular scars 1–5 mm long; scars of perianth and stamens along torus under fruit 2–5 mm long. ..... 16
16(15). Leaves glaucous beneath; twigs glabrous to tomentose; fruits 13.5–15.5 cm. ..... 23. *Michelia wilsonii*
16. Leaves not glaucous beneath; twigs pubescent; fruits 3.5–13 cm long. ..... 22. *Michelia velutina*
17(3). Leaves glabrous. ..... 18
17. Leaves hairy beneath at least when young. 25
18(17). Gynophore under fruit 2–3 mm long; midrib prominent above, at least toward base; fruits 3.5–4 cm long; follicles 2–4.5 × 1–2.5 cm with a stipe of 3–8 mm. ..... 25. *Michelia hypolampra*
18. Gynophore under fruit 8–30 mm long; midrib not prominent above. ..... 19
19(18). Leaves glaucous beneath; stipules silky; twigs 5–7 mm diam.; fruits 6–10 cm long; follicles sessile, 9–14 × 7–10 mm. ..... 13. *Michelia ingrata*
19. Leaves not glaucous beneath; stipules glabrous, pubescent, puberulous, or tomentellous. ..... 20
20(19). Scars of perianth and stamens along torus under fruit 20–22 mm long; fruits 7–10 cm long; twigs 4–6(–10) mm diam. ..... 15. *Michelia lacei*
20. Scars of perianth and stamens along torus under fruit 2–8 mm long. ..... 21
21(22). Plant entirely glabrous; twigs 2–3 mm diam.; leaves 9.5–17.5 × 3–7 cm; nerves in 7–12 pairs; petiole 1–3 cm; fruit 10–14 cm long; brachyblast 17–30 mm. ..... 18. *Michelia maudiae*
21. Plant hairy at least in innovations; brachyblast hairy. ..... 22
22(21). Reticulation rather obscure; twigs 1–2 mm diam.; leaves 4–12 × 1.5–3.5 cm; nerves in 8–15 pairs; fruits 5–7 cm long; brachyblast 3–8 mm long. .... 4. *Michelia compressa*
22. Reticulation distinct; twigs 2–7 mm diam.; leaves 5.5–18 × 2–6.5 cm; fruits 3–10 cm; brachyblast 6–25 mm. ..... 23
23(22). Twigs glabrous, sometimes pubescent, 2–4 mm diam.; stipules pubescent; fruits 6.5–

10 cm long; brachyblasts 13–14 × 4–9 mm. ..... 30. *Michelia martinii*
23. Twigs puberulous or tomentellous; stipules glabrous, puberulous, or tomentellous, leaf base cuneate or rounded. ..... 24
24(23). Reticulation of leaf laxly netted; twigs tomentellous; petiole not dilated at base; fruits 3–10 cm long; brachyblast 6–12 mm long; follicles 6–15 × 8–10 mm. ..... 28. *Michelia chapensis*
24. Reticulation of leaf densely netted; twigs puberulous; petiole dilated at base; fruit 3–6 cm long; brachyblast 8–25 mm long; follicles 18–25 × 12–17 mm. ..... 5. *Michelia coriacea*
25(17). leaves glaucous beneath. 13. *Michelia ingrata*
25. Leaves not glaucous beneath. ..... 26
26(25). Pedicle present. ..... 27
26. Pedicle absent. ..... 32
27(26). Leaves 1.5–2.5 cm broad, apex rounded. ..... 26. *Michelia angustioblonga*
27. Leaves 2.8–7.5 cm broad, apex acuminate or acute. ..... 28
28(27). Pairs of lateral nerves 16–18; twigs tomentose; scars of perianth and stamens along torus under fruit 12–14 mm long. ..... 1. *Michelia aenea*
28. Pairs of lateral nerves 9–15; twigs pubescent or tomentellous; scars of perianth and stamens along torus under fruit 3–10 mm long. ..... 29
29(28). Fruiting brachyblasts 3 cm long; twigs tomentellous; stipules glabrous or tomentellous; young leaves rufous pubescent beneath, apex acuminate or acute, reticulation rather obscure; pedicle 4–6 mm, tepals 6, gynoecium cylindric. 29. *Michelia leveilleana*
29. Fruiting brachyblasts 1–2.5 cm long. ..... 30
30(29). Twigs pubescent; stipules pubescent; leaves obovate or narrowly elliptic, 12–20 × 3.5–5.5 cm; petiole 1.5–3 cm; fruit 5–15 cm; gynophore 10–25 mm. 2. *Michelia cavaleriei*
30. Twigs tomentellous; stipules tomentellous; leaves elliptic or ovate, 5–14 × 3–6.5 cm; fruits 2–5 cm long; gynophore 5–10 mm. 31
31(30). Carpels 13–18; leaves 6.5–10 × 3–4 cm; petiole 1.5–2.5 cm. ... 19. *Michelia mediocris*
31. Carpels 28; leaves 6.5–14 × 4–6.5 cm; petiole 2.5–4 cm. ..... 16. *Michelia macclurei*
32(26). Leaves 1.5–2.5 cm broad. ..... 33
32. Leaves 2.6–16.5 cm broad. ..... 34
33(32). Apex of leaf rounded, reticulation distinct; treelet to 4 m high; leaves narrowly oblong, 6.5–10 × 1.5–2.5 cm; petiole 10–15 cm. ..... 26. *Michelia angustioblonga*
33. Leaves (narrowly) elliptic, 4–12 × 1.5–3.5 cm, apex acuminate or acute, reticulation rather obscure; petiole 5–22 mm. ... 4. *Michelia compressa*
34(32). Pairs of lateral nerves 16–19. ..... 35
34. Pairs of lateral nerves 8–15. ..... 37
35(34). Twigs pubescent, 2–5 mm diam.; leaves 8–28 × 4.5–10.5 cm, reticulation laxly netted; petiole 19–45 mm; nerves in 12–14 pairs; follicles 20–65 × 13–18 mm. ..... 27. *Michelia balansae*
35. Twigs tomentose; reticulation of leaf densely netted, nerves in 16–18 pairs; follicles 14–25 × 10–15 or 8–22 × 7–14 mm. 36
36(35). Scars of perianth and stamens along torus under fruit 5–7 mm long; stipules silky; reticulation of leaf rather obscure; follicles hairy. ..... 10. *Michelia foveolata*
36. Scars of perianth and stamens along torus under fruit 12–14 mm long; stipules pubescent; reticulation of leaf distinct; follicles glabrous. ..... 1. *Michelia aenea*
37(34). Twigs puberulous, 1–2 mm diam.; leaves 4–12 × 1.5–3.5 cm; fruits 5–7 cm. ..... 4. *Michelia compressa*
37. Twigs pubescent or tomentose. ..... 38
38(37). Twigs tomentose; leaf apex acuminate or acute, reticulation rather obscure; fruits 5.5–14 cm long; follicles 8–22 × 7–14 mm. ..... 10. *Michelia foveolata*
38. Twigs pubescent, leaf apex short-acuminate, reticulation distinct. ..... 39
39(38). Young leaves pubescent beneath, 8–28 × 4.5–16.5 cm; petiole dilated at base; fruits 4–12 cm long; follicles 2–6.5 × 1.3–1.8 cm. ..... 27. *Michelia balansae*
39. Leaves finely scattered appressed-pubescent beneath; petiole not dilated at base; fruits 5–53 cm long; follicles 6–14 or to 100. ..... 40
40(39). Reticulation of leaf laxly netted; stipules silky; fruit 10–53 cm long, follicles to 100. ..... 17. *Michelia masticata*
40. Reticulation of leaf densely netted; stipules pubescent; fruits 5–15 cm long, follicles 6–14. ..... 2. *Michelia cavaleriei*

**1. Michelia** section **Michelia.** *Michelia* L. *Champaca* Adans. *Sampacca* O. Kuntze.

*Liriopsis* Spach.

Stipules free from or adnate to the petiole. Bracts 2–6. Tepals 6–21, 3–6-merous, subsimilar or dissimilar with those of the outer whorl, smaller or thinner in texture than those of the inner whorl or whorls. Fruits apocarpous.

KEY TO THE SPECIES OF SECTION *MICHELIA*

1. Stipules adnate to petiole. ..... 2
1. Stipules free. ..... 10
2(1). Gynoecium shorter than androecium, often entirely hidden, twigs in innovations 8–12 mm thick, stipules (rufous) villous, stamens 33–39 mm long, filaments 7–8 mm long, gynoecium 24 mm high. ... 12. *Michelia fulva*
2. Gynoecium longer than androecium, twigs in innovations 1–3 mm thick, stipules pubescent, silky, or tomentellous, stamens 7–24 mm long, filaments 1–4 mm long, gynoecium 6–20 mm high. ..... 3
3(2). Leaves minutely (scattered) hairy beneath, connective appendage very long, narrowly triangular, or linguiform. 14. *Michelia kisopa*
3. Leaves with longer hairs beneath, connective appendage triangular. ..... 4

4(3). Gynophore 30 mm long, twigs silky, stipules silky, brachyblast 30–35 mm long, stamens 20–24 mm long. ... 7. *Michelia elliptilimba*

4. Gynophore 2–15 mm long, twigs pubescent, tomentose, or tomentellous, stipules pubescent or tomentellous, brachyblast 3–17 mm long, stamens 7–15 mm long. ... 5

5(4). Reticulation rather obscure. ... 6

5. Reticulation distinct. ... 8

6(5). Pedicle present, twigs tomentellous. ... 20. *Michelia microtricha*

6. Pedicle absent, twigs tomentose. ... 7

7(6). Stipules pubescent, leaf apex shortly acuminate, fruiting brachyblasts 11 cm long, 8 mm thick, fruits 13.5–15.5 cm long, gynophore under fruit 20–25 mm long. ... 23. *Michelia wilsonii*

7. Stipules tomentellous, leaf apex acuminate or acute, fruiting brachyblasts 0.5–0.8 cm long, 3–4 mm thick, fruits 2.5–6 cm long, gynophore under fruit 10–15 mm long. ... 9. *Michelia floribunda*

8(5). Outer tepals 14–30 mm broad, twigs and stipules tomentellous. ... 6. *Michelia doltsopa*

8. Outer tepals 7–9 mm broad, twigs and stipules pubescent. ... 9

9(8). Stipular scars 3–5 mm long, leaves elliptic or narrowly elliptic, brachyblast stout. ... 22. *Michelia velutina*

9. Stipular scars 17–28 mm long, leaves ovate or narrowly ovate, brachyblast slender. ... 3. *Michelia champaca*

10(1). Gynoecium glabrous. ... 11

10. Gynoecium hairy. ... 13

11(10). Plant entirely glabrous. 18. *Michelia maudiae*

11. Plant hairy at least in innovations, stipules pubescent or tomentellous. ... 12

12(11). Petiole 25–30 mm, twigs tomentose, stipules pubescent, reticulation laxly netted, petiole not dilated at base, brachyblast 15–25 mm long, outer tepals 5.5–7 cm long, 15–30 mm broad, stamens 20–25 mm long, gynoecium 17–20 mm high, gynophore 10–20 mm long, fruiting brachyblasts 5–10 mm thick, fruits 7–10 cm long, scars of perianth and stamens along torus under fruit 20–22 mm long, gynophore under fruit 29 mm long. ... 15. *Michelia lacei*

12. Petiole 10–20 mm, twigs puberulous, stipules tomentellous, reticulation densely netted, petiole dilated at base, brachyblast 2.5 mm long, outer tepals 2.3–3 cm long, outer tepals 8–10 mm broad, stamens 8–10 mm long, gynoecium 10–12 mm high, gynophore 2–7 mm long, fruiting brachyblasts 3–3.5 mm thick, fruits 3–6 cm long, scars of perianth and stamens along torus under fruit 4–6 mm long, gynophore under fruit 12–15 mm long. ... 5. *Michelia coriacea*

13(10). Gynophore 10–15 mm long. ... 14

13. Gynophore 2–6 mm long. ... 15

14(13). Gynoecium 3–6 mm high, twigs pubescent, leaves minutely (scattered) hairy beneath, apex shortly acuminate, reticulation distinct, laxly netted, filaments 3 mm long, fruiting brachyblasts 5–7 cm long, fruiting carpels glabrous. ... 17. *Michelia masticata*

14. Gynoecium 17–20 mm high, twigs tomentose, young leaves with longer hairs beneath, apex acuminate or acute, reticulation rather obscure, densely netted, filaments 4–6 mm long, fruiting brachyblasts 1.5–3 cm long, fruiting carpels hairy. ... 10. *Michelia foveolata*

15(13). Outer tepals 1–3 cm long. ... 16

15. Outer tepals 3.2–7 cm long. ... 17

16(15). Leaves minutely (scattered) hairy beneath, twigs and stipules tomentellous, reticulation distinct, pedicle present, connective appendage linguiform, 2–4 mm long, filaments 1.5 2 mm long, gynoecium cylindric, gynophore under fruit 5 8 mm long. ... 19. *Michelia mediocris*

16. Leaves with longer hairs beneath, twigs puberulous, stipules pubescent, reticulation rather obscure, pedicle absent, connective appendage triangular, 0.5–1 mm long, filaments 1 mm long, gynoecium ovoid, gynophore under fruit 10–17 mm long. ... 4. *Michelia compressa*

17(15). Leaves glaucous beneath, twigs villous, stipules silky, gynoecium 20 mm high. ... 13. *Michelia ingrata*

17. Leaves not glaucous beneath, twigs pubescent, tomentose, or tomentellous, stipules pubescent or tomentellous, gynoecium 6–13 mm high. ... 18

18(17). Pairs of lateral nerves 16–18, twigs tomentose, leaf base rounded, inner tepals 10–14, filaments 4 mm long, scars of perianth and stamens along torus under fruit 12–14 mm long. ... 1. *Michelia aenea*

18. Pairs of lateral nerves 10–15, twigs pubescent, or tomentellous, leaf base cuneate or broadly cuneate, inner tepals 6–9, filaments 1–3 mm long, scars of perianth and stamens along torus under fruit 4–7 mm long. ... 19

19(18). Leaves with longer hairs beneath, twigs and stipules tomentellous, leaves elliptic or ovate, outer tepals ovate or spathulate, connective appendage linguiform, gynoecium cylindric. ... 16. *Michelia macclurei*

19. Leaves minutely (scattered) hairy beneath, twigs and stipules pubescent, leaves obovate or narrowly elliptic, outer tepals obovate or elliptic, connective appendage triangular, gynoecium ellipsoid. ... 2. *Michelia cavaleriei*

1. **Michelia aenea** Dandy, J. Bot. 68: 211. 1930. TYPE: *Poilane 12611* (holotype, P; isotype, K).

*Michelia oblongifolia* Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 3: 86. 1987. TYPE: *B. L. Chen 86S193* (holotype, SYS).

*Michelia longistyla* Law & Y. F. Wu, Acta Bot. Yunnanica 10, 3: 341, t. 7. 1988. TYPE: China. Yunnan: Jinping, 1,800 m, *Q. Wang 142* (holotype, PE not seen).

Tree to 16 m high and 50 cm diam. Indument straight to slightly undulate, usually cupreous, sometimes clear to gray. Young twigs terete, ca.

4 mm diam., purplish brown, densely short-tomentose, glabrescent; old ones dull dark brown, somewhat rough, ± pubescent to glabrous, conspicuously lenticellate and fissured. Stipules densely long-pubescent, free from the petiole. Leaves coriaceous, rigidulous, bright green and glabrous above, pale green, densely appressed-tomentellous below, oblong to narrowly oblong, 18.7–25(–28.5) × 4–6(–7.5) cm; apex shortly acuminate to acute; acumen 3–18 mm; base rounded or obtuse to cuneate or narrowly cuneate; midrib impressed above, prominent below; nerves in 16–18 pairs, anastomosing and meeting in an intramarginal vein, which is slightly more prominent than the fine, densely netted reticulation, inconspicuous above, prominent below. Petiole appressed hairy, glabrescent, slightly thickened toward its base, without scars, 1.3–2.8 cm long. Brachyblasts stout, finely tomentose; spathaceous bracts 2, coriaceous, pubescent outside with same indument as stipules. Flowers white to yellowish; tepals 13–17, the outer 3 obovate, fleshy, 32–35 × 10–12 mm, the inner tepals 10–14, narrowly obovate to spathulate, 21–27 × 5–7 mm; stamens many, 13–16 mm long, connective appendage short-triangular, 0.5–2.5 mm long, filaments yellowish puberulent, ca. 4 mm long; gynoecium ellipsoid, tomentellous, exserted from the androecium, 8–13 mm long; gynophore 2–4 mm long; carpels many, ovoid; ovaries ca. 1 mm long; ovules 8–10; styles ca. 2 mm long. Fruiting brachyblasts pubescent, 3–3.5 cm long, ca. 5 mm wide at the top. Fruits cylindric, 6–10.5 cm long; ripe fertile carpels 4–25, obovoid to ellipsoid, sessile to short-stipitate, 1.4–2.5 × 1–1.5 cm, apically short-beaked; gynophore 1.8–2.5 × 0.4 cm; scars of perianth and stamens along the torus 12–14 × 6 mm. Seeds not seen.

*Distribution.* China and Vietnam. In CHINA. **southeastern Yunnan**: Jinping, Maguan, *Chen B.L. GS 302, Chen B.L. GS 86187.*

*Ecology.* In forests. Altitude: 1,800–1,950 m. Flowering April; fruiting September–October.

*Uses.* Wood very hard and dense, generally used for pillars, planks, and other purposes.

*Collector's note.* Bark rough, slightly brownish.

*Note.* The specimens examined are quite uniform in all characters. There was no material of *Michelia longistyla* available; it is reduced to *Michelia aenea* based on the published description and figure.

2. **Michelia cavaleriei** Finet & Gagnep., Bull. Soc. Bot. France 53: 573, f. 1–8 of t. 1. 1906. TYPE: *Cavalerie & Fortunat 2263* (holotype, P; isotypes, E, K).

*Michelia fallax* Dandy, Notes Roy. Bot. Gard. Edinburgh 16: 130. 1928. TYPE: *Hand.- Mazz. 12281* (holotype, W). [The flowering material collected by Wang Te-Hui is not *M. fallax.*]

*Michelia platypetala* Hand.-Mazz., Akad. Wiss. Wien Math.-Natuurwiss Kl. 58: 89. 1921. TYPE: *T. H. Wang in Hand.-Mazz. 12281* (holotype, W; isotypes, A, K, WU). [Only the flowering material is *M. platypetala.*]

Much branched tree 10–20 m high and 50 cm diam.; bark white-gray; buds, young twigs, stipules, petiole, brachyblasts, and bracts outside densely appressed-pubescent with fine, short to long, straight, clear to brown, glossy hairs; young twigs terete, dull black, 2–3 mm diam., later glabrescent; old ones brownish to brownish gray, smooth or longitudinally fissured, white lenticellate, glabrous to ± pubescent; terminal buds narrowly ovoid, 1–2 cm long. Stipules free from the petiole. Leaves thinly coriaceous, dark green, sparsely scattered-pubescent with short or long, straight or sometimes undulate, clear or brown hairs above, pale green, finely appressed-pubescent with short, straight, clear and brownish hairs, except the midrib beneath soon glabrescent, narrowly elliptic or obovate-elliptic, (10–)12–20(–24) × 3.5–5.5(–7) cm; apex short-acuminate, acumen 7–20 mm long; base cuneate to broadly cuneate; midrib conspicuously prominent below, ± impressed above; nerves fine, visible on both sides, in 11–15 pairs, reticulation fine, closely netted. Petiole ca. 1.5–3 cm long, without stipular scars. Flower buds narrowly ovoid, 2–3 cm long; brachyblasts 5–15(–25) mm long, 3–5 mm wide at the top, pedicles 0–2 mm long; bracts 3–4. Tepals 9–12, white, the outer 3–4, obovate-elliptic, 4.5–5.6(–7) × 2–2.5 cm, the inner tepals narrowly obovate to spathulate; stamens 7–15 mm long, connective appendage triangular, ca. 1 mm long, filaments 2–3 mm long, ca. 1 mm wide; gynoecium ellipsoid, tomentellous, 6–10 mm long, slightly protruding from the androecium; gynophore tomentellous, 4–5 mm long, ovaries ovoid, 1.5–2.5 mm long; ovules ca. 10; styles glabrous, 1.5–3 mm long. Fruits 5–15 cm long; ripe carpels 6–14 (some carpels abortive), ovoid to obovoid, dark brown, smooth to lenticellate, short-stipitate to sessile, with short beaks at the apex, 13–25 × 7–13 mm; gynophore 10–25 × 2–3 mm; torus with the scars of perianth and stamens 5–7 × 5–6 mm. Seeds 1–4 in each carpel, ellipsoid to subcordate, 5–9 × 6–8 mm.

*Michelia pubinervia* Blume, Fl. Javae Magnoliaceae: 14, t. 4. 1829. *Michelia rufinervis* Blume, Bijdr.: 8. 1825, non *Michelia rufinervis* DC., 1817. *Michelia champacca* var. *pubinervia* (Blume) Miq., Ann. Mus. Bot. Lugduno-Batavum 4: 72. 1868. TYPE: *Blume 670* (holotype, L; isotypes, B, K).

*Talauma villosa* Miq. forma *celebica* Miq., Ann. Mus. Bot. Lugduno-Batavum 4: 70. 1868. TYPE: *De Vriese & Teijsmann s.n.* (holotype, BO).

*Magnolia champaca* Baillon ex Pierre, F. Forest. Cochinch.: t. 3. 1880. TYPE: *Herb. Pierre 187.* (?)

*Magnolia membranacea* P. Parm., Bull. Sci. France Belgique 27: 200, 258. 1895. SYNTYPES: Mauritius, *Sieber III* (K, L, MEL), *Sieber 156* (MEL, P), locality unknown, *D.J. Anderson*, 1868 (MEL).

Tree to 30–40 m high and 1 m diam.; indument composed of short, straight or slightly undulate, appressed or erect, clear to yellow, rarely brownish hairs; young twigs 2–3 mm diam., brown-gray, pubescent, glabrescent; old ones gray to black-brown, ± lenticellate. Stipules pubescent, adnate to the petiole from about half of its length to nearly to the top, scars 1.7–2.8 cm long. Leaves thinly coriaceous, green, above glabrous, or at first especially on the midrib sparsely pubescent, later glabrescent, beneath paler green, pubescent, glabrescent, ovate-oblong to narrowly ovate, 8–23(–34) × 3.4–9(–12) cm; apex acute to gradually long-acuminate; base attenuate to cuneate or more often rounded; midrib ± impressed above, prominent below, nerves fine, visible on both sides, more prominent below than above, in 11–22 pairs. Petiole pubescent, glabrescent, 2–3.2(–4.5) cm long. Flowers very fragrant; bud ovoid to ovoid-ellipsoid; bracts 3 or more rarely 4, tomentellous or pubescent outside; brachyblast usually slender, 7–12 × 2–3 mm, tomentose or densely pubescent, pedicles 0–1 mm long. Tepals 12–15(–21), yellow to orange, subsimilar, glabrous or pubescent outside at the base; the outer 4–6 narrowly obovate, narrowly obovate-linear, to spathulate, 20–40 × 7–9 mm; stamens 7.5–8 mm long, connective appendage short-triangular, 0.5–1 mm long, filaments 1.5–2 mm long; gynoecium ovoid-cylindric, 7–12 mm long; gynophore tomentellous, 3–5 mm long; carpels ca. 30, tomentellous; scars of perianth and stamens along torus 1–2 mm long. Fruiting brachyblast glabrescent, gray-brown, 10–30 × 3–5 mm. Fruit 2–15 cm long; ripe carpels 4–19 or more, ovoid to ellipsoid, densely lenticellate, glabrescent, 10–20 × 7–11 mm, sessile and without a beak. Seeds subcordate, ellipsoid to irregularly shaped, 9–10 × 6–8 mm, 2–4 in each carpel.

*Distribution.* India, China, Burma, Vietnam, and Malesia. In CHINA. **Southern and southwestern Yunnan**: Che-li Hsien, *Wang C.W. 77767*; Fo Hai, *Wang C.W. 73905*; Jengyueh, 25°N, 98°36′E, *Forrest G. 25302.* Southeastern Xizang. Cultivated in Guangdong, Hainan, and Giangxi.

*Ecology.* In forests. Altitude: 650–1,600 m. Flowering June–July; fruiting September–October.

*Uses.* Wood used for furniture and ships; the flowers and leaves are extracted for volatile oil; the tree is grown as an ornamental.

*Collector's note.* Flowers ivory yellow to yellow, strongly fragrant.

*Note.* De Candolle (1817, 1824), Decaisne (1835), Spanoghe (1841), Moritzi in Zollinger

(1846), and Miquel (1858) misspelled the name as *Michelia tsiampacca* (auct. non L., 1797).

For further misapplied names and nomina nuda see Nooteboom (1985).

4. **Michelia compressa** (Maxim.) Sarg., Forest Fl. Japan. 4: 75, 77, t. 13. 1893. *Magnolia compressa* Maxim., Bull. Acad. Imp. Sci. Saint-Petersbourg 17: 417. 1872. TYPE: Yagami, near Nagasaki, Hizen Prov., Kiushu, *Maximowicz*, 1862 (holotype,?; isotype, BM).

*Magnolia philippinensis* P. Parm., Bull. Sci. France Belgique (Parmentier) 27: 206, 270. 1895. *Michelia philippinensis* (P. Parm.) Dandy, Kew Bull. 1927: 263. 1927. *Michelia cumingii* Merr. & Rolfe, Philipp. J. Sci. 3 Bot.: 100. 1908. TYPE: *Cuming 783* (holotype, MEL; isotypes, A, BM, K, L, NY).
*Michelia compressa* var. *formosa* Kanehira, Trans. Nat. Hist. Soc. Taiwan 20: 384. 1930. *Michelia formosana* (Kanehira) Masamune & Suzuki, Annual Rep. Taihchu Bot. Gard. 3: 57. 1933. *Michelia taiwaniana* Y. W. Law, Iconogr. Cormoph. Sinicorum 1: 796, t. 1592. 1972, nomen illeg. *Michelia iteophylla* C. Y. Wu ex Law & Y. F. Wu, Acta Bot. Yunnanica 10, 3: 337, t. 7. 1988. TYPE: *Lo 1359* (holotype, KUN).

Small tree, 8–12 m high; young twigs terete, slender, 1–2 mm diam., dull brownish to dark black-brown, smooth and appressed-puberulent with short, straight, clear, brown to rufous hairs; old ones purple-brown, glabrescent, sparsely lenticellate; terminal buds obovoid to cylindric, 8–11 mm long, densely appressed-pubescent with gray or rufous, glistening hairs. Stipules pubescent, free from the petiole. Leaves chartaceous to coriaceous, glabrous on both surfaces, or at first sparsely pubescent with long, straight and slightly undulate hairs on both sides, or below, especially on the midrib and toward the base, densely hairy with long, straight, erect, rufous hairs, finally glabrescent, elliptic to narrowly elliptic, 4–12 × 1.5–3.5 cm; apex acute to acuminate, acumen 1–15 mm long, sometimes obtuse and occasionally slightly emarginate, base cuneate, rarely obtuse and often slightly unequal; midrib slightly impressed above; nerves in 8–15 pairs, obscure, slightly more prominent than the rather fine reticulation below, reticulation densely netted. Petiole slender, glabrous or with same indument as young twigs, without stipular scars, 5–22 mm long. Brachyblast tomentellous with gray to brown hairs, 3–6 × 1.5–3 mm, pedicle absent; bracts 2–3, pubescent outside as are terminal buds. Flower white to creamy yellow, much scented; tepals 9(–14), subsimilar, the outer 3 oblanceolate to oblanceolate-linear, mostly broader than the inner tepals, 10–28 × 3–10 mm; stamens many, 2.5–7 mm long, connective appendage triangular, 0.5–1 mm long, filaments ca. 1 mm long; gynoecium ovoid to ovoid-oblong, tomentellous, 4–6 mm long, much longer than the androecium; gynophore with same indument as gynoecium, 2–6 mm long; carpels 5–13 or more, ovaries ca. 1.8 mm long; styles ca. 0.2 mm long; ovules 2–8. Fruiting brachyblast gray hairy, 3–8 × 1.5–8 mm. Fruit 5–7 cm long; ripe carpels 1–12 or more, ovoid to ellipsoid, dark brown, sessile or with a ca. 2–9-mm-long stipe, sparsely white-lenticellate, apically short-beaked, 11–15 × 8–14 mm; gynophore ± pubescent, 10–17 × 2–4 mm; torus with the scars of perianth and stamens, 2–3 × 2.5–6 mm. Seeds 1–2, subcordate, ellipsoid to irregularly shaped, 7–9 × 6–7 mm.

*Distribution.* China, the Philippines, and southern Japan. In CHINA. **Taiwan**: Taihokushy, *Sasaki S. 93*; Taipei, Kankou, *Hsu C.C. & M.T. Kao K 3680*; Bon Bon, I Lan, *Liao Jih-Ching 10006*; Botel Tobago, *Chang C.E. 3651*; Henchun Peninsula, *Chang C.E. 3289*. Also eastern and southern Yunnan.

*Ecology.* In forest. Altitude: 200–2,600 m. Flowering, fruiting January.

*Uses.* Wood straight-grained, fine-textured, heavy and hard, used for building, furniture, ships, woodcarving, and other purposes.

*Note.* After comparative studies of collections of all the cited synonyms from Japan, China, and the Philippines, we came to the conclusion that they all belong to a single species: *Michelia compressa* is the most widely distributed species of the genus.

It is noteworthy that *Michelia compressa* shows much variation throughout its area in size of the flowers, number of carpels and ovules, as well as length of the stipe of the ripe carpels. The flowers are smaller in the specimens of the Philippines, larger in Taiwan and Japan. Both carpels and ovules from Taiwan and Japan are slightly more in number than from the Philippines. The length of the stipe of the follicles varies from 0 to 8 mm. These variations can be observed even in the same specimen.

Gagnepain (1929) named this species *Michelia figo* (auct. non Loureiro, 1790). Merrill (1906) used the name *Michelia parviflora* (non DC., 1817).

5. **Michelia coriacea** Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni 3: 89. July 1988. TYPE: *B. L. Chen & B. Li GS 9035* (holotype, SYS). Figure 9.

FIGURE 9. *Michelia coriacea* Chang & B. L. Chen.—1. Fruiting branch.—2. Seed.—3. Seeds with testa removed. Based on *SYS 161742 = Chen Bao Liang GS 9035*. Drawing by Xie Qing Jian.

FIGURE 10. *Michelia doltsopa* Buch.-Ham. ex DC.—1. Fruiting branch.—2. Flower. Based on *SYS 161753* = *Chen Bao Liang 86 S 049*. Drawing by Xie Qing Jian.

*Michelia polyneura* C. Y. Wu ex Law & Y. F. Wu, Acta Bot. Yunnanica 10(3): 340, f. 1–8 of t. 5. Aug. 1988. TYPE: *K. M. Feng 12030* (holotype, KUN; isotype, A).

Tree 10–18 m high and 20–45 cm diam.; young twigs dull brown, 3–7 mm diam., ± gray puberulent; old ones dark brown, glabrescent, with sparse orbicular and white lenticels; terminal buds ovoid, densely tomentellous with short, straight, clear, gray to brownish hairs. Stipules with same indument as the terminal buds, free from the petiole. Leaves coriaceous, green, glossy above, pale green

beneath, both surfaces glabrous, oblong to broadly elliptic, sometimes obovate, often unequal, 9.7–13.9(–16.1) × 2.2–3.6(–6) cm; apex acute to acuminate, acumen 5–10 mm long, base cuneate or rounded; midrib slightly impressed above, rather prominent beneath; nerves in 12–13(–16) pairs, much visible on both sides, curved upward and meeting in an intramarginal vein, all lesser veins forming together a dense reticulation that is prominent on both surfaces, the larger alveoli filled with the smaller veins, which are obvious to obscured. Petiole glabrous, dilatate toward the base, 1–2 cm long. Brachyblast tomentose, 2.5 mm long (mature flowers not seen). Flower buds ellipsoid, tepals 9, white, subsimilar, obovate to narrowly obovate, 2.3–3 × 0.8–1 cm; stamens ca. 80, 8–10 mm long, connective appendage narrowly triangular, 1.5–2 mm long, filaments 2.5–3 mm; gynoecium glabrous, subcylindric, exserted from the androecium, 1–1.2 cm long; gynophore 2–7 mm long. Fruiting brachyblasts yellowish pubescent, with 3 scars of bracts, 8–25 × 3–3.5 mm, pedicles absent or very short, ca. 1.5–2 mm long if present. Fruits 3–6 cm long with 1–4(–10) fertile carpels and 6–8(–17) abortive carpels, the ripe carpels sessile, ovoid, dull and dark brown, conspicuously lenticellate, 18–25 × 12–17 mm; gynophore 1.2–1.5 cm long, scars of perianth and stamens along 4–6 mm of the torus. Seeds ellipsoid, smooth, 10–11 × 6–7 mm.

*Distribution.* CHINA. **Southeastern Yunnan**: Guangnan, *Wang C.W. 88023*; Malipo, *86915*; Si Chour Hsien, *Feng K.M. 12030.*

*Ecology.* In forests, on limestone formations. Altitude: 1,450 m. Flowering April; fruiting September–October.

*Note.* The type of *Michelia coriacea* bears fruits. In the absence of flowers, we misrepresented the tepals as 6–7 in number, based on the faint scars of the perianth on the torus. The collections with flowers collected from the same tree one year later showed that the flower has 9 tepals.

6. **Michelia doltsopa** Buch.-Ham. ex DC., Syst. Nat. 1: 448. 1817. TYPE: *Buchanan-Hamilton s.n.* (holotype, BM). Figure 10.

*Michelia excelsa* (Wall.) Blume, Fl. Javae Magnoliaceae: 9. 1829. *Magnolia excelsa* Wall., Tent. Fl. Nepal.: 5, t. 2. 1824. *Sampacca excelsa* (Blume) Kuntze, Revis. Gen. Pl. 1: 6. 1891. TYPE: *Wallich 6494* (holotype, K; isotypes, BM, NY).

*Michelia calcuttensis* P. Parm., Bull. Sci. France Belgique (Parmentier) 27: 283. 1895. TYPE: Type specimen not traced. According to P. Parm., its label said: "Michelia ?Assam. ex herb. hort. bot. calcuttensis."

*Michelia manipurensis* G. Watt ex Brandis, Indian Trees: 8. 1906. TYPE: *G. Watt 6329* (K).

*Michelia wardii* Dandy, Kew Bull. 1929: 222. 1929. TYPE: *F. Kingdon Ward 8060* (holotype, K).

*Michelia opipara* Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 3: 90. 1987. TYPE: *B. L. Chen GS86237* (holotype, SYS).

Tree or rarely a shrub, to 30 m high; buds appressed-rufous or gray tomentellous, later glabrescent; young twigs 2.5–3 mm diam., sparsely tomentellous, glabrescent, brownish to dull black-brown. Stipules appressed-rufous or gray tomentellous, adnate to the petiole, scars 2–6(–20) mm long. Leaves chartaceous to thinly coriaceous, green, olive green to brown when dry, above scattered-pubescent with slender, straight to undulate, clear hairs, glabrescent, beneath pale green to glaucous, appressed-tomentose with short or long, straight to occasionally undulate, usually rufous, sometimes clear to brownish hairs, elliptic, oblong-elliptic, oblong to narrowly ovate-elliptic, usually ± unequal, 9–22 × 4–8 cm; apex acuminate or subacuminate, acumen 1–3 cm long, base broadly cuneate or rounded, the margin slightly wavy; midrib impressed above, prominent below, nerves prominent below, in 10–14 pairs, reticulation fine, densely netted. Petiole pubescent, glabrescent, 0.8–2.5 cm long. Brachyblasts densely appressed-rufous to gray tomentose, 4–13(–23) × 4–6 mm, pedicles 2–5 mm long; bracts 2–3(–5), densely rufous tomentose. Flowers with pleasant smell; buds ovoid to oblong, 4–5 cm long; tepals (8–)12–16, white to yellow, the outer 4–5 obovate to spathulate-obovate or oblanceolate, 3.7–7.5 × 1.4–3 cm, glabrous to pubescent outside toward the base; stamens 8–15 mm long, connective appendage short to long triangular, 1–3 mm long, filaments 2–3 mm long; gynoecium subcylindric, 1–2 cm long, exserted from stamens; gynophore 5–12 mm long, tomentellous; carpels many, subovoid, ca. 1.5 cm long, appressed-tomentellous; styles glabrous; scars of perianth and stamens on torus 4–6 mm long. Fruiting brachyblasts glabrous or ± pubescent, 9–13(–23) × 4–7 mm. Fruits (2–)5–12.5 cm long, some carpels abortive; ripe carpels sessile or substipitate, 10–15 × 8–12 mm; gynophore 10–22 × 2–4 mm, scars of perianth and stamens under fruit 7–10 × 4–7 mm. Seeds ovoid to ellipsoid, 8–11 × 8 mm.

*Distribution.* Nepal, Bhutan, northeastern India, China, and northern Burma. In CHINA. **Southern Xizang**: *Kingdon Ward F. 19299, 19211.* **Yunnan**: Shweli-Salwin divide, 24°20′, *Forrest G. 8949*; Jinping, *Sino-Rossica Yunnan Exped. 1532*; Mienning, Poshang, *Yu T.T. 18055*; Shange-pa, *Tsai H.T. 58995*; Shunning, Hila, Wumulung, *Yu T.T. 16662*; Taron-Taru divide, *Yu*

*T.T. 20866*; Yengyueh, 25°25′N, 98°30′E, *Forrest G. 26258*.

*Ecology.* In broad-leaved forest. Altitude: 1,600–2,400 m. Flowering April–May; , fruiting September–October.

*Uses.* Wood light, soft, fine-textured, very durable and easily workable; used for various objects of construction work and carpentry, as well as for planking, doors, window frames, and furniture.

*Collector's note.* Flowers pale yellow or white, fragrant.

*Note.* See Dandy (1927b). *Michelia opipara* is similar to *Michelia doltsopa* except for its gray to yellowish indument. The former name is therefore reduced to a synonym of the latter.

7. **Michelia elliptilimba** B. L. Chen & Nooteboom, sp. nov. TYPE: China. Yunnan: Meng-hua, Chukai, alt. 2,000 m, 12 May 1938, *T. T. Yü 15854* (holotype, A; isotypes, E, IBSC). Figure 11.

Arbor 5 ad 6 m alta, ramunculis, stipulis extra, foliis utrinque, petiolibus, brachyblastis, bracteis, gynophoris, ovariisque indumento pilis tenuibus parvis vel longis, undulatis, brunneis. Ramunculi 2–3 mm diametro. Stipulae petiolis 2–2.5 cm longis cicatricibus 3–4 mm longis adnatae. Folia elliptica ad ovato-elliptica 16 ad 22 cm longa, 7.5 ad 10 cm lata apicibus acutis vel acuminatis basibus obtusis glabrescentia, glaucescentia, nervis primariis 9–14 paribus dense reticulata. Brachiblasti 3 ad 3.5 cm longi cicatricibus bractearum 3 ad 4. Flores pedicello 5 ad 7 mm longo, tepalis exterioribus 3, obovatis, 5.5 ad 6.5 cm longis, tepalis interioribus 8, obovatis ad spathulatis, ca. 5.7 cm longis, staminibus 20 ad 24 mm longis, gynaecio cylindrico 15 mm longo gynophoro 30 mm longo et 6 mmm lato.

Tree 5–6 m high; bark greenish gray, smooth; young twigs, stipules outside, leaves on both sides, petioles, brachyblasts, bracts, gynophore, and ovaries covered with fine, short or long, undulate, brownish to brown hairs. Young twigs 2–3 mm diam., old ones ± hairy or glabrous; terminal buds ca. 15 mm long; stipules adnate to the lower bases of the petiole, stipular scars 3–4 mm long. Leaves thinly coriaceous, green above, glabrescent and becoming glaucous beneath, elliptic to ovate-elliptic, 16–22 × 7.5–10 cm; apex acute or acuminate, base obtuse; midrib impressed above, conspicuously prominent below, nerves visible on both sides, more prominent beneath than above, in 9–14 pairs, reticulation closely netted, prominent on both sides. Petiole 2–2.5 cm long. Flowers creamy white, with a pleasant scent; brachyblasts with 3–4 scars of bracts, 3–3.5 cm long, 5–6 mm wide at the base, pedicles 5–7 mm long; tepals 11–12, subsimilar, the outer 3 obovate, attenuate toward the base, short-clawed, 5.5–6.5 × 2.5–3 cm, the inner tepals 8, obovate to spathulate, ca. 5.7 × 1.5–2 cm; stamens 20–24 mm long, connective appendage triangular, ca. 0.5 mm long, filaments 2–4 mm long; gynoecium cylindric, much longer than the androecium, ca. 15 mm long; gynophore ca. 30 × 6 mm; carpels many, ovaries ovoid, 4–5 mm long; styles glabrous, 2.5–3 mm long. Fruits not seen.

*Distribution.* CHINA. **Yunnan**: Meng-hua, Chukai, *T. T. Yü 15854*.

*Note.* This species resembles *Michelia baillonii* in the vegetative characters except in its glaucous lower leaf surface. The flowers, however, are very similar in size and shape to those of *Michelia foveolata*. Only one collection available.

8. **Michelia flaviflora** Law & Y. F. Wu.

See under dubious species.

9. **Michelia floribunda** Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 46, f. b of t. 7. 1905. TYPE: *Bons d'Anty 30* (holotype, P; isotypes, K, E).

*Michelia kerrii* Craib, Kew Bull. 1922: 166. 1922. TYPE: *Kerr 4679* (holotype, K; isotypes, BM, K, P, UC).

Tree to 28 m high and 1 m diam.; bark gray; young twigs slender, 1.5–2 mm diam., brown or purple-brown to purple-black, at first tomentose with short or long, straight, glistening, brown, yellowish to gray hairs, soon glabrescent. Stipules appressed-tomentellous with same hairs as young twigs, adnate to the petiole, stipular scars 2–14 mm long, sometimes to 2.2 cm long. Leaves thinly coriaceous to coriaceous, dark green, glossy, at first sparsely appressed-pubescent with slender, clear hairs, especially on the midrib, later glabrescent above, glaucous or not, appressed-pubescent with long to rather long, straight, clear, brown, rarely dark brown hairs, glabrescent beneath, narrowly elliptic, narrowly obovate-elliptic, ovate-elliptic, oblong-elliptic to narrowly ovate; 6–14.5(–17) × 1–4.5(–5) cm; apex acute to acuminate, sometimes ± caudate, acumen 5–15 mm long, occasionally to 2 cm long, base cuneate or rounded; midrib impressed above, nerves fine, obscure on both sides, more prominent beneath than above, in 8–14 pairs, reticulation fine and dense, hardly visible on both sides. Petiole appressed-tomentellous or pubescent, 9–25(–40) mm long. Brachyblast covered with same indument as young

FIGURE 11. *Michelia elliptilimba* B. L. Chen & Noot.—1. Branch with deflorated flower.—2. Flower.—3. Stamen.—4. Follicle. Based on *T. T. Yü 15854* (A). Drawing by Joop Wessendorp, Rijksherbarium, Leiden.

twigs, 3–6(–8) × 2.5–4 mm, pedicle absent; bracts 3(–4), brown or silver sericeous outside. Flower bud ovoid to cylindric, 2–4.4 cm long; flower fragrant; tepals 12–15, outer tepals 3, white, subsimilar, glabrous to puberulent outside toward the base, spathulate, broadly obovate, obovate-linear, rarely narrowly rhombic, tapering toward the base, usually basally with short or long claw, 19–45(–50)

× 6–18(–23) mm; stamens 7–11 mm long, connective appendage short- or long-triangular, 1–3 mm long, filaments ca. 2 mm long; gynoecium cylindric, longer than the androecium, 9–14 mm long; gynophore brown to gray tomentellous, 3–15 mm long; carpels tomentellous; styles glabrous; ovules 3–8 in each carpel; torus with scars of perianth and stamens 2–6 × 3–5 mm. Fruiting brachyblast pubescent, 5–8 × 3–4 mm. Fruit 2.5–6 cm long, contorted; ripe carpels 1–14, subglobose, brown to dark brown, lenticellate, ± puberulent, apically beaked, 7–20 × 8–14 mm. Scars of perianth and stamens 3–5 × 3–4 mm. Gynophore under fruit pubescent, 1–1.5 cm. Seeds ellipsoid, cordate to irregularly shaped, 6–8 × 5–6 mm.

*Distribution.* China, Thailand, Vietnam, Laos, and Burma. In CHINA. **Guangxi**: Jinxiu Xian, *Da Yao Shan Exped. 10756.* **Hubei–Sichuan**: Metaseqoia area, *Hwa C.T. 503*, **Jiangxi**: *Gongda 740250.* **Guizhou**: Fan Ching Shan, *A.N. & Cheo, H.C. 870*; Yinkiang, *Tsiang Y. 7589.* **Sichuan**: Guan Xian, *Yi G.P. 76002*; Pei Pah, *Law Y.W. 306.* **Yunnan**: Ma Chang Kai valley, *Forrest G. 9460*; Mienning,Poshang, *Yu T.T. 17894*; Chen kang hsien, *Wang C.W. 72551*; Si Chou Hsien, *Wang C.W. 85542*; Tengyueh, *Rock J.F. 7933*; Szemao, *Rock J.F. 2766.*

*Ecology.* In forests. Altitude: 800–2,700 m. Flowering February–June; fruiting July–October.

*Collector's notes.* Flowers white to creamy yellow; fruits green, with red fleshy seeds.

*Note.* The ranges of both *Michelia doltsopa* and *Michelia floribunda* overlap in western Yunnan. Some collections are difficult to identify and probably are hybrids.

L. Diels. (1912, 1913) and Hu in Hu & Chun (1929 pro parte) erroneously dealt with this species under *Michelia wilsonii* (auct. non Finet & Gagnep. 1905). Craib (1925a) named it *Michelia manipurensis* [auct. non Watt ex Brandis. 1906: *Kerr 4926* (BM, E, K)].

10. **Michelia foveolata** Merr. ex Dandy, J. Bot. 66: 360. 1928. TYPE: *W. T. Tsang & K. C. Wong 2738* (in *C. C. C. 14599*) (holotype, UC; isotype, SYS).

*Michelia fulgens* Dandy, J. Bot. 68: 210. 1930. TYPE: *Poilane 7092* (holotype, P; isotype, K).

*Michelia foveolata* var. *cinerascens* Law & Y. F. Wu, Bull. Bot. Res. (China) 6, 2: 99. 1986. TYPE: China. Zhejiang: Qingyuan Xian, *X. Wu 7720* (holotype, IBSC not seen).

Tree to 45 m high and 90 cm diam.; bark pale gray or dark gray; young twigs yellow or brown, appressed-tomentose with short, straight, glossy, clear to yellowish or brown hairs; old ones purple-brown, ± pubescent, lenticellate. Stipules brown tomentose or sericeous, free from the petiole. Leaves coriaceous, rigid, above dark green, glossy, appressed-pubescent with slender, straight, brown (when young) to clear (when old) hairs, especially on the midrib, below appressed-tomentose with short, straight, silver to brown hairs, glabrescent, considerably variable in shape and size, narrowly to broadly obovate, obovate-elliptic, narrowly obovate-elliptic to elliptic-oblong, 9.5–26 × 4.5–12.5 cm; apex acute to acuminate, base cuneate or obtuse to rounded, sometimes nearly cordate, ± oblique; midrib impressed above, prominent beneath, nerves visible on both sides, in 12–16 pairs, reticulation dense, seemingly foveolate, obscure on both sides. Petiole tomentose, glabrescent, 1.5–3.5 cm long, without scars. Brachyblast tomentose with same indument as young twigs, 13–25 × 4–7 mm, pedicle absent; bracts 3–4(–5), densely brown sericeous outside. Flower bud oblong, ca. 3.7 cm long; flower fragrant; tepals 9–12, white or greenish white, subsimilar, broadly obovate to spathulate, 3–4.5 × 1.6–2.4 cm, pubescent toward the base; stamens 17–20 mm long, connective appendage rather short, ca. 0.5 mm long, filaments 4–6 mm long; gynoecium cylindric, exserted from stamens, 1.7–2 cm long; gynophore tomentose with silver to yellow hairs, 1.2–1.5 × 0.2 cm; carpels many, tomentose with the same hairs as gynophore; ovules 10 or more; scars of perianth and stamens along torus ca. 3 × 3 mm. Fruiting brachyblast 15–30 × 4–7 mm. Fruit 5.5–14 cm long; ripe carpels 2–12, subglobose, obovoid, black-brown, ± pubescent, lenticellate, stipitate to short-sessile, beaked, 8–22 × 7–14 mm; gynophore tomentose, 17–30 mm long; scars of perianth and stamens 5–7 × 4–5 mm. Seeds subglobose to ellipsoid, 7–8 × 5–7 mm.

*Distribution.* Vietnam, China. In CHINA. **Guangdong**: *Chun W.Y. 7179.* **Guangzhou**: Ah Po Shan, *Taam Y.W. 572*; Chang Ki Tong, Shi Shan, Yuyuen, *Kwok S.P. 80335*; Kook Kiang, *Ko S.P. 50410*; Lok Chong, *Tso C.L. 20354.* **Guangxi**: Dayao Shan, *Li Z.Q. 99*; Debao, *Li Z.T. 604032*; Jinxui Xian, *Da Yao Shan Exped. 11080*; Lingui, *Liang C.F. 31751*; Longshen, *Zhang, B.N. 406132.* **Guizhou**: Jiangkou Xian, *Sino-American Guizhou Bot. *Ecology.* In evergreen broad-leaved and mixed forest. Altitude: 500–1,800 m. Flowering March–April; fruiting September–November.

*Uses.* Wood straight-grained and fine-textured, suitable for building, furniture, and plywood.

*Collector's notes.* Fairly common, flowers white or yellow; fruits greenish, light gray, or purplish red.

*Note.* *Michelia foveolata* is a recognizable species. However, the shape and size of the leaves and color of the indument varies.

11. **Michelia fujianensis** Q. F. Zheng.

See under dubious species.

12. **Michelia fulva** Chang & B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 3: 87. 1987. TYPE: *B. L. Chen GL86-193* (holotype, SYS). Figure 12.

Tree to 15 m high and 15 cm diam.; buds, young twigs, stipules outside, leaves beneath, petiole, brachyblasts, and bracts outside densely appressed-hispid with short to long, straight to undulate, somewhat glistening, fulvous hairs; young twigs 8–12 mm diam., dull brown, rough; old ones provided with lenticels, longitudinally fissured. Stipules adnate to the base of the petiole, stipular scars 7–10 mm long. Leaves coriaceous, rigid, bright green, above glabrous to ± pubescent, below pale green to glaucous, glabrescent when old, elliptic, ovate, obovate to oblong, (14–)18–24(–29) × 7–10(–12) cm; apex acuminate to acute, base cuneate, sometimes rounded; midrib impressed above, much prominent beneath; nerves in 7–11(–14) pairs, meeting in a looped intramarginal vein; reticulation densely netted, both nerves and reticulation prominent on both sides. Petiole stout, dilatate toward the base, 2–3 cm long. Brachyblast 2–2.2 × 1–1.2 cm, pedicle absent; spathaceous bracts 2–3, broadly elliptic, ca. 52 × 21 mm. Flower bud long ovoid, ca. 3.7 × 2 cm; tepals 12–13, white, subsimilar, fleshy, obovate to elliptic, the inner tepals smaller than the 3 outer ones, 4.4–5.3 × 2–3 cm; stamens ca. 146, 33–39 mm long, filaments 7–8 mm, anthers 25–30 mm, connective appendage short-triangular, ca. 1 mm; gynoecium cylindric, ca. 24 mm long hidden within and much shorter than stamens; gynophore pubescent, ca. 6 mm long; carpels ca. 152, fulvous pubescent, ovaries 2–3 mm long; styles glabrous, 1–2.5 mm long, scars of perianth and stamens on torus ca. 10 mm long. Ripe carpels ovoid, sessile, 10–15 × 9–10 mm.

*Distribution.* CHINA. **Yunnan**: Maguan, *B. L. Chen GL86-193.*

*Ecology.* In forest on limestone formations. Altitude: 1,690 m. Flowering April.

*Collector's note.* The natural color of the tepals is not known precisely because the flowers collected seemed nearly dry.

*Note.* The distinguishing characters of this species are: plant covered with fulvous hispid hairs; leaves large and rigid, pale green to glaucous beneath; flowers quite big.

13. **Michelia ingrata** B. L. Chen & S. C. Yang, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 3: 95. July 1988. TYPE: *B. L. Chen & C. N. Mai 87 T 019* (holotype, SYS). Figure 13.

*Michelia calcicola* C. Y. Wu ex Law & Y. F. Wu, Acta Bot. Yunnanica 10, 3: 339, f. 9–16 of t. 5. Aug. 1988. TYPE: *C. W. Wang 87716* (holotype, KUN).

Tree to 16 m high and 40 cm diam. Young twigs dull brown, stout, 5–7 mm diam., villous with long, straight, crisped to undulate, brown to rufous hairs, soon glabrescent; old ones black-brown, fissured and lenticellate, ± hairy to glabrous; terminal buds narrowly ovoid, yellow to brown tomentose. Stipules coriaceous, pubescent with long silky hairs outside, free from the petiole. Leaves coriaceous, rigidulous, dark bright green, at first scattered-pubescent over both surfaces and pilose along the midrib, later glabrescent above, beneath glaucous, appressed-tomentose with same hairs as the young twigs, sooner glabrescent or only pubescent along midrib and nerves, or glabrous everywhere, elliptic to obovate, the margin slightly revolute and bony; 13–21.5(–24) × 4.5–9.5 cm; apex acute to short-acuminate, acumen 3–5 mm long, base cuneate to subrounded; midrib impressed above, prominent beneath; nerves in 12–14 pairs, visible on both sides, reticulation densely netted, prominent on both sides. Petiole pubescent, glabrescent, 2.7–4 cm long. Brachyblasts covered with same indument as young twigs, 3–4 × 0.6–0.8 cm, pedicles absent; spathaceous bracts 3, coriaceous, tomentose outside. Flower golden-yellow, malodorous; tepals 9–12, subsimilar, the outer 3 obovate, glabrous, ca. 5.7 × 3.5 cm, the inner tepals 6–9, narrowly elliptic to spathulate, 4–4.5 × 1.9–2.1 cm; stamens ca. 60 or more, 17–22 mm long, connective appendage triangular, 0.8–1 mm long, filaments 4–6 mm long; gynoecium cylindrical, golden puberulent, ca. 2 cm long, exserted from stamens; gynophore ca. 6 mm long; carpels ca. 63, ovate, 3–4 mm long; styles 1.5–3 mm long, glabrous.

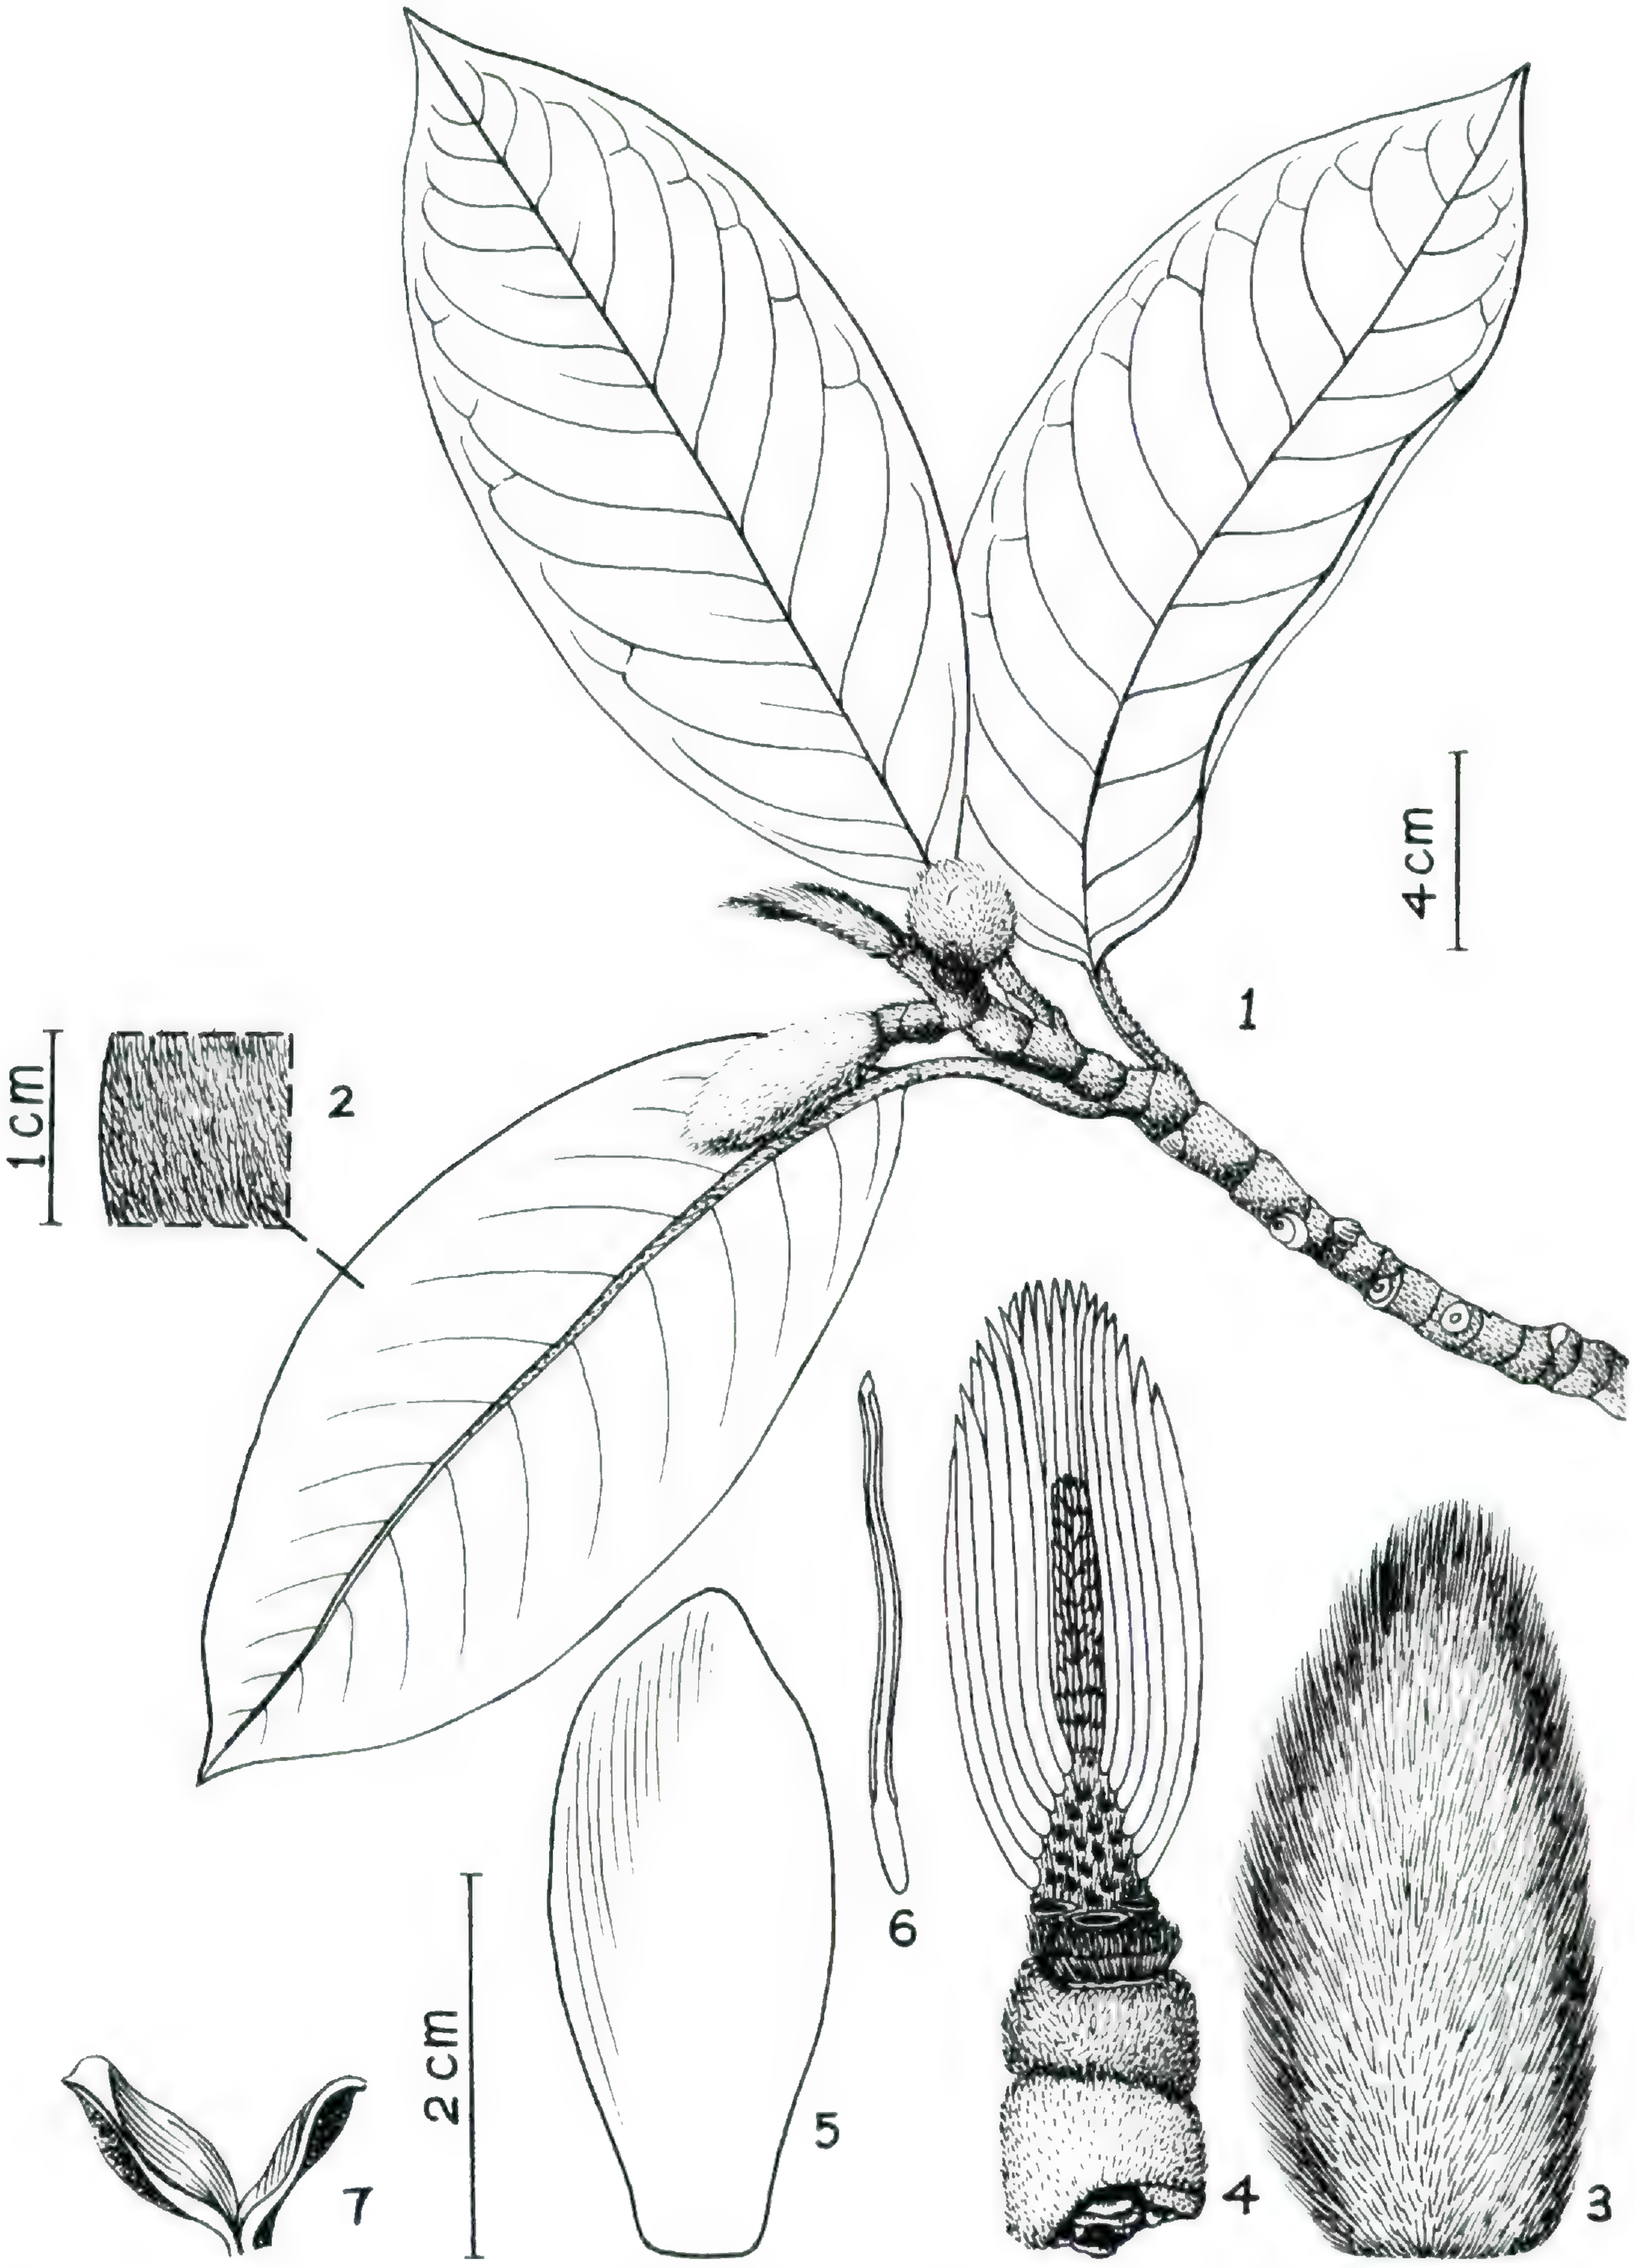

FIGURE 12. *Michelia fulva* H. T. Chang & B. L. Chen.—1. Flowering branch.—2. Underside of leaf.—3. Bract.—4. Deflorated flower with gynoecium and part of androecium.—5. Outer tepal.—6. Stamen.—7. Follicle. Based on *SYS 161751 = Chen Bao Liang G1 86-193*. Drawing by Xie Qing Jian.

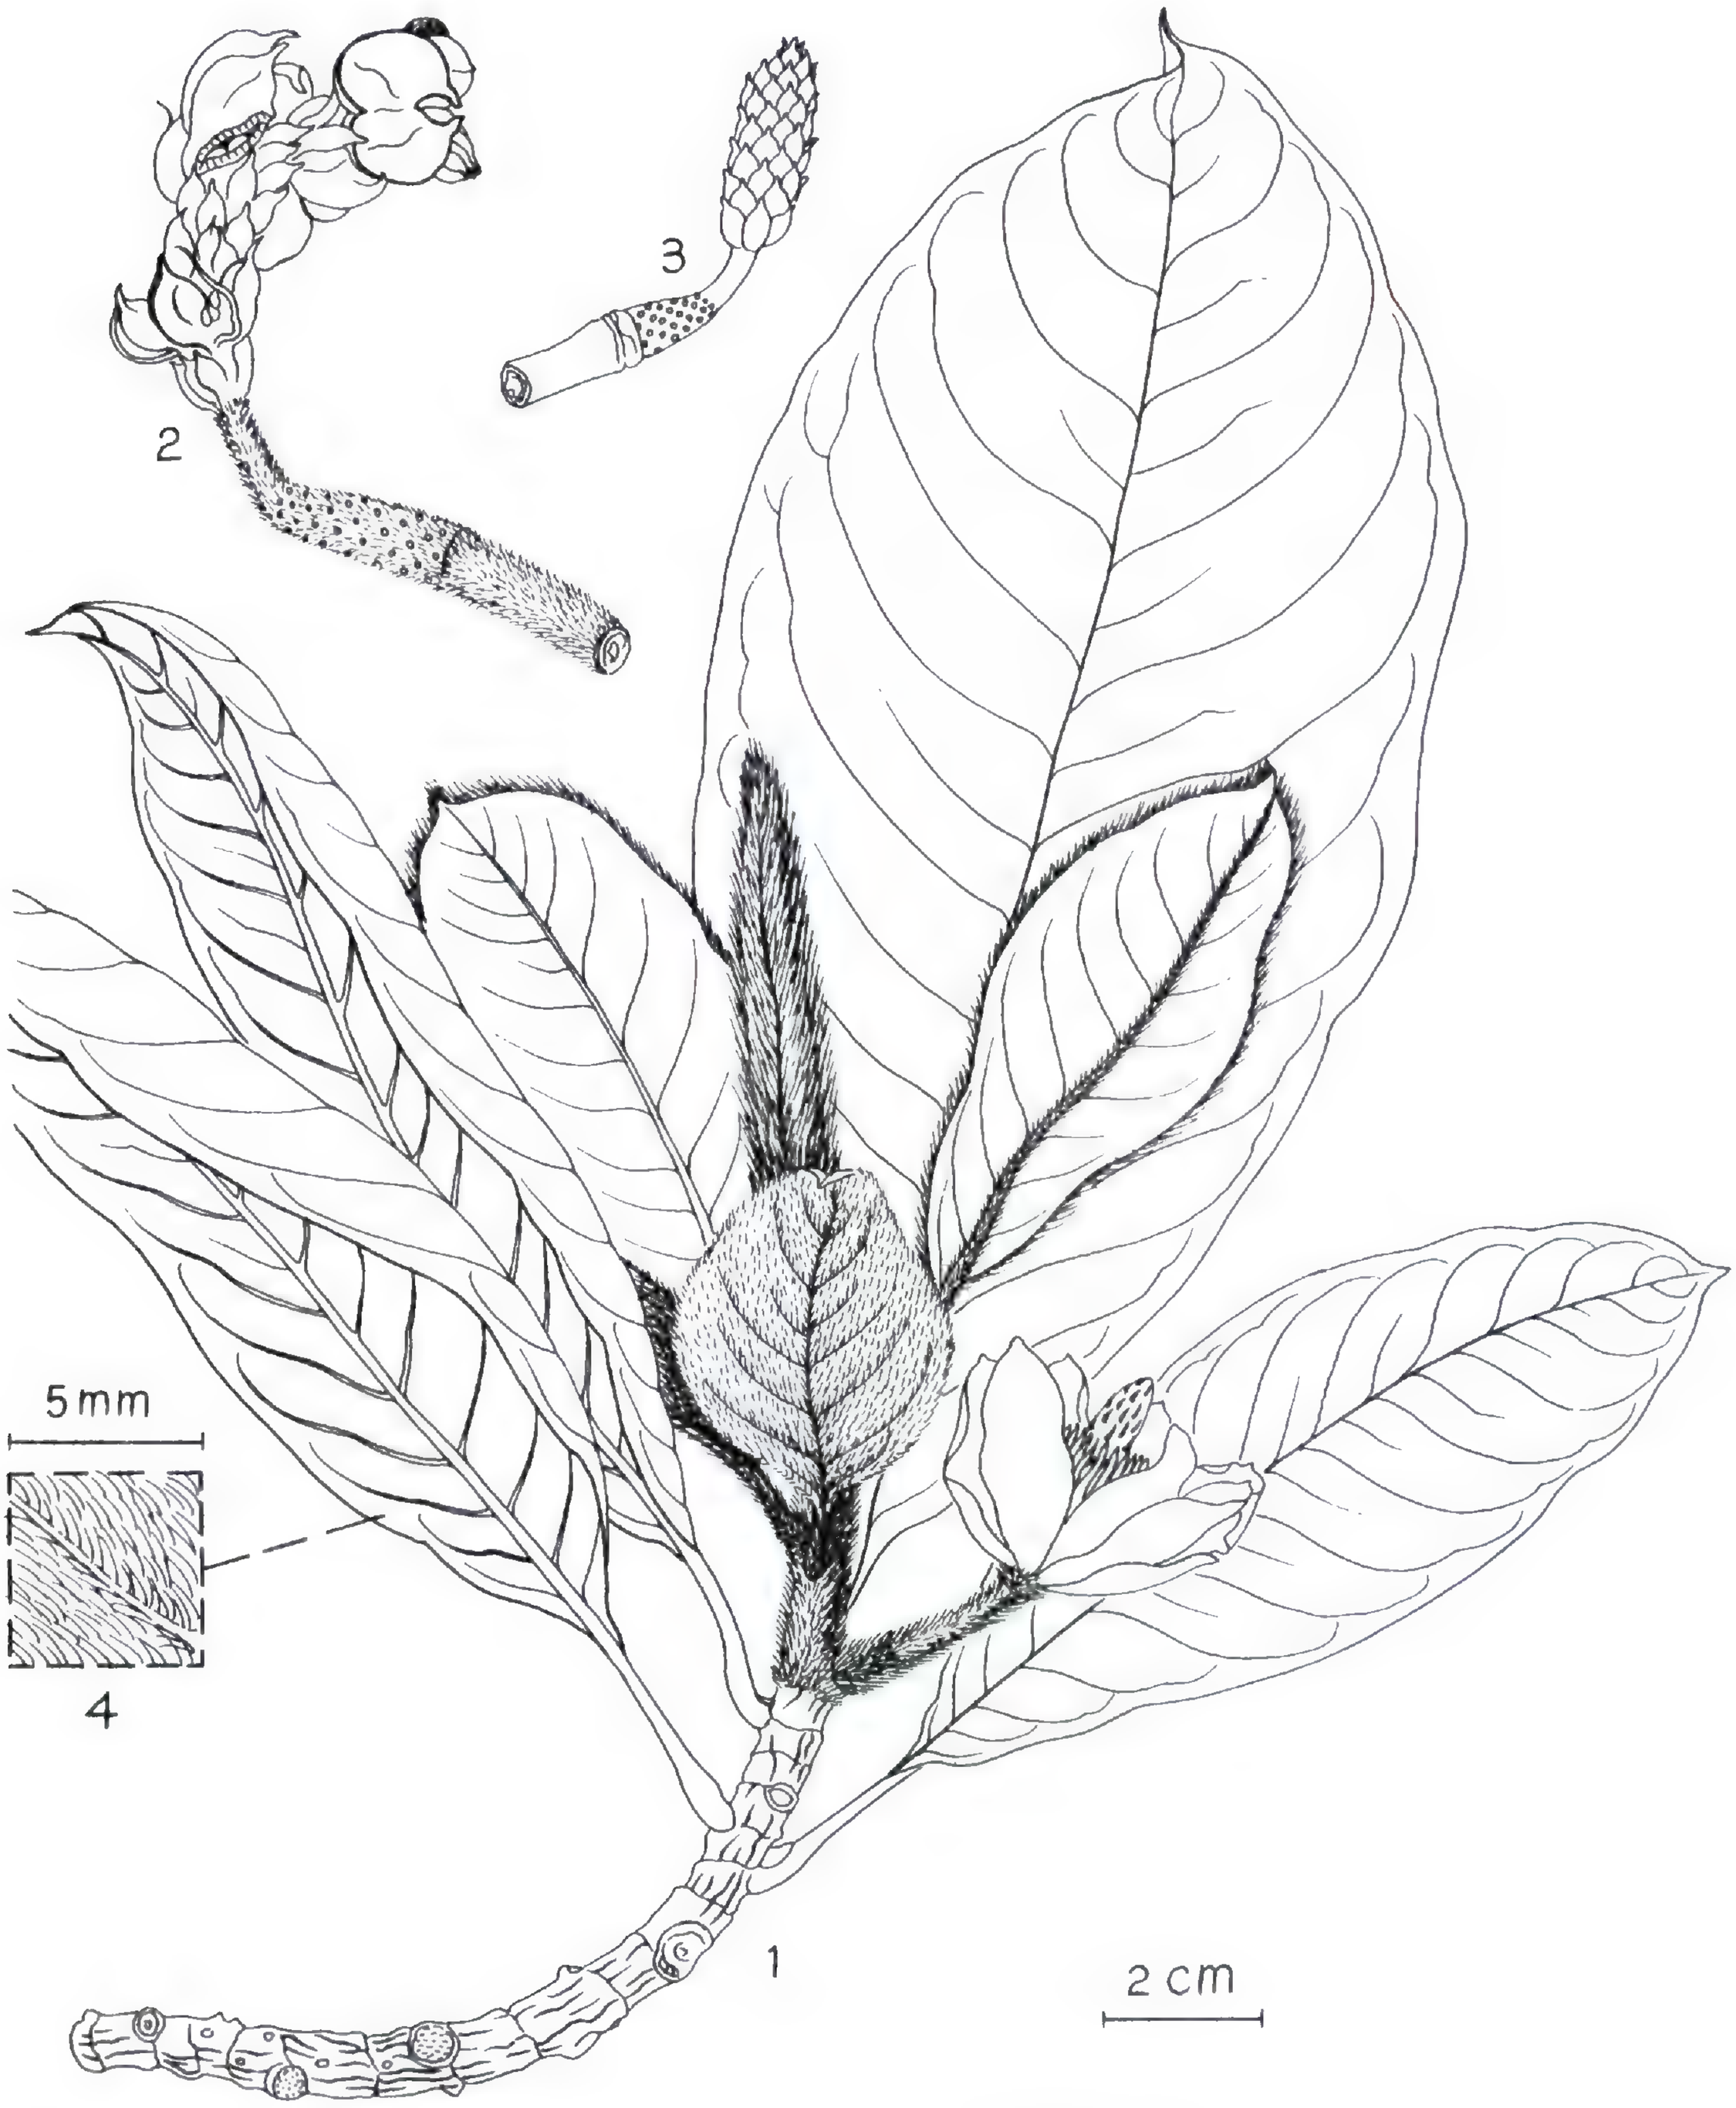

FIGURE 13. *Michelia ingrata* B. L. Chen & S. C. Yang.—1. Flowering branch.—2. Fruit.—3. Deflorated flower showing gynoecium.—4. Undersurface of leaf. Based on *SYS 161515* = *Chen Bao Liang 87 T 019*. Drawing by Xie Qing Jian.

Fruits 6–10 cm long, the fertile carpels sessile, 8.9–14 × 7–10 mm, with 2–5-mm-long beak. Gynophore under fruit 17 × 4 mm. Seeds 2–3 in each carpel.

*Distribution.* CHINA. **Eastern and southern Yunnan**: Goang-nan, *Wang C.W. 87715*; Maguan, *Chen B.L. & C.N. Mai 87 T 19*; Malipo, *Wang C.W. 87033*. Also in Xichou and Guangxi (Longzhou).

*Ecology.* In thickets on limestone. Altitude: 1,600–2,000 m. Flowering March–May.

*Collector's note.* Flowers with putrid smell.

*Note.* This species varies in size of the leaves and length of the peduncles.

14. **Michelia kisopa** Buch.-Ham. ex DC. Syst. Nat. 1: 448. 1817. *Sampacca kisopa* (Buch.-Ham. ex DC.) Kuntze, Revis. Gen. Pl. 1: 6. 1891. TYPE: Nepal, Narain-hetty, 22 Oct. 1802, *Buchanan-Hamilton s.n.* (BM).

*Michelia zila* Buch.-Ham. ex Madden, Trans. Bot. Soc. Edinburgh 5: 127. 1858. TYPE: *Buchanan-Hamilton 1262* (E).

Tree, bark gray; young twigs 1.5–3 mm diam., yellow-brown, purple-brown, to dull brown-black, sparsely minute-puberulent or tomentellous with short, straight to slightly undulate, clear hairs, glabrescent; old twigs brown, gray-brown, to gray-black, longitudinally fissured or wrinkled, sparsely lenticellate. Stipules tomentellous with straight, clear hairs, adnate to the petiole usually up to or beyond half its length, scars 1.4–2 cm long. Leaves thinly coriaceous to coriaceous, bright green, sparsely puberulent, especially on the midrib and toward the base above, paler green, minutely appressed-pubescent with straight, clear hairs, glabrescent beneath, oblong-elliptic, obovate-elliptic, oblong, ovate-oblong to ovate, somewhat unequal; 5.2–16.5(–19) × 2.2–5 cm; apex acuminate to long-acuminate, acumen 7–12(–20) mm long, occasionally acute, base cuneate to rounded; midrib slightly impressed above, nerves in 10–15 pairs, obscure or hardly visible on both sides, reticulation prominent on both sides. Petiole slender, puberulent, glabrescent, 1.6–3.5 cm long. Brachyblast densely tomentose with short, straight to slightly undulate, clear or gray hairs, 4–6 × 3–5 mm, pedicle absent; bracts 3(–4), appressed-tomentose with same hairs as the brachyblast. Flowers not or faintly scented; tepals 9–15, white to yellow, glabrous or puberulent outside toward the base, subsimilar, the outer 3 obovate, obovate-oblong, to spathulate, tapering toward the base, becoming short or long clawed, 3–3.5 × 1–1.3 cm, the inner tepals narrowly obovate-elliptic, 2.2–2.7 × 0.4–0.7 cm; stamens 8–11 mm long, connective appendage usually linguiform or long-triangular, 2–4 mm long, filaments 1–2 mm long; gynoecium cylindric, longer than the androecium, ca. 6–10 × 2 mm; gynophore yellowish tomentellous, ca. 1–4 × 1 mm; carpels ca. 26, ovoid, covered with the same indument as the gynophore; styles short and wide, glabrous; ovules 3–8; scars of perianth and stamens on torus 1–2 × 2.5–3 mm. Fruiting brachyblast ca. 7 × 5 mm. Fruit 3–10 cm long; mature carpels 3–14, nearly globose or ellipsoid, yellow-brown, sessile, beaked apically, ± puberulent, 8–14 × 7–10 mm; scars of perianth and stamens ca. 4 × 4 mm. Gynophore under fruit 1 cm long.

*Distribution.* Southern Kumaon to Sikkim, China. In CHINA: **Xizang**.

*Ecology.* In forests. Altitude: 1,500–2,250 m.

*Uses.* According to Aikin, the wood is used for light construction.

*Note.* See Dandy (1927b).

15. **Michelia lacei** W. W. Smith, Notes Roy. Bot. Gard. Edinburgh 12: 216. 1902. TYPE: *J. H. Lace 5928* (holotype, E; isotype, K).

*Michelia uniflora* Dandy, Kew Bull. 1927: 203. 1927. TYPE: Burma. Mawson, southern Shan States, *N. Manders, 1888* (holotype, K).

*Michelia tignifera* Dandy, J. Bot. 68: 213. 1930. TYPE: *Poilane 12864* (holotype, P; isotype, K).

*Michelia magnifica* Hu, Bull. Fan. Mem. Inst. Biol. (Peiping) 10: 118. 1940. TYPE: *H. T. Tsai 56961* (holotype, PE; isotypes, A, BM).

*Michelia pachycarpa* Law & R. Z. Zhou, Bull. Bot. Res. (China) 7, 1: 85, t. 1987. TYPE: *R. Z. Zhou 25* (IBSC, seen alive).

Tree to 40 m high and 1 m diam.; young twigs stout, 4–6(–10) mm diam., glabrous or at first gray- to yellowish tomentose, later glabrescent, terete, brown-yellow to purple-brown, usually glaucous when dry, conspicuously elliptic lenticellate and with annular scars; old ones longitudinally fissured. Stipules thinly coriaceous, appressed-pubescent with short, straight, yellowish hairs, glabrescent, free from the petiole. Leaves coriaceous, rigidulous, bright green above, pale green beneath, glabrous on both sides, obovate-elliptic to elliptic, 14–28 × 6–10 cm; apex short-acuminate to acute, base cuneate to broadly cuneate, margin somewhat revolute; midrib impressed above, prominent below, nerves in 9–15(–20) pairs, reticulation lax, nerves and reticulation prominent on both sides when dry. Petiole glabrous, wide sulcate above, 2.5–3 cm long, without scars. Brachyblast glabrous to tomentose, 15–25 × 5–7 mm, pedicle absent; bracts 3–4, chartaceous, ± puberulent outside, especially toward the base. Flower fragrant, solitary, sometimes abnormally two-flowered; bud ovoid-cylindric, ca. 4 cm long; tepals 9, white, subsimilar, glabrous, obovate to spathulate, 5.5–7 × 1.5–3 cm; stamens 2–2.5 cm long, connective appendage short-triangular, ca. 1 mm long, filaments 2–3 mm long; gynophore tomentellous, 1–2 cm long, gynoecium 1.7–2 cm long-exserted from stamens; carpels ca. 12, glabrous; styles long and recurved;

ovules ca. 10; scars of perianth and stamens on torus ca. 7 mm long. Fruiting brachyblast 15–25 × 5–10 mm. Fruit 7–10 cm long; ripe carpels 4–6, obovoid, brown to dark brown, lenticellate, ca. 2–4.5 × 2 cm, 5–6 mm thick; gynophore ca. 29 × 6 mm; scars of perianth and stamens ca. 2–2.2 × 0.9 cm.

*Distribution.* China, Vietnam, and Burma. In CHINA. **Southwestern and southeastern Yunnan**: *Chen B.L. 86 S 51, GS 86102, Tsai H.T. 56961.*

*Ecology.* In forests. Altitude: 1,450–1,550 m. Flowering February–March; fruiting September–October.

*Uses.* Wood soft, for planks.

*Collector's note.* Big tree, flowers white, heavily sweet-scented.

Note. The first author has collected material with flowers and fruits from the type tree of *Michelia pachycarpa*. There is no doubt that it is synonymous with *Michelia lacei*.

16. **Michelia macclurei** Dandy, J. Bot. 66: 360. 1928. TYPE: *F. A. McClure 1468* (*in C. C. C. 13292*) (holotype, UC; isotypes, A, K, US).

*Michelia macclurei* var. *sublanea* Dandy, J. Bot. 68: 212. 1930. TYPE: *Tsiang 2609* (holotype, NY; isotypes, A, BM, E, K, P).

Tree to 30 m high and 1 m diam.; bark white-gray; buds, young twigs, stipules, petiole, brachyblasts and bracts outside appressed-tomentellous with short, straight, clear, silver, brown or rufous hairs, glabrescent; young twigs 2–4 mm diam., yellow-brown, blackish to purple-brown; old ones rough, sparsely lenticellate, longitudinally striped. Stipules free from the petiole. Leaves coriaceous, at first somewhat sericeous, later glabrescent above, appressed-tomentose with short to long, straight, rufous (when young) to clear or yellowish (when older), glistening hairs beneath, broadly elliptic to broadly ovate, rhombic-elliptic, or broadly obovate, occasionally narrowly elliptic, 6.5–14 × 4–6.5 cm; apex short-acuminate to acute, base cuneate to broadly cuneate; midrib impressed above, prominent, at first densely brown pubescent with long hairs, soon glabrescent, nerves fine, in 10–15 pairs, conspicuous on both sides; reticulation usually densely netted, prominent on both sides. Petiole sulcate above, 2.5–4 cm long, without stipular scars. Brachyblast 10–13 × 3–4 mm, with 3 bract scars; pedicle 2–5 mm. Tepals 9–12, white, subsimilar, the outer 3 narrowly obovate to spathulate, 3.5–4.5 × 1–1.5 cm, the inner 6–9 smaller and narrower than the outer ones; stamens 9–13 mm long, connective sparsely puberulent, its appendage tonguelike, 1–2 mm long, filaments 1–2 mm long; gynoecium narrowly cylindric, 7–9 mm long, tomentellous, slightly longer than the androecium; gynophore brown tomentellous, 5 mm long; carpels ca. 28 or more. Fruiting brachyblast 10–15 × 4–5 mm, glabrescent. Fruit 3–7 cm long; gynophore 8–10 × 3–4 mm, glabrescent; ripe carpels ellipsoid or subglobose, dull brown, sessile, ± lenticellate, 15–23 × 9–10 mm; scars of perianth and stamens on torus ca. 4–5 × 5 mm. Seeds 1–3, flat-ovoid, 8–10 mm long.

*Distribution.* China and northern Vietnam. In CHINA. **Guangdong**: Fangcheng, *Chun S.H. 4466*; Wuchuan, *Chen S.P. 1131*; Yangchun, *Wang Q 830001.* **Guangxi**: Rongshui, *Long G.R. 830090*; Ronxian, *Liang C.F. 31845*; Yulin, *Lee S.K. 200723.* **Hainan**: Manning, *How F.C. 73194.* Also in Yunnan.

*Ecology.* In mixed forest. Altitude: 500–1,000 m. Flowering March–April; fruiting September–November.

*Uses.* Wood fine-textured, straight-grained and fragrant; commonly used for construction, planks, and furniture; the tree is grown as an ornamental.

*Note.* The indument varies in this species. Therefore, we prefer to reduce *Michelia macclurei* var. *sublanea* to *Michelia macclurei*.

17. **Michelia masticata** Dandy, J. Bot. 67: 222. 1929. TYPE: *Poilane 11253* (holotype, P; isotypes, BM, K).

*Michelia sphaerantha* Law & Y. F. Wu, Acta Bot. Yunnanica 10, 3: 335, t. 1. 1988, nom. illeg., non *Michelia sphaerantha* Z. S. Yue 1987. TYPE: *M. K. Li 2539* (KUN not seen).

See *Michelia sphaerantha* Yue under dubious species.

Tree to 18–25 m high and 80 cm diam.; bark gray-brown, irregularly fissured lengthwise, conspicuously lenticellate; young twigs pubescent or glabrous, slender, bright yellow-green; old ones dark green, with white lenticels; bud cylindric, ca. 13 mm long. Stipules yellowish sericeous or brownish pubescent outside toward the apex, free from the petiole. Leaves coriaceous, dark green, slightly glossy above, pale green beneath, scattered appressed-pubescent with short, straight to slightly undulate, clear to brownish hairs, glabrescent on both sides, broadly elliptic, elliptic-oblong, ovate, or obovate, 12–22(–28) × 5–8(–10) cm; apex short-acuminate, base cuneate to rounded; midrib and nerves impressed above, much prominent below, nerves in 8–13 pairs, reticulation laxly netted, visible on both sides. Petiole appressed-tomentellous, glabrescent, 2–3(–4.5) cm long, without scars.

Brachyblast yellowish sericeous, glabrescent, ca. 10 × 3–4 mm; pedicle absent; bracts 3, covered with same indument as the stipule. Tepals 9–12, white to yellowish white, subsimilar, the outer 3 obovate, narrowly obovate to spathulate, 5–9(–11) × 1–2.5 cm, the inner 6–9 narrower than the outer ones, 3–6(–8) mm long; stamens many, ca. 2 cm long, filament ca. 3 mm, connective appendage ca. 1 mm long; gynoecium cylindric, tomentellous with short, straight, brownish hairs, 3–6(–8) cm long, longer than stamens; gynophore tomentellous, ca. 1 cm long; carpels many, ca. 6 mm long; styles ca. 2.2 mm long; scars of perianth and stamens on torus 6–8 × 5 mm. Fruiting brachyblasts 5–7 cm long. Fruit 10–40(–53) cm long; follicles to 100(–128), dull brown, ovoid to ellipsoid, densely gray-white lenticellate, reddish glandular, apically beaked. Seeds 2–6 in each carpel, red, globose and slightly compressed to irregularly shaped, ca. 10 mm long. Gynophore under fruit ca. 2.5 cm long.

*Distribution.* China, Laos, and Vietnam. In CHINA. **Yunnan**: Wulinag shan, *Tsiang T. 12059*; Menghua, *Yu T.T. 15884*; Nanjiang Xian, *Yue Z.S. 86- 107*; Pingpien, *Mao P.I. 27216*; Chu-hsiun, *Li M.K. 3.*

*Ecology.* In forest. Altitude: 500–2,110 m. Flowering April–May; fruiting October.

*Uses.* Wood hard and dense, useful for all purposes. The tree is grown as an ornamental.

*Note.* We were unable to study the type specimen of *Michelia sphaerantha* C. Y. Wu ex Law & Y. F. Wu. Fortunately, there were some other collections available (including *Mao Ping-i 3621*, *0321*, and *02728*). There is no doubt that *Michelia sphaerantha* C. Y. Wu ex Law & Y. F. Wu (nomen illeg.) belongs to *Michelia masticata*. The only differences are in the degree of indument and the number of carpels. Generally, the Chinese collections have a more dense indument and more carpels. *Michelia sphaerantha*, published by Yue (1987) is based on another type and represents another species.

18. **Michelia maudiae** Dunn, J. Linn. Soc. Bot. 38: 353. 1908. SYNTYPES: *Hongkong Herb. 2449, 2065* (HK, A).

*Michelia chingii* Cheng, Contr. Biol. Lab. Sci. Soc. China, Bot. Ser. 10: 110. 1936. TYPE: *R. C. Ching 2452* (holotype, PE; isotypes, A, E, K).

Tree to 20 m high and 60 cm diam.; bark pale gray or gray-brown; plant entirely glabrous; buds, young twigs, stipules outside, leaves beneath, petiole, brachyblasts, bracts outside, and gynoecium pale green to glaucous when dry; young twigs 2–3 mm diam., dull purple-brown, yellow-black to dull yellow; old ones yellow-gray, black-gray to dull black, lenticellate, longitudinally fissured. Stipules free from the petiole. Leaves coriaceous, dark green, glossy above, broadly elliptic, obovate-elliptic to obovate, 9.5–17.5 × 3–7 cm; apex abruptly short-acuminate, acumen 3–12 mm long, occasionally long-acuminate, to 2 cm long, base cuneate to nearly rounded; midrib flat to ± impressed above; nerves fine, visible on both sides, in 7–12 pairs, reticulation densely netted, prominent on both sides. Petiole 1–3 cm long, without stipular scar. Brachyblast 10–28 × 4–7 mm, pedicle absent; bracts 2–4, sometimes leaflike. Flower solitary, occasionally two, fragrant; tepals 9–12, white, subsimilar, the outer 3 broadly obovate, attenuate toward the base, 5–8 × 2.3–4 cm, the inner tepals 6–9, obovate, elliptic to broadly spathulate, short-clawed at the base, 4.5–5 × 1.8–2.5 cm; stamens 13–17 mm long, connective appendage short to long triangular, 0.5–2 mm long, filaments pale purple, 2–5 × 2 mm; gynoecium subcylindric, longer than the androecium, 10–13 mm long; gynophore 6–12 mm long; carpels many, ovoid, 2–3 mm long; styles 3–3.5 mm long; ovules 6–14 in each carpel; scars of perianth and stamens on torus ca. 4 × 6 mm. Fruiting brachyblast 17–30 × 4–8 mm. Fruits 10–12(–14) cm long; ripe carpels 2–19, obovoid to ovoid, dull brown, lenticellate, short-beaked apically, 1–2.5 × 1–1.7 cm; gynophore 13–30 × 4–5 mm; scars of perianth and stamens 5–6 × 6–7 mm. Seeds subovoid, ca. 1 × 0.5 cm, slightly compressed.

*Distribution.* CHINA. **Fujian**: Yenping, Buong, *Chung H.H. 3667*. **Guangdong**: North river region, *Wang C. 31404*; Ruyuan, *Chen B.L. 80110*; Ying Tak, *Tsang W.T. 3044*; Fan Shiu Shan, *Lau S.K. 2552*. **Guangxi**: Guangyang, *Zhao R.F. 54*; Lingui, *Zhao R.F. 197*; Longshen, *Liu L.F. 5671*; Xingan, *Xing An Exped. 285*. **Guizhou**: Tuhshan, *Tsiang Y. 6933*; Liping Xian, *Yuan J.M. 621*; Lipo county, *Song X.H. 244*. **Hainan**: Jiangyong, *Tam P.C. 63667*. **Jiangxi**: Lungnan distr., *Lau S.K. 4854*. **Zhejiang**: Lungtsuau, *Ho Y.Y. 3200*; Pang Yung, *Ching R.C. 2066*. Also reported from southern Hunan.

*Ecology.* In evergreen broad-leaved forests. Altitude: 500–1,500 m. Flowering February–March; fruiting September–October.

*Uses.* Wood straight-grained and fine-textured, used for furniture and planks.

19. **Michelia mediocris** Dandy, J. Bot. 66: 47. 1928. TYPE: *McClure* in *C. C. C. 8593* (holotype, BM; isotypes, A, E, K, MO).

Tree to 35 m high and 90 cm diam.; bark white-gray; buds rufous or silver appressed-tomentellous; young twigs 2–3 mm diam., dull black-gray to yellow-brown, appressed-tomentellous with short, straight, silver to brown hairs, glabrescent, sparsely lenticellate. Stipules silver appressed-tomentellous, free from the petiole. Leaves thinly coriaceous to coriaceous, bright green, scattered-puberulent with short, straight, clear to brown hairs, especially on midrib and toward the base, glabrescent or glabrous above, ± pale green, at first appressed-tomentellous with short, straight, glistening, yellowish hairs, soon glabrescent beneath, elliptic, broadly elliptic, obovate-elliptic to rhombic-elliptic, 5–10(–13.5) × 3–4(–7) cm; apex acute to acuminate, base attenuate or cuneate to broadly cuneate; midrib prominent, appressed-puberulent with short, straight, brown and yellowish hairs, glabrescent below, nerves rather fine, in 10–15 pairs, obscure to visible on both sides, more prominent beneath than above, reticulation densely netted, conspicuous on both sides when dry. Petiole densely tomentellous with same hairs as young twigs, glabrescent, 1.5–2.5 cm long, without scars. Brachyblast brown or yellow appressed-tomentellous, ca. 6–10 × 3 mm, pedicle ca. 2 mm long; bracts 3–4, silver or brown tomentellous outside. Tepals 9–10, white, subsimilar, obovate, spathulate to obovate-linear, usually attenuate toward the base, clawed at the base, 1.8–3 × 0.4–1.8 cm; stamens 1–1.5 cm long, connective appendage tonguelike, variable in length, 2–4 mm long, filaments 1.5–2 mm long; gynoecium short-cylindric, 6–12 mm long, usually longer than the androecium, occasionally equal to the latter; gynophore gray to brown tomentellous, 3–5 mm long; carpels 13–18, tomentellous with same hairs as gynoecium; ovules 4–6; scars of perianth and stamens on torus ca. 3 × 3 mm. Fruiting brachyblast ca. 1 × 0.4 cm, tomentellous. Fruit 2–3.5(–5) cm long; carpels glabrescent, obovoid to ellipsoid, slightly compressed, sessile, ca. 2 × 1.2 cm; gynophore under fruit 5–8 mm long. Seeds 5–8 mm long.

*Distribution.* China, Cambodia, and Vietnam. In CHINA. **Guangdong**: Dinghushan, *Shi G.L. 14241*; Fachou distr., *McClure F.A. 582*. **Guangzhou**: *Wang X.W. 5690*; Kochow, *Pasheng 2*; Yingde Xian, *Liang H.Y. 61546*. **Guangxi**: Dafongshan, *Chang C.C. 11316*; Zhaoping Xian, *Li Y.K. 402692*. **Hainan**: Bawangling, *Zheng P. 13465*; Chim Fung Mt., *Lau S.K. 5245*; Five Finger Mts., *McClure F.A. CCC 8593*; Hung Mo Tung, *Sing I.Y.* (herb.nr 18350) *817*; Tianchi, *Wang C. 2888*.

*Ecology.* In forest. Altitude: 400–1,300 m. Flowering December–January; fruiting June–July.

*Uses.* Sapwood yellow-brown, heartwood brown-yellow; wood straight-grained, fine-textured, light, soft, and durable; commonly used for furniture, millwork, veneer, plywood, musical instruments, and also for bridges and ships.

*Collector's notes.* On sandy soil; flowers fragrant.

*Note.* G. W. Groff, Ding & Groff (1923) and Merrill (1927a) misidentified this species as *Michelia maudiae* (auct. non Dunn, 1908).

20. **Michelia microtricha** Hand.-Mazz., Akad. Wiss. Wien 58, 18: 81. 1921. TYPE: *Ten 339* (holotype, C; isotypes, K, V). Figure 14.

Tree to 3–20 m high. Young twigs 2–3 mm diam., dull yellow-brown or black-brown, appressed-tomentellous with minute, straight, brown to gray hairs, glabrescent; old ones dull brown, ± pubescent, lenticellate; buds narrowly ovoid, 1.2 cm long. Stipules minutely gray or dark brown tomentellous outside, stipular scars ca. 1.5 cm long. Leaves coriaceous, dark green, glossy, appressed-puberulous with straight, clear to gray hairs, especially on the midrib and toward the base above, glabrescent, appressed-tomentellous with short, straight, yellowish to brown hairs beneath, elliptic to narrowly obovate, 8–16 × 3–5 cm; apex acute to short-acuminate, base cuneate; midrib impressed above, conspicuous below, nerves fine, visible on both sides, in 8–14 pairs, reticulation densely netted, obscure on both sides. Petiole tomentellous, glabrescent, narrowly sulcate above, 2.5–3 cm long. Brachyblast densely tomentose, 7–10 × 3.5–4 mm, pedicle ca. 3 × 4 mm; bracts 3, broadly ovate, cupreous sericeous outside, 3.5–3.9 cm long. Flower bud long-ovoid; tepals 12, white, fleshy, the outer 3 obovate to spathulate, abruptly constricted near the middle or tapering gradually toward the base, finally becoming long clawed, 3.2–3.7 × 1.4–1.5 cm, the inner tepals 6, spathulate, ca. 3–3.7 × 1.2 cm, the 3 innermost ones obovate-linear, ca. 2.5 × 0.8 cm; stamens numerous, 10–11 mm long, connective appendage short triangular, 1–2.5 mm long; filaments 1–2.5 mm long; gynoecium subcylindric, 6–11 mm long; gynophore minutely puberulent with clear or brownish hairs, ca. 4 mm long; carpels ca. 25–40, ellipsoid, covered with the same indument as gynophore; styles glabrous, erect, 1–1.5 mm long; ovules 6–8; scars of perianth and stamens on torus ca. 2 mm long. Fruit not seen.

*Distribution.* CHINA. **Yunnan**: Lungtji, Peyentjing, Dali, *Teng, S.M. 339*; Jinping, *Wu S.K. 3867*.

FIGURE 14. *Michelia microtricha* Hand.-Mazz. — 1. Flowering branch. — 2. Deflorated flower. — 3. Fragment of leaf underside. Based on *Simeon Ten 339* (WU). Drawing by Joop Wessendorp, Rijksherbarium, Leiden.

*Ecology.* In forest.

*Note.* *Michelia microtricha* is relatively rare and is closely related to *Michelia floribunda*. It differs from the latter chiefly by the indument with minute hairs and by the longer brachyblasts.

21. **Michelia shiluensis** Chun & Y. Wu.

See under dubious species.

22. **Michelia velutina** DC., Prodr. 1: 79. Jan. 1824. TYPE: Nepal: *Wallich s.n.* (K).

*Michelia lanuginosa* Wall., Tent. Fl. Nepal., 1: 8, t. 5. June 1824. *Sampacca lanuginosa* (Wall.) Kuntze, Revis. Gen. Pl. 1: 6. 1891. TYPE: *Wallich 6493* (holotype, K; isotypes, A, BM).

*Michelia lanceolata* E. H. Wilson, J. Arnold Arbor. 7: 237. 1926. TYPE: *J. F. Rock 6919* (holotype, A; isotypes, E, NY, UC).

Tree to 15–20 m high by 90 cm diam.; bark dull brown; indument yellowish to brown, sometimes glossy; young twigs 2–3 mm diam., brown to purple-black, pubescent with short, appressed or spreading, undulate to curly hairs, glabrescent; old ones ± hairy. Stipules densely pubescent with long, straight or undulate hairs outside, adnate to the petiole, stipular scars 3–5(–11) mm long. Leaves chartaceous to thinly coriaceous, dark green, glabrous or scattered-pubescent with slender, undulate hairs, especially dense on the midrib above, paler green, densely appressed-pubescent with long, undulate, clear or brown hairs, seemingly velvet, finally glabrescent below, narrowly elliptic, sometimes elliptic to broadly elliptic or ovate-elliptic, (6.2–)11–24(–29.5) × (2.5–)3.5–6.5(–8.5) cm; apex acute to short- or long-acuminate, acumen 1–1.7 cm long, occasionally obtuse, base cuneate to rounded; midrib impressed above, prominent below, nerves fine, slightly impressed, obscure above, visible beneath, in 11–23(–28) pairs, reticulation densely netted, faint on both sides. Petiole densely pubescent, glabrescent, somewhat dilatate toward the base, 0.9–1.4(–2.3) cm long. Brachyblast densely pubescent with short, undulate to curly, yellowish or brown hairs, 4–17 × 4–5 mm, pedicle 0–2 mm long; bracts 3, pubescent with same hairs as stipules outside. Flower bud long-ovoid, ca. 2.7 cm long; flower very fragrant; tepals 10–12(–13), white to yellowish, subsimilar, spathulate to elliptic-linear, basally long-clawed, the outer 4–6 glabrous to puberulent outside at the base, 2.2–5.5 × 0.7–0.8 cm; stamens 9–12 mm long, connective appendage triangular, 1–2 mm long, filaments ca. 2 mm long; gynoecium ovoid-oblong to narrowly ovoid, longer than the androecium, 9–15 × 3–6 mm; gynophore densely pubescent, 6–7 × 2–3 mm; carpels ca. 35, subglobose, densely pubescent; styles erect, glabrous, ca. 1 mm long; ovules 3–6 in each carpel; scars of perianth and stamens on torus 3–5 × 4–5 mm. Fruiting brachyblast ± pubescent, ca. 1–1.7 × 0.5 cm. Fruit 3.5–13 cm long; ripe carpels ovoid to ellipsoid, dull brown, densely lenticellate outside, stipitate, 7–25 × 10–17 mm; gynophore 17–20 × 4–4.5 mm; scars of perianth and stamens ca. 5 × 5 mm. Seeds subcordate to subglobose, 7–10 × 6–8 mm.

*Distribution.* CHINA. **Xizang**: Putsang River, Rong To valley, Zayul, *Kingdon Ward F. 10980.* **Yunnan**: W of Talifu, Mekong watershed, *Rock J.F. 6919*; Che li Hsien, *Wang C.W. 78441*; Chu hsian, *Li M.K. 59.*

*Ecology.* In mixed forests. Altitude: 1,500–2,300 m. Flowering May–June; fruiting August–September.

*Uses.* Wood usually grayish white and soft, not useful.

23. **Michelia wilsonii** Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 45, t. 7A. 1905. TYPE: *Wilson 3136* (holotype, P; isotypes, A, BM, K).

*Michelia sinensis* Hemsl. & E. H. Wilson, Kew Bull. 1906: 149. 1906. TYPE: *Wilson* (*Veitch Exped.*) *3136* (holotype, K; isotypes, A, BM, P).

*Michelia szechuanica* Dandy, Notes Roy. Bot. Gard. Edinburgh 16: 131. 1928. TYPE: *Wilson 4598* (holotype, K; isotype, A).

Tree to 20 m high; indument appressed to spreading; young twigs 1–3 mm diam., yellow or black-brown, glabrous to tomentose; old ones brown to purple-brown, lenticellate. Stipules densely pubescent with short, straight to undulate, yellowish to brown hairs, adnate to base of the petiole, scars 1–5 mm long. Leaves thinly coriaceous, dark green, glossy, pubescent especially on the midrib, later glabrescent above, glaucous, at first densely pubescent or tomentellous with minute, straight or undulate, yellowish to brown hairs, finally glabrescent beneath, obovate, obovate-elliptic, narrowly obovate-elliptic, rarely broadly elliptic, somewhat unequal, 11.5–14(–18) × 4–6 cm; apex short-acuminate, acumen 4–10 mm long, occasionally acute, base attenuate to cuneate or broadly cuneate; midrib slightly impressed above, nerves obscure above, visible below, in 8–13 pairs, reticulation densely netted, faint on both sides when dry. Petiole pubescent, glabrescent, 1.2–1.5 cm long. Brachyblast pubescent with short, undulate hairs, 7–10 × 3–8 mm, pedicle absent; bracts 3(–4),

pubescent outside. Flower bud ovoid to ellipsoid, ca. 13 mm long; flower fragrant; tepals 9–12, yellowish white, subsimilar, obovate to spathulate, 2–3 × 0.6–0.8 cm; stamens 10–12 mm long, connective appendage very short-triangular, ca. 0.5 mm long, filaments 2–2.5 mm long; gynoecium cylindric, longer than the androecium, ca. 14 mm long; gynophore tomentellous, 2–3 mm long; carpels many, brown or silver tomentellous; ovules 6 or more; scars of perianth and stamens on torus 2–2.5 × 3–3.5 mm. Fruiting brachyblast ± pubescent, ca. 11 × 8 mm. Fruit 13.5–15.5 cm long; ripe carpels subglobose, ovoid to ellipsoid, purple-brown, lenticellate outside, sessile to short-stipitate, apex curved-beaked, 10–20 × 15 mm; gynophore 2–2.2 cm × 0.4–0.5 mm.

*Distribution.* CHINA. **Guizhou**: Chishui Xian, *Dang C.Z. 1656*. **Hubei–Sichuan**: Metaseqoia area, *Hwa C.T. 502*. **Jiangxi**: *Li Z.Z. 8220423*. **Sichuan**: Nanchuan, *Yang G.H. 54716*; Mabian, *Chang Q.L. 12055*; Kai Hsien, *Wilson E.H. 4598*; Mt. Omei, *4720*.

*Ecology.* In forests. Altitude: 1,000–1,500 m. Flowering March–May; fruiting August–September.

*Collector's note.* In forests on slope or in temple gardens.

*Note.* *Michelia sinensis*, like *Michelia szechuanica*, is not different from *Michelia wilsonii*. The type specimen of *Michelia szechuanica* possesses appressed hairs, whereas that of *Michelia wilsonii* has spreading hairs. Unfortunately, we did not have much material to study, but in some collections examined we observed an intermediate indument.

24. **Michelia ×alba** DC., Syst. Nat. 1: 449. 1817. TYPE: This species is based on *Sampaca domestica* IV *alba* Rumph., Herb. Amboin. 2: 200. 1741.

*Michelia longifolia* Blume, Verh. Batav. Genootsch. Kunsten 9: 155. 1823. *Sampaca longifolia* O. Kuntze, Rev. Gen. Pl. 1: 6. 1891. TYPE: *Blume s.n.* (L, sheet no. 908.126-1242; isotype, K).

*Michelia longifolia* var. *racemosa* Blume, Fl. Javae Magnoliaceae: 13, t. 3. 1829. TYPE: *Blume s.n.* (L).

Tree to 30 m high, bark gray; young twigs and buds densely grayish appressed-pubescent or puberulent, soon glabrescent. Stipules covered with same indument as the young twigs, adnate to the base of the petiole, stipular scars never over halfway the length of the petiole. Leaves thinly coriaceous, glabrous above, sparsely pubescent below, elliptic to obovate-elliptic, 10–35 × 4–11 cm; apex acuminate, acumen 7–30 mm long, base cuneate. Petiole sparsely appressed-puberulent to glabrous, 1.5–5 cm long. Brachyblasts with 2–3 evenly distributed scars, densely grayish pubescent. Flowers often many, nicely scented, white; tepals 10–12, subequal, lanceolate, 3–5.5 × 0.3–0.5 cm; stamens 8–10 mm long, connective appendage tonguelike, 1–1.5 mm long, filaments 1–1.5 mm long; gynoecium minutely hairy, exserted from the androecium, 8–13 mm long; carpels ca. 10; gynophore grayish puberulent, 2–4 mm long. Fruits usually with a few ripening carpels but most carpels abortive, 10–13 cm long; ripe carpels ovoid to ellipsoid, 1.2–1.8 cm × 8–12 mm, ± hairy, beaked at the apex; gynophore 18–24 mm long; scars of perianth and stamens ca. 16 × 6 mm. Fruiting peduncle pubescent, glabrescent, 1.7–3.2 × 0.5 cm.

*Distribution.* Widely cultivated in southern Fujian, Guangdong, Hainan, Guangxi, and Yunnan, as well as in other tropical and subtropical countries.

*Ecology.* Flowering April–September.

*Uses.* Flower and root used for medicinal purposes, flowers and leaves for volatile oil; the tree is grown as an ornamental.

*Note.* Ridley (1913) and Merrill (1921a p.p.) dealt with this species under *Michelia champaca* (auct. non Linnaeus, 1753). It is probably a hybrid of *Michelia champaca* L. and *Michelia montana* Blume.

**2. Michelia** section **Anisochlamys** Dandy in Praglowski, World Pollen Spore F. 3: 5. 1974. TYPE SPECIES: *Michelia mannii* King.

Stipules free from the petiole, the latter at least 10 mm long. Bracts 3. Tepals 9, 3-merous, very dissimilar, those of the outer whorl much shorter and narrower than those of the inner whorls. Fruits apocarpous.

25. **Michelia hypolampra** Dandy, J. Bot. 66: 32. 1928. TYPE: *Fleury* in *Chevalier 30158* (holotype, P; isotype, K).

*Talauma gioii* A. Chev., Bull. Econ. 132: 790. 1918. TYPE: *Service forestier 38204* (holotype, P).

*Michelia hedyosperma* Law, Bull. Bot. Res. (China) 5, 3: 123, t. 3. 1985. TYPE: *L. C. Chia & S. L. Feng 605* (IBSC not seen).

Tree to 21 m high and 60 cm diam.; buds, stipules outside, young petiole, brachyblast, bracts outside, carpels and gynophore densely covered with minute, straight or slightly undulate, clear to silver, appressed hairs; young twigs slender, 1–2 mm diam., dull brown or black-gray, glabrous; old

ones dull gray, longitudinally wrinkled. Stipules free from the petiole. Leaves thinly coriaceous, glabrous on both sides, or sparsely puberulent, on both the midrib and the margin near the base above, bright green, glossy, broadly elliptic, elliptic to obovate-elliptic, 6–13 × 3–6 cm; apex acuminate, acumen 4–10 mm long, occasionally acute, base cuneate, ± attenuate along the petiole; midrib slightly prominent above, prominent beneath, nerves fine, in 8–16 pairs, reticulation fine and dense, nerves and reticulation prominent on both sides. Petiole wide sulcate above, 1–2 cm long, without scars. Brachyblast rather short, 3–4 × 1.5–2 mm, pedicle absent to very short; bracts 3. Flower buds oblong to ellipsoid, ca. 1 cm long; tepals 9, dissimilar, the outer 3 membranous, linear, ca. 15 × 1 mm, the inner tepals 6, narrowly elliptic, 15–20 × 0.4–6 mm; stamens ca. 25, 8–9 mm long, connective appendage triangular, 1–1.5 mm long, anthers ca. 5 mm long; gynoecium ovoid, 1–2 cm long, exserted from stamens; gynophore 4–6 × 1 mm; carpels 4–10, free from each other, narrowly elliptic, 6–7 mm long; styles ca. 2 mm long, recurved; ovules 6–8; scars of perianth and stamens on torus ca. 2–3 × 2 mm. Fruiting brachyblast 5–20 × 2–5 mm, ± puberulent. Fruit 3.5–4 cm long; ripe carpels ovoid to obovoid-ellipsoid, gray brownish to brownish, densely lenticellate, with a stipe 3–8 mm long at the base, beaked at the apex, 2–4.5 × 1–2.5 cm; gynophore 2–3 × 0.2–0.5 cm; scars of perianth and stamens ca. 4 × 5 mm. Seeds irregularly shaped, 1–4 in each ripe carpel, 9–10 × 6–8 mm.

*Distribution.* CHINA. **Southwestern Guangxi**: Longzhou, *Huang D.Z. 3883*; Ningming, *Liang J.Y. 100316*; Nonggan, *Chang H.T. 6825.* **Hainan**: Bawangling, *Zheng P. 13419.* **Southern Yunnan**: Xishuang Banna, *Li Y.H. 4262.*

*Ecology.* In broad-leaved forest. Altitude: 300–800 m. Flowering March–April; fruiting September–October.

*Uses.* Wood straight-grained and fine-textured, suitable for furniture, construction work, and plywood; crown elegant and flower scented, thus the tree is grown for timber as well as an ornamental.

*Note.* There was no type specimen of *Michelia hedyosperma* available for study. Based on Law's description and figure, there is no doubt, however, that *Michelia hedyosperma* is conspecific with *Michelia hypolampra.*

This species differs strikingly from other species in *Michelia* by rather small flowers with linear outer tepals and few carpels.

**3. Michelia** section **Dichlamys** Dandy in Praglowski, World Pollen Spore Fl. 3: 5. 1974. TYPE SPECIES: *Michelia balansae* (A. DC.) Dandy.

Stipules free from the petiole. Bracts 3–6. Tepals 6 (or occasionally 4), 2-merous, subsimilar. Fruits apocarpous.

KEY TO THE SPECIES OF *MICHELIA*

SECTION *DICHLAMYS*

1. Leaves glabrous. ..... 2
1. Leaves hairy beneath at least when young. ..... 3
2(1). Twigs pubescent, stipules pubescent, leaf base broadly cuneate or attenuate-cuneate, apex short-acuminate or acute, reticulation densely netted; scars of perianth and stamens along torus under fruit 6–8 mm long. ..... 30. *Michelia martinii*
2. Twigs tomentellous, stipules glabrous, puberulous, or tomentellous, leaf base cuneate or rounded, apex acuminate, reticulation laxly netted; scars of perianth and stamens along torus under fruit 4–5 mm long. ..... 29. *Michelia chapensis*
3(1). Gynophore 3–4 mm long, treelet to 4 m high, leaves 1.5–2.5 cm broad, apex rounded; outer tepals spathulate, gynoecium ellipsoid. ..... 26. *Michelia angustioblonga*
3. Gynophore 5–10 mm long, tree to 15–18 m high, leaves 2.8–16.5 cm broad, apex short-acuminate, acuminate, or acute; outer tepals obovate, oblong, or elliptic, gynoecium ovoid or cylindric. ..... 4
4(3) Pedicle present, twigs tomentellous, stipules glabrous or tomentellous, apex acuminate or acute, reticulation rather obscure, petiole not dilated at base; gynoecium cylindric. ..... 29. *Michelia leveilleana*
4. Pedicle absent, twigs pubescent, stipules pubescent, apex short-acuminate, reticulation distinct, petiole dilated at base; gynoecium ovoid. ..... 27. *Michelia balansae*

**26. Michelia angustioblonga** Law, Bull. Bot. Res. (China) 6(2): 97. 1986. TYPE: *Z. R. Xu L12163* (holotype, IBSC; isotype, SYS). Figure 15.

Treelet to 4 m high; indument appressed, glistening; buds densely brown villous; twigs nearly black-brown. Stipules free from the petiole. Leaves coriaceous, dark green, glabrous above, pale green, brown villous beneath, narrowly oblong, 6.5–10 × 1.5–2.5 cm; apex obtuse, base cuneate to broadly cuneate; midrib impressed above; nerves anastomosing, obscure; reticulation densely netted. Petiole 1–1.5 cm long. Brachyblasts sparsely brown pilose. Flowers white, tepals 6, subsimilar, narrowly obovate to spathulate, the outer three 18–20 × 4–5 mm, the inner three 14–16 mm long; stamens 11–15 mm long, anthers 6–10 mm long, connec-

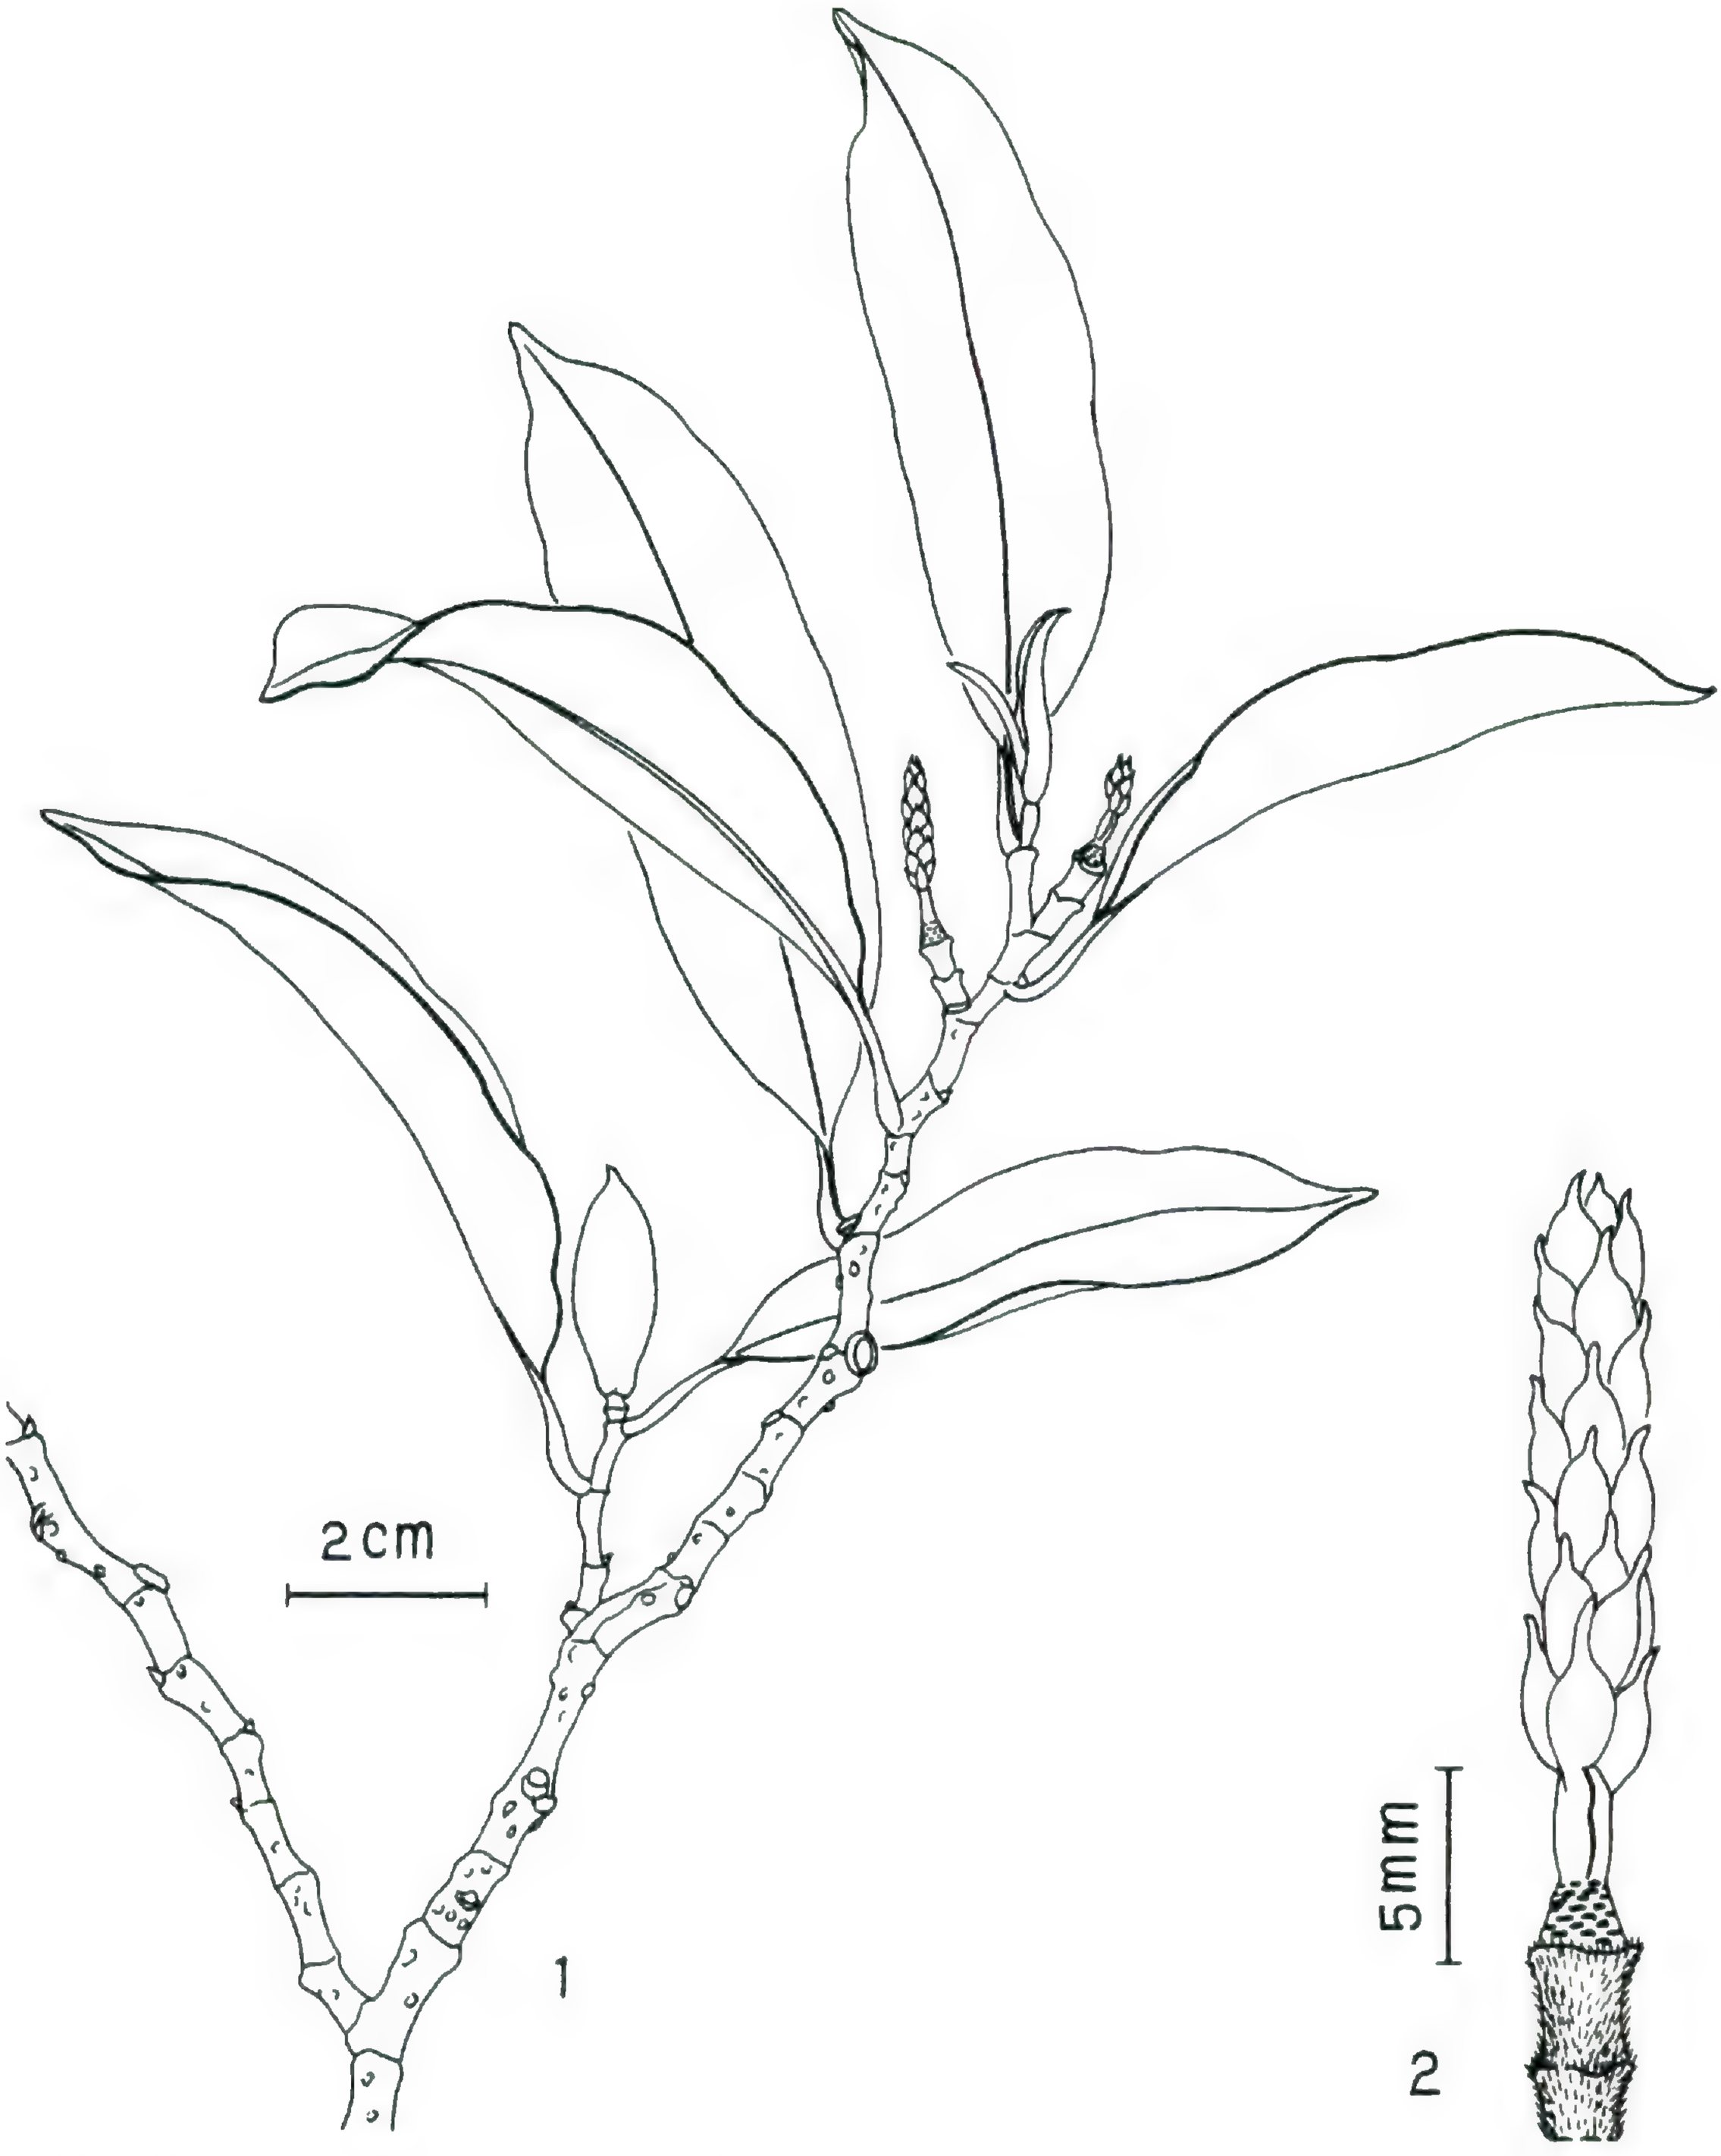

FIGURE 15. *Michelia angustioblonga* Law.—1. Flowering branch.—2. Deflorated flower with gynoecium. Based on *SYS 164643 = Xu Zhao Ran L 12163*. Drawing by Xie Qing Jian.

tive appendage triangular, ca. 1 mm long, filaments 2–3 mm long; gynoecium narrowly ellipsoid, entirely hidden by the androecium, 1–1.5 cm long; gynophore 3–4 mm long; carpels brown pubescent; scars of perianth and stamens on torus ca. 3 × 3 mm. Fruits not known.

*Distribution.* CHINA. **Guizhou**: Libo, *Z. R. Xu L1263*.

*Ecology.* In forest.

27. **Michelia balansae** (A. DC.) Dandy, Kew Bull. 1927: 263. 1927. *Magnolia balansae*

A. DC., Bull. Herb. Boissier 4: 294. 1904. *Michelia baviensis* Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 44, t. 5B. 1905. TYPE: *Balansa 3886* (holotype, P; isotype, L).

*Michelia tonkinensis* A. Chev. ex Gagnep. in Humbert, Fl. Indo-Chine Suppl.: 44. 1938. TYPE: No specimen has been preserved in Chevalier's herbarium.

*Michelia balansae* var. *appressipubescens* Law, Bull. Bot. Res. (China) 5, 3: 124. 1985. TYPE: *S. P. Kuo 52279* (holotype, IBSC; isotypes, A, BM, K, NY).

*Michelia balansae* var. *brevipes* B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 112. 1988. TYPE: *B. L. Chen & C. N. Mai 87TO34* (SYS).

Tree to 18 m high and 60 cm diam.; bark smooth, gray or gray-brown; indument with long, straight to slightly undulate, spreading to appressed, dark brown or brownish to yellowish hairs; young twigs 2–5 mm diam., densely pubescent, subterete, dull brown; old ones glabrescent, sparsely lenticellate. Stipules densely pubescent, free from the petiole. Leaves thinly coriaceous, at first scattered-pubescent, especially on the midrib, later glabrescent above, pubescent, glabrescent beneath, elliptic to broadly elliptic or obovate-elliptic to narrowly obovate-oblong, 8–21.5(–28) × 4.5–10(–16.5) cm; apex short-acuminate to sometimes acute, acumen 3–5 mm long, base cuneate to obtuse; midrib impressed above, prominent below; nerves visible on both sides, more prominent below than above, in 12–14(–19) pairs; reticulation laxly netted, prominent when dried. Petiole pubescent, glabrescent, conspicuously dilatate toward the base, 1.9–4.5 cm long, without scars. Brachyblast densely pubescent, 1.2–3.7 cm long, ca. 3 mm wide, pedicle absent; bracts 3, densely pubescent outside. Flower fragrant; tepals 6, subsimilar, the outer 3 ± appressed-tomentellous outside, white or greenish white to yellow, narrowly obovate-oblong, 3.5–3.7 × 1.3–1.5 cm, the inner tepals 3, spathulate, narrower and smaller than the outer ones; stamens 7.5–15 mm long, connective appendage short-triangular, ca. 0.5 mm long, filaments 0.5–2 mm long; gynoecium ovoid, 1–1.4 cm long; gynophore tawny tomentose, 5–7 mm long; carpels ovoid, tomentose; styles glabrous; ovules ca. 6–11; scars of perianth and stamens on the torus 3–4 mm long. Fruiting brachyblast 1.2–7 × 0.3–1.1 cm, glabrescent. Fruit 4–12 cm long; ripe carpels ovoid to ovoid-ellipsoid, dull dark brown, glabrescent, usually densely small lenticellate, 2–6.5 × 1.3–1.8 cm, ligneous, apically with a stout beak of 3–5 mm long; scars of perianth and stamens 5–10 × 5–14 mm. Seeds ellipsoid, ovoid, subcordate to irregularly shaped, 1–3 in each carpel, 10–15 × 8–12 mm.

*Distribution.* China and Vietnam. In CHINA. **Southern Fujian**: Guangdong, Kung Ping Shan, *Tsang W.T. 26866*; Yaichow, *How F.C. & N.K. Chun 70147*. **Guangxi**: Fang Cheng distr., *Tsang W.T. 26868*; Jingxi, *Ko S.P. 55702*; Shiwandashan, *Tso C.L. 23510*; Yangshou, *Qin H.F. 53*; Nanning, *Liang C.F. 34214*. **Hainan**: Boting, *Lau S.K. 27946*; Jianfong, *Chang H.T. 6081*; Lehui, *How F.C. 73242*; Lin Fa Shan, Lam Ko Distr., *Tsang W.T. (LU 15822) 323*; Lingshui, *Tso C.L. 43749*. **Yunnan**: Funing, *Wang C.W. 89653*; Malipo, *86545, Feng K.M. 13599*; Ping pien hsien, *Tsai H.T. 61621*.

*Ecology.* In evergreen broad-leaved forest, in shaded and mixed forests, along stream side, on moist sandy soil. Altitude: 350–1,000 m. Flowering April–June; fruiting September.

*Uses.* Heartwood brown-yellow, sapwood yellowish brown; wood straight-grained, fine- and even-textured, slightly heavy and durable, commonly used for furniture, plywood, and constructions.

*Collector's note.* Trees dark gray covered with purple hairs, flowers white, greenish white, yellowish or red, fragrant.

*Note.* *Michelia balansae* is a distinct species. Variations in the indument, size of the leaves, and length of the brachyblasts are very noticeable. The indument of *Michelia balansae* var. *appressipubescens* is appressed-pubescent on the leaves beneath and the petioles. However, a continuous variation of the indument can be seen within the species; for example, an indument with short and long, straight and slightly undulate, appressed, spreading hairs is found in the collections of *N. K. Chun & C. L. Tso 43749*; the indument is short, straight, and appressed in *S. P. Ko 52279* and *F. C. How 73480*. The brachyblasts are rather short in the collections of *Michelia balansae* var. *brevipes* collected in southeastern Yunnan, but intermediate forms are found throughout the area of distribution.

28. **Michelia chapensis** Dandy, J. Bot. 67: 223. 1929. TYPE: *Pételot 3379* (holotype, UC; isotypes, BM, NY). Figure 16.

*Michelia nitida* B. L. Chen, Acta Sci. Nat. Univ. Sunyatseni (Guangzhou) 1: 111. 1988. TYPE: *B. L. Chen & C. N. Mai 87TO33* (holotype, SYS).

Tree to 15–30 m high and 1 m diam.; bark gray-brown, smooth; young twigs brown to dull dark brown, 2–3 mm diam., smooth, glabrous or at first densely appressed-tomentellous with short, straight, brownish hairs, later glabrescent, with suborbiculate, white lenticels; old ones gray to brownish, fissured longitudinally; terminal buds narrowly ovoid, ca. 1 cm long. Stipules glabrous to puberulent or tomentellous outside, free from the petiole. Leaves coriaceous or thinly coriaceous, glabrous, pale brown when dry on both surfaces, obovate or obovate-oblong, occasionally elliptic-oblong or elliptic, 5.5–16 × 2.6–6.5 cm; apex acuminate to subacuminate, base cuneate to obtuse or rounded, slightly unequal; midrib prominent below, impressed above; nerves visible on both sides, in 9–12 pairs, reticulation coarse. Petiole slender, longitudinally grooved above, glabrous or ± minutely appressed-pubescent, 1.5–2.5 cm long, without scars. Brachyblasts tomentellous or puberulent, 3–11 mm long, 2–4 mm wide at top, pedicles 0–3 mm long; bracts 3–4, tomentellous or puberulent outside. Tepals 6, yellow to pale yellowish, glabrous or puberulent outside at the very base, subsimilar, the outer 3 (narrowly) obovate-oblong, convex outside, 3–3.5 cm long, the inner tepals slightly narrower; stamens 14–22 mm long, connective appendage triangular, 1–1.5 mm long, filaments glabrous, ca. 4 mm long; gynoecium glabrous but sometimes sparsely hairy, narrowly cylindric, entirely hidden by the androecium or slightly exceeding it, 11–15 mm long; gynophore 5–7 mm long, silver gray tomentellous with appressed hairs; carpels many, with same indument as gynophore. Fruiting brachyblasts 6–12 × 3–5 mm. Fruits cylindric, 3–10 cm long; ripe carpels 1–14 or more, oblong to ovoid, 6–15 × 8–10 mm, apically short-beaked, sparsely beset with inconspicuous lenticels; gynophore ± pubescent, 8–12 × 3–4 mm; scars of perianth and stamens on torus 4–5 mm long. Seeds obovoid to oblong-ovoid, ca. 10 × 6 mm.

*Distribution.* China and northern Vietnam. In CHINA: **Guangdong**: Kook Kaing, *Ko S.P. 50777*; Kwai Shan, *Tsang W.T. 28559*; Lok Chong, *Tso C.L. 21033*; Nanxiong Xian, *Liu Y.Z. 1*. **Guangxi**: Damiaoshan, *Chen T.C. 707*; Debao, *Chang C.C. 13670*; Gongdeng, *He J.D. 5040*; Guan Xian, *Chen Z.Z. 52375*; He Xian, *Li Y.K. 401573*. **Guizhou**: Congjiang, *Yuan J.M. 692*; Liping Xiang, *Yuan J.M. 373*. **Hunan**: Zixing Xian, *Liang P.H. 86163*. **Jiangxi**: Chongyi, *Nie M.X. 8831*; Jingan, *Gongda 1547*; Shangsa, *Yang X.X. 831164*. **Yunnan**: Xichou, *Wu C.A. 62012*; Marlipo, *Feng K.M. 13973*.

*Ecology.* In evergreen broad-leaved forests. Altitude: 500–1,650 m. Flowering March–April; fruiting August–October.

*Uses.* Wood is used for general construction and furniture, the tree is grown as an ornamental.

*Note.* *Michelia chapensis* is one of the widespread species in China. It is distinguished by glabrous leaves, petioles without scars, 6 tepals, and gynoecium generally hidden by the androecium. The taxa reduced above are essentially the same as *Michelia chapensis*. However, the gynoecium in *Michelia constricta*, *Michelia brachyandra*, and *Michelia nitida* is slightly exserted from instead of hidden within the androecium. *Michelia brachyandra* generally possesses a glabrous gynoecium, but sometimes it is hairy. Thus, usually the gynoecium of *Michelia chapensis* is glabrous. The length of the gynoecium varies from hidden to clearly exserted.

29. **Michelia leveilleana** Dandy, Kew Bull. 1927: 263. 1927. *Michelia cavaleriei* H. Léveillé, Feddes Repert. Spec. Nov. Regni. Veg. 9: 459. 1911, nom. illeg. non Finet & Gagnep. (1906). TYPE: *J. Cavalerie 3045* (holotype, E; isotypes, K, P). Figure 17.

*Michelia longipetiolata* C. Y. Wu ex Law & Y. F. Wu, Acta Bot. Yunnanica 10, 3: 336, t. 2. 1988. TYPE: *P. H. Yu 251* (holotype, PE).

Tree ca. 15 m by 30 cm diam.; young twigs slender, 2–3 mm diam., black-brown, appressed-tomentellous with straight, dark brown to rufous hairs, glabrescent, sparsely lenticellate; buds ovoid, ca. 1 cm long, rufous tomentose. Stipules glabrous to rufous tomentose, free from the petiole. Leaves coriaceous, dark green, glabrous above, pale green, at first rufous pubescent, later glabrescent beneath, elliptic, broadly elliptic, ovate, obovate, to narrowly obovate, 7.6–15 × 2.8–4.5 cm; apex acuminate or acute, acumen 5–10 mm long, base cuneate, broadly cuneate, obtuse, sometimes unequal; midrib impressed above, prominent below, nerves fine, somewhat obscure, more visible below than above, in 9–15 pairs, reticulation rather faint. Petiole minutely pubescent, glabrescent, 2.5–4.5 cm long, without stipular scars. Brachyblasts stout, tomentose with dark brown to rufous hairs, 5–10 × 4–5 mm, pedicles 4–6 mm long; bracts 2–3, tomentose with long, straight to undulate, dark brown

FIGURE 17. *Michelia leveilleana* Dandy. Branch with flower buds and fruit. Based on *W. C. Chen & C. T. Hwa 889* (K). Drawing by Joop Wessendorp, Rijksherbarium, Leiden.

hairs outside. Tepals 6, sometimes 4 or 7, white, glabrous, the outer 2–3 oblong to narrowly elliptic-oblong, 30–35 × 7–15 mm, the inner tepals elliptic to spathulate; stamens many, 12–15 mm long, connective appendage narrowly triangular, ca. 0.5 mm long, filaments 2–3 mm long, glabrous; gynoecium cylindric, 1–2 cm long, hidden by the androecium in bud but slightly longer than the androecium when flowers open; carpels many, tawny tomentellous; styles glabrous, ca. 1 mm long; gynophore tomentellous, 5–10 mm long; ovules more than 12 in each carpel; scars of perianth and stamens on torus 2–5 mm long. Fruiting brachyblasts 3 cm long. Fruits 7–9 cm long; gynophore 1–1.5 cm long, abortive carpels ca. 20; ripe carpels 7–10, ovoid, 12 × 9 mm, dark brown, lenticellate; scars of perianth and stamens 5–8 mm along the torus.

*Distribution.* CHINA. **Guizhou**: Bijie Xian, *Yu P.H. 251*; Leigongshan, *Li Y.K. 8879*. **Hubei–Sichuan, Metaseqoia area**: *Hwa C.T. 357*. **Hunan**: Dao Xian. **Yunnan**: Xiliang, *Dian Dongbei Exped. 754*; Zhenxiong, *Yu P.H. 1060*.

*Ecology.* In forest. Altitude: 1,000 m.

*Note.* After its publication by Dandy (1927), this species was never mentioned again in the literature. Type specimens of *Michelia leveilleana* bear flower buds and open flowers and possess obovate leaves. The type of *Michelia longipetiolata* only has fruits, and the leaves are broadly elliptic with relatively long petioles. Fortunately, we were able to study some collections (*C. T. Hwa 357*, *W. C. Cheng & C. T. Hwa 889, 938*), which were identified as *Michelia wilsonii* by S. Y. Hu, gathered from Hubei to Sichuan. These collections closely resemble the type of *Michelia leveilleana* and show the variations in shape and size of the leaves as well as length of the petioles, not only in different collections but within single specimens, e.g., *W. C. Cheng & C. T. Hwa 889*. Therefore, it is clear that these variations are continuous throughout the area of distribution. We conclude that all of these collections belong to a single species.

30. **Michelia martinii** (H. Lév.) Finet & Gagnep. ex H. Lév., Fl. Kouy Tchéou: 270. 1914. *Magnolia martini* H. Lév., Bull. Soc. Agric. Sarthe 59: 321. 1904. TYPE: *L. Martin & E. Bodinier 2066* (holotype, E; isotope, P).

*Michelia bodinieri* Finet & Gagnep., Bull. Soc. Bot. France 53: 1906. TYPE: *Farges 1324* (holotype, P).
*Michelia longistaminata* Law, Bull. Bot. Res. (China) 5(3): 122. 1985. TYPE: *S. P. Kuo 80358* (holotype, IBSC; isotype, BM).

Tree to 20 m high and ca. 50 cm diam.; bark gray, smooth; young twigs 2–4 mm diam., yellow-green to dull dark brown, smooth, glabrous to occasionally appressed-pubescent; old ones rough, sparsely lenticellate; buds ovoid or elliptic-ovoid, densely pubescent. Stipules densely pubescent with long, straight to slightly undulate, spreading, brownish or rarely gray hairs, free from the petiole. Leaves thinly coriaceous to coriaceous, dark green, glossy above, glabrous on both sides, elliptic-oblong, oblong, broadly to narrowly elliptic or narrowly obovate, 6.7–18 × 2–5.5 cm; apex short-acuminate to acute, base attenuate to cuneate or broadly cuneate; midrib impressed above, nerves fine, visible on both sides, more prominent below than above, in 7–17 pairs; reticulation laxly netted, conspicuous below. Petiole glabrous, 1.5–2 cm long, without scars. Brachyblast short and stout, 7–15 × 3–9 mm, densely pubescent with same indument as stipules, pedicle very short; bracts 3–6, densely pubescent outside. Flower bud ovoid to long-ovoid, 3–4.5 cm long; tepals 6(–8), white to yellow, glabrous or tomentose outside toward the base, subsimilar to unequal, the outer 3 broadly obovate, obovate-oblong, narrowly obovate to spathulate, 5–7 × 1.7–5 cm, the inner 3–4 smaller than the outer ones, broadly elliptic to narrowly oblong, short-clawed, 3–6 × 0.8–2.8 cm; stamens 8–25 mm long, connective appendage long-triangular, 0.5–2 mm long, filaments 3–7 mm long; gynoecium narrowly cylindric, glabrous, 8–18 mm long; gynophore glabrous, 6–12 mm long; carpels many, glabrous; ovules 10 or more in each carpel; scars of perianth and stamens on torus 2–5 × 5 mm. Fruiting brachyblast 13–14 × 4–9 mm, glabrescent. Fruit 6.5–10 cm long; ripe carpels dull brown, subglobose to ellipsoid, 1–16 × 4–11 mm. Scars of perianth and stamens 6–8 mm; gynophore under fruit ca. 15 mm long.

*Distribution.* China and Vietnam. In CHINA: **Guangdong**: Yuyuen, *Ko S.P. 52762*; Zhanjiang, *Nanzhidi 3719*. **Guangxi**: Huanjang, *Liang C.X. 77- 15*. **Guizhou**: Siuwen, *Tsiang Y. 8671*; Bijie, *Li Y.K. 11284*; Daping Xian, *Qian Bei Exped. 2250*. Henan. Southern Hubei. **Hubei–Szechwan, Metaseqoia area**: *Hwa C.T. 441*. **Sichuan**: Tchen Kéou Tin, *Farges R.P. 1394*; Mt. Omei, *Chow H.C. 8255*. **Yunnan**: Guangnan, *Wang C.W. 87594*; Mar li po, *Feng K.M. 13274*; Mengtze, *Henry A 11441*.

*Ecology.* In forests. Altitude: 1,000–2,000 m. Flowering February–March; fruiting August–September.

*Uses.* The flowers are extracted for volatile oil.

*Collector's notes.* Big tree, in mixed forests, on open hillside or near temples. Flowers fragrant.

*Note.* The type specimens of *Michelia bodinieri* and *Michelia longistaminata* strikingly resemble those of *Michelia martinii*. This species varies continuously throughout its range in texture of the leaves, width and length of brachyblasts, and length of stamens. The collections from Vietnam possess rigid coriaceous leaves, stout brachyblasts, and rather long stamens; the collections from Guangdong named *Michelia longistaminata* possess some extreme characters, such as thin leaves, thin brachyblasts, and rather long stamens. Because of the continuous variation, *Michelia longistaminata* is reduced here to *Michelia martinii*.

31. **Michelia xanthantha** C. Y. Wu ex Law & Y. F. Wu.

See under dubious species.

**4. Michelia** section **Micheliopsis** (Baill.) Dandy in Praglowski, World Pollen Spore Fl. 3: 5. 1974. *Magnolia* sect. *Micheliopsis* Baill., Adansonia 7: 4, 66. 1866. *Liriopsis* Spach,

Nat. Vég. 7: 460. 1839, non *Liriopsis* Reichenb. (1828). TYPE SPECIES: *Michelia figo* (Lour.) Sprengel.

Stipules adnate to the petiole, the latter short, not exceeding 10 mm. Bracts 3 (or occasionally 2 or 4). Tepals 6 or more, 3–4-merous, subsimilar. Usually shrubs or small trees. Fruits apocarpous.

32a. **Michelia figo** var. **figo.**

Shrub to small tree to 15 m high and 30 cm diam.; bark gray; young twigs slender, 1–2 mm diam., brown gray, purple-brown, pubescent with short, straight hairs, glabrescent, the indument at first brown, later dark brown to gray; old twigs white-gray to purple-brown, irregularly longitudinally fissured. Stipules densely pubescent or tomentose, adnate to the petiole, scars to half of its length, 2–3 mm long. Leaves chartaceous to thinly coriaceous, dark green, glossy, glabrous or rather sparsely scattered-pubescent above, light green, appressed-pubescent with short to long, straight to slightly undulate, brown to dark brown hairs, glabrescent beneath, obovate-elliptic to narrowly obovate-elliptic or elliptic to broadly elliptic, occasionally subrhombic, 2–12(–17) × 1.5–4.5 cm; apex subcaudate, acuminate, acumen 5–20 mm long, sometimes acute, base cuneate to obtuse; midrib slightly impressed toward the base, densely pubescent, glabrescent above, prominent, densely long-pubescent, glabrescent beneath, nerves obscure on both sides, in 7–12 pairs, reticulation lax, hardly visible on both sides. Petiole densely spreading-pubescent, 3–5 mm long, scarred. Brachyblast densely spreading-pubescent, variable in length and width, 4–20(–27) × 2–4 mm, pedicle absent; bracts ca. 3, densely pubescent or tomentose outside. Flower bud ovoid to ellipsoid, 1.5–2 cm long; flower sweet-scented, white or yellow, often tinged with purple, sometimes purplish; tepals 6, subsimilar, fleshy, glabrous, oblong-obovate, obovate to spathulate, 1.5–2.5 × 0.6–1.2 cm; stamens 7–11 mm long, connective appendage triangular, 0.5–1 mm long, filaments glabrous, 1.5–3 mm long; gynoecium subcylindric, exceeding above the androecium, 2–11 mm long; gynophore pubescent with spreading, yellow to brown hairs, occasionally glabrous, 1–3 mm long; carpels many, glabrous or tomentellous; scars of perianth and stamens on torus 1–3 mm long. Fruiting brachyblast 7–20(–27) × 2–4 mm. Fruit 1–5 cm long; ripe carpels 1–15, subovoid to subglobose, black-brown to brown, ± pubescent, with a ca. 1-mm-long beak at apex, 7–12 × 7–9 mm; gynophore 2–11 mm long; scars of perianth and stamens 2–5 mm long.

*Distribution.* Southeastern CHINA. **Anhui**: Fujian, Amoy, Nanputo, *Chung H.H. 5921*; Buon Kang, *Chung H.H. 3374*; Foochow, *Tang S.G. 7167*; Hok Chang, *Tang S.G. 16106*; Kiuliang, *Chung H.H. 6815*. **Guangdong, Guangzhou, on hills**: *Chow K.S. 145*; Kau Fung, Loh Chang Distr., *Tsang W.T. 20992*; Lofoushan, *Chun N.K. 40574*; Ngok Shing Shan, *Taam Y.W. 542*; Pan Ling Tsze, *Chun W.Y. 5856*. **Guangxi**: Tung Hoo, *Ching R.C. 5613*; Baishou, *Li Z.J. 653*; Lingui, *Huang S.L. 2000014*; Longsheng, *Qin H.F. 70033*; Xingan, *Chen Z.Z. 51516*. **Jiangxi**: Dagangshan, *Yao Kan 9283*; Kouyang, *Tsiang Y. 10012*; Sai Hang Cheung, *Lau S.K. 4047*; Yi Feng, *Hsiung Y.K. 6307*. **Zhejiang**: Nan Hoo, *Hu H.H. 190*; Ping Yung, *Ching R.C. 1986*. Widely cultivated in most of China and other warm parts of the world.

*Ecology.* In forests. Altitude: 60–1,000 m. Flowering March–May; fruiting July–August.

*Collector's note.* Flowers sweet-scented, odor detected at a distance.

*Uses.* Flowers used for perfuming tea; leaves for volatile oil and medicinal purposes; shrub grown as an ornamental.

*Note.* No original Loureiro specimen has been traced. However, there is no doubt that this is the plant described by Loureiro as *Michelia figo.*

The species varies greatly in the following characters: size and shape of the leaves, length and width of the brachyblast, size and color of the flowers, and the indument of the carpels. For example, the carpels usually are glabrous, but a continuous variation of the indument of the carpels can be observed throughout its distribution.

None of the type specimens or other collections of *Michelia amoena* and *Michelia brevipes* were available for study. We consider both as synonymous with *Michelia figo,* according to their description and the published figures.

Sometimes abnormalities are found, such as leaf-like bracts, more-flowered brachyblasts, terminal unibracteate flowers, and carpellody of the inner stamens.

32b. **Michelia figo** var. **crassipes** (Law) B. L. Chen & Nooteboom, stat. nov. *Michelia crassipes* Law, Bull. Bot. Res. (China) 5(3): 121, t. 1. 1985. TYPE: China. Guangdong: Lechang, 1,000 m, *S. H. Chun 3115* (holotype, IBSC not seen).

Shrub or small tree, 2–5 m high; bark gray-brown; buds, young twigs, stipules outside, petiole and brachyblasts densely pubescent with long, tawny or rufous hairs. Young twigs 2–3 mm diam. Stipules adnate to very high on the petioles, scars to whole length of the petioles. Leaves thinly coriaceous, dark green, glossy, glabrous above, pale green, at first brown to rufous tomentose everywhere, especially long-hairy on the veins, later glabrescent beneath, obovate or narrowly obovate, rarely narrowly elliptic, 7–13 × 2.5–4 cm; apex short- or long-acuminate, base cuneate to broadly cuneate; nerves fine, in 6–9 pairs. Petiole 2–4 mm long. Brachyblasts stout and short, 3–4 mm long, flowers heavily scented, purple-red to dark purple; tepals 6, subsimilar, long-elliptic, 18–20 × 6–8 mm; stamens ca. 1 cm long; gynoecium short-cylindric, densely pubescent, shorter than the androecium, ca. 8 mm long; gynophore ca. 2 mm long; carpels ovoid, densely tomentellous, 3.5–5 mm long; styles ca. 2 mm long. Fruits 2.5–5 cm long; ripe carpels compressed ovoid to subglobose, glabrescent, papilliferous; fruiting brachyblasts stout and short, 10–20 × 3–5 mm.

*Distribution.* CHINA. **Northern Guangdong**: *Chen B.L. 81007, Zheng P. 10406.* **Northeastern Guangxi**: Ruyuan, *Chen B.L. 81006*; Jinxiu Xian, *Pen Z.H. 51279.* Also in southern Hunan.

*Ecology.* In forests. Altitude: 300–700 m. Flowering April–May; fruiting August–September.

*Note. Michelia crassipes* is treated as a variety of *Michelia figo* because there are few vegetative characters to separate the two. However, the tepals are purple, the brachyblast is stout, and the gynoecium is shorter than the androecium in *Michelia crassipes. Michelia figo* has white to yellow flowers with purple, short to long, slender brachyblasts, and the gynoecium exceeding the androecium. We observed that the flowers are variable when *Michelia crassipes* is cultivated in Guangzhou, e.g., brachyblasts become slender, the tepals are rose to pale rose instead of purple, the gynoecium is longer than the androecium. In cultivation the flowers of *Michelia crassipes* become more or less like those of *Michelia figo.* Therefore, we consider *Michelia crassipes* to be a wild strain of *Michelia figo.*

33. **Michelia yunnanensis** Franchet ex Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 43, t. 6A. 1905. TYPE: *Delavay 4848* (holotype, P; isotypes, E, K).

*Michelia yunnanensis* Franchet ex Finet & Gagnep. var. *angustifolia* Finet & Gagnep., Bull. Soc. France (Mémoires) 4: 44, t. 6B. 1905. TYPE: *Bodinier & Ducloux 168* (holotype, P; isotypes, BM, K).

*Michelia dandyi* Hu, Bull. Fan. Mem. Inst. Biol. (Peiping) 8: 34. 1937. TYPE: *H. T. Tsai 53380* (holotype, PE; isotype, A).

Shrub to small tree, 6–12 m high; buds, young twigs, stipules outside, young leaves beneath, petiole, brachyblast, bracts outside, gynophore and carpels appressed- to spreading-tomentose or pubescent with short to long, straight to slightly undulate, brown, rufous, black-brown to gray hairs; young twigs 1.5–2 mm diam., olive-green, gray-brown to purple-brown. Stipules adnate to nearly the whole length of the petiole, stipular scars 3–7 mm long. Leaves membranous to coriaceous, bright green, ± brown pubescent, glabrescent above, greenish, at first densely or sparsely pubescent, finally glabrescent beneath, obovate or narrowly obovate to elliptic, 2–10 × 1–4 cm; apex obtuse or rounded, or acute to short-acuminate, occasionally retuse, base cuneate to obtuse; midrib slightly impressed, densely pubescent, especially

toward the base above, prominent, densely or sparsely pubescent, glabrescent beneath, nerves obscure or visible on both sides, in 7–9 pairs, reticulation faint on both sides when dry. Petiole stout, 5–10 mm long. Brachyblast 4–9(–14) × 2–2.5 mm, pedicle absent; bracts 3. Flower bud ovoid to narrowly ovoid, 2–3 cm long; flower heavily scented; tepals 6–12(–17), white, yellowish white to greenish white, subsimilar, the outer 3–4 obovate, broadly obovate to obovate-elliptic, abruptly constricted near the base, becoming rather short-clawed, glabrous to tomentellous outside at the base, 2.2–3.5 × (0.8–)1.4–1.8 cm, the inner 3–8 obovate, oblong to subspathulate, 2–2.2 × 0.9–1.2 cm; stamens 5–10 mm long, connective appendage very short-triangular or semiorbicular, 0.5–1 mm long, filaments 2–3 mm long; gynoecium subovoid to oblong, longer than the androecium, 3–5 mm long; gynophore 5–8 mm long; carpels ca. 15 or fewer; ovules 3–8; scars of perianth and stamens on torus 0.5–3 mm long. Fruiting brachyblast 4–9 × 2–3 mm. Fruit 1–4.5 cm long; ripe carpels 1–8, subglobose, dull brown, ± pubescent, lenticellate, sessile, apically with a 1–1.5 mm long beak, 7–14 × 7–12 mm; gynophore 7–10 mm long; scars of perianth and stamens 2–5 mm long. Seeds 1–2 in each carpel, ellipsoid to ovoid, 6–8 × 5–7 mm.

*Distribution.* CHINA. **Guizhou**: Anlong Xian, *Dang C.Z. 886*. **Sichuan**: between Yimen and Pai kuo wan, *Schneider C. 607*. **Yunnan**: Likiang snow range, *Rock J.F. 10661*, *Wang C.W. 70468*; Juanchiang, *Henry A 13277*; Kunming, *Sino-Amer. Bot. Exped. 1413*; Mar li po, *Feng K.M. 12636*; Mengtze, *Henry A 9429*.

*Ecology.* In forest or thickets. Altitude: 1,100–2,300 m. Flowering March–April; fruiting August–September.

*Uses.* Flowers and leaves are used as spices; the tree is grown as an ornamental.

*Note.* *Michelia yunnanensis* varies in shape and size of the leaves. Although variety *angustifolia* has relatively narrow and small leaves, intermediate forms can be found throughout the range. *Michelia dandyi* is similar to *Michelia yunnanensis*.

**5. Michelia** section **Tsoongiodendron** Nooteboom & B. L. Chen. *Tsoongiodendron* W. Y. Chun, Acta Phytotax. Sin. 8: 7. 1963. TYPE SPECIES: *Tsoongiodendron odorum* Chun = *Michelia odora* (Chun) Nooteboom & B. L. Chen.

Stipules adnate to the petiole. Tepals 9, subsimilar. Fruits syncarpous, very large; follicles crowded, sessile, woody, large, without a beak, rounded on the back.

34. **Michelia odora** (Chun) Nooteboom & B. L. Chen, comb. nov. *Tsoongiodendron odorum* Chun, Acta Phytotax. Sin. 8, 4: 281, 9 tt. 35, 36. 1963. TYPE: *S. P. Ko 51928* (holotype, IBSC; isotype, BM not seen).

Tree to 25 m high and 1 m diam.; bark grayish brown, deeply wrinkled; buds, stipules outside, young twigs, leaves beneath (especially on the midrib and nerves), petiole, brachyblast, bracts outside, gynophore and carpels densely covered with an indument of short to long, straight to undulate, spreading, yellowish to brown or clear hairs; young twigs 2–3 mm diam., dull black-brown; old ones gray-brown, longitudinally wrinkled, irregularly transverse-fissured, lenticellate. Stipules adnate to the petiole from the lower base to its middle or higher, stipular scars 6–18 mm long. Leaves thinly coriaceous, green, glossy, glabrous but densely pubescent on the midrib above, greenish beneath, elliptic or narrowly to broadly obovate-elliptic, 8–20 × 3.5–7 cm; apex short-acuminate, occasionally acute, base cuneate to rounded; midrib slightly impressed above, conspicuously elevated below, nerves in ca. 12 pairs, hardly visible above, reticulation laxly netted, prominent beneath. Petiole 0.9–3 cm long. Brachyblast 7–10 × 2–3 mm, pedicle absent, bracts 2–3. Flower white to yellowish, very fragrant; tepals 9, subsimilar, narrowly obovate-elliptic, the outer three, 17–20 × 6.5–7.5 mm, the innermost tepals three, ca. 15–16 × 5 mm; stamens 40–45, 7.5–8.5 mm long, connective appendage very short, ca. 0.5 mm long, filaments 1.5–3 mm long; gynoecium subovoid, 3–4 mm long, shorter than androecium; gynophore stout, 2–2.5 × 1–2 mm; carpels 10–12, narrowly ovoid; styles glabrous, ca. 2 mm long. Fruiting brachyblast 1–2 × 1–1.3 cm. Fruit syncarpous, long-elliptic, sometimes subglobose because of the abortion of the upper carpels, 13–16 × 7–9 cm; ripe carpels crowded, sessile, woody, large, without a beak, 4–6 cm long; the exocarp thin and fleshy, olive-green, white lenticellate, dark brown and yellow-dotted when dry, mesocarp woody, 1–2 cm thick, endocarp thin, greenish yellow. Seeds 4–6 in each carpel, ellipsoid to irregularly shaped, ca. 15 × 8 mm.

*Distribution.* China and northern Vietnam. In CHINA. **Fujian**: Jing Xian, *Ye G.D. 1690*. **Guangxi**: Longjin, *Tam P.C. 57604*. **Guangdong**: Lockchong distr., *Ko S.P. 51109*. **Hainan**: *Chun N.K. & C.L. Tso 44257*. Also in southern Jiangxi and southeastern Yunnan.

*Ecology.* In forest. Altitude: 500–1,000 m. Flowering March–April; fruiting September–October.

*Uses.* Wood white, straight-grained, fine-textured, light and hard; used for furniture, building, plywood, musical instruments, and work not in contact with the soil; tree grown as an ornamental.

*Collector's note.* Flower light red.

*Note.* This species is characterized by very small flowers and huge syncarpous fruits. Its leaves are easily confused with those of *Michelia balansae*, which has, however, free stipules.

Dandy (ex Gagnepain, 1938) already mentioned the species as a nomen nudum, *Michelia gravis*.

**6. Michelia** section **Paramichelia** Nooteboom & B. L. Chen, stat. et sect. nov. *Paramichelia* H. H. Hu, Sunyatsenia 4: 142. 1940. TYPE: *Paramichelia baillonii* (Pierre) Hu = *Michelia baillonii* (Pierre) Finet & Gagnep.

Stipules adnate to the whole length or almost the whole length of the petiole. Bracts 3. Tepals 12, 4-merous, subsimilar. Fruits syncarpous.

35. **Michelia baillonii** (Pierre) Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 46. 1905. *Magnolia baillonii* Pierre, Fl. Forest. Cochinch. 1: t. 2. 1880. *Paramichelia baillonii* (Pierre) Hu, Sunyatsenia 4: 144. 1940. TYPE: *Pierre 750* (holotype, A; isotype, K).

*Talauma spongocarpa* King, Magnol. Brit. India 3: 205, t. 47 bis. 1891. *Aromadendron spongocarpum* (King) Craib, Fl. Siam 1: 25. 1925. TYPE: *Calcutta Botanic Garden collector* (*Badal Khan*) *102* (holotype, CAL; isotype, L).

*Talauma phellocarpa* King, Magnol. Brit. India 3: 205, t. 47 ter. 1891. *Michelia phellocarpa* (King) Finet & Gagnep., Bull. Soc. Bot. France (Mémoires) 4: 44. 1905 TYPE: *Peal s.n.* (holotype, CAL; isotypes, BM, L, US).

Huge tree to 50 m high and 1 m diam.; young twigs slender, 2–3 mm diam., dull brown, densely pubescent with long, straight to slightly undulate, ± spreading, yellowish to brownish hairs; old ones black-brown, sparsely white lenticellate. Stipules densely pubescent with same hairs as the young twigs, adnate to the petiole nearly to half its length, scars 6–10 mm long. Leaves chartaceous, above dark green, appressed-pubescent with slender, straight, clear to yellowish hairs, brown pubescent on the midrib when young, glabrescent when old, below pale green, pubescent with short and long to rather long, straight to undulate, yellowish to brownish hairs at first, finally glabrescent, narrowly obovate, obovate, obovate-elliptic to narrowly elliptic, usually somewhat unequal, 6–16.5(–23.5) × 3–8.5 cm; apex short-acuminate to acute; base cuneate or broadly cuneate, sometimes rounded; midrib impressed above; nerves fine, obscure above, visible beneath, in 9–15 pairs; reticulation rather densely netted, faint on both sides when dry. Petiole densely pubescent, glabrescent, 1.5–3.5 cm long. Brachyblast slender to stout, 8–14 × 2–3 mm, yellowish tomentose, pedicle absent; bracts 3, densely yellowish or brown tomentose outside. Flower bud ovoid-cylindric, 2.7–3 mm long; flower heavily scented; tepals 12–18(–20), white or yellow-white, subsimilar, spathulate to obovate-linear, glabrous to pubescent outside toward the base, apex acuminate to acute, base attenuate to the base, usually becoming long-clawed, 23–35 × 2.5–7 mm; stamens 7–9 mm long, connective appendage narrowly triangular, 1–2 mm long, filaments glabrous, 1–2 mm long; gynoecium ovoid-cylindric, 6–9 mm long, longer than the androecium; gynophore yellow pubescent, 3–4 mm long; carpels densely yellow pubescent; styles red, glabrous; scars of perianth and stamens on torus 5–7 × 7–11 mm. Fruiting brachyblast dull black-brown, ± pubescent, 1–2 × 0.6 cm. Fruit syncarpous, ovoid, ovoid-ellipsoid, to irregularly shaped, dull gray-black, densely lenticellate outside, 3–9 × 2.5–4.5 cm; ripe carpels connate, falling off when maturing in irregular masses, midrib lignified and persistent in the form of an upcurved laterally compressed hook; gynophore 7–13 × 5–9 mm; scars of perianth and stamens 5–7 × 7–11 mm. Seeds subovoid, cordate to irregularly shaped, 7–10 × 6–7 mm.

*Distribution.* Assam, China, Thailand, Burma, Vietnam, and Cambodia. In CHINA. **Southern Yunnan**: Chenkang, Maliling, *Yu T.T. 17395*; Che-li Hsien, *Wang C.W. 78590*; Fo-Hai, *74653*; Lincang, *Xin J.S. 383*; Menglian Xian, *Menglian Exped. 10145*; Xishuang Banna, *Sino-Rossica Exped. 5627*.

*Ecology.* In forest. Altitude: 300–1,600 m. Flowering February–March; fruiting August–September.

*Uses.* Wood straight-grained, fine-textured, and durable; used for building, bridges, furniture, interior finish, and plywood.

*Collector's note.* Trees in mixed forests or thickets, fruits green-black, seeds with red aril.

*Note.* This species has not only a wide distribution, but also a considerable variation in shape and size of the leaves.

Hu (1938) named this species *Aromadendron yunnanensis*, nom. nudum.

DUBIOUS SPECIES

**Michelia chongjiangensis** Y. K. Li & X. M. Wang, Guizhou Sin. 3: 18. 1983. TYPE: China. Guizhou: Taiyangsun, Chongjiang, 1,300 m, *Y. K. Li 9294* (HGAS not seen) = *Michelia ?leveilleana* Dandy.

**Michelia caloptila** Law & Y. F. Wu, Bull. Bot. Res. (China) 4(2): 152, t. s.n. 1984. TYPE: China. Jiangxi: Zixi, *Jiangxi gong-da linxue-xi 80069* (IBSC not seen).

**Michelia elegans** Law & Y. F. Wu, Bull. Bot. Res. (China) 8(3): 71, t. 1. 1988. TYPE: China. Guangzhou: South China Botanic Garden, 27 Apr. 1986, *Y. W. Law 6109* (IBSC not seen) = *Michelia ?cavalerieri* Finet & Gagnep.

**Michelia laevifolia** Law & Y. F. Wu, Bull. Bot. Res. (China) 8(3): 72, t. 2. 1988. TYPE: China. Guizhou: Anlong, 1,500 m, 22 June 1960, *T. S. Chang 4852* (IBSC not seen) = *Michelia ?yunnanensis* Franchet ex Finet & Gagnep.

**Michelia sphaerantha** Z. S. Yue, Acta Bot. Yunnanica 9(4): 413, t. 1, 1987. SYNTYPES: *Z. S. Yue 83-111, 86-107* (KUN not seen).

*Note.* Yue meant to describe *Michelia sphaerantha* C.Y. Wu (in manuscript), later again published by Wu in Acta Bot. Yunnanensis 10: 335. 1988, nom. illeg., with another type. The latter is *Michelia masticata*. According to the drawing published by Yue and a leaf fragment we received from him, it appears that *Michelia sphaerantha* Z. S. Yue is a different species: it has its stipules adnate to the petiole. Study of the type is necessary to conclude its status.

11. **Michelia fujianensis** Q. F. Zheng, Bull. Bot. Res. (China) 1(3): 92, t. 1981. TYPE: China. Fujian: Sanming Shi, *K. R. Wu 79100* (in herb. Fujian Forestry College not seen).

Tree to 15 m, ca. 40 cm diam.; bark gray-brown to dark brown, smooth or slightly rough; buds, young twigs, petioles, and brachyblasts densely pubescent with gray or brown hairs. Stipules free from the petiole. Leaves thinly coriaceous, pubescent, glabrescent, especially on the midrib above, densely brown appressed-pubescent beneath, oblong to narrowly ovate-elliptic, 6–11 × 2.5–4 cm; apex acuminate to acute, base cuneate to obtuse; midrib prominent below, nerves prominent on both sides, in 8–9 pairs. Petiole 1–1.5 cm long. Brachyblast ca. 5 mm (15 mm?) long; bracts densely brown pubescent. Flower bud ellipsoid-ovoid, ca. 1.5 × 0.8–1 cm; tepals ca. 15 mm long, anthers ca. 5 mm long; gynoecium ovoid; gynophore densely pubescent with long hairs, ca. 2 mm long; carpels ca. 20 or more, gray pubescent. Fruiting brachyblast 5 mm long. Fruit ca. 3 cm long; ripe carpels 1–4, ovoid to subglobose, 1–1.5 cm long, short-stipitate.

*Distribution.* CHINA. **Fujian**.

*Ecology.* In forest. Altitude: below 500 m. Flowering February–April; fruiting August–October.

*Note.* The original description only mentioned "fruiting brachyblast 5 mm long." Later, Lin (1985) described "brachyblast stout, ca. 15 mm long" and "fruiting brachyblast 5 mm long." Obviously the length of the brachyblast was misrepresented by him.

We had no opportunity to study collections of *Michelia fujianensis*, but it seems closely allied with and might be conspecific to *Michelia cavaleriei*, especially in number of tepals and length of fruit, which are variable in that species.

8. **Michelia flaviflora** Law & Y. F. Wu, Acta Bot. Yunnanica 10(3): 340, t. 6. 1988. TYPE: *H. Wang 100120* (IBSC not seen).

Tree to ca. 15 m high; buds, young twigs, stipules, petiole, and brachyblasts yellowish tomentose; young twigs brown tomentellous; old ones white lenticellate. Stipules free from the petiole. Leaves thinly coriaceous, dark green, glabrous above, glaucous, brown sericeous beneath, narrowly elliptic or obovate-elliptic, 15–24 × 3.6–5.5 cm; apex acuminate, base cuneate; midrib slightly prominent to impressed above, nerves fine, in 16–24 pairs. Petiole dilatate toward the base, without scars, ca. 0.5–1.2 cm long. Brachyblasts ca. 1 cm long. Tepals 15, yellow, subsimilar; stamens ca. 90, 1.1–1.5 cm long, connective appendage triangular, 1–2 mm long; gynoecium narrowly ovoid, ca. 1.2 cm long, exceeding beyond the androecium; gynophore tomentellous, ca. 1 cm long, ovaries ovoid, densely villous, 4 mm long; styles glabrous, ca. 2 mm long.

*Distribution.* Vietnam and China. In CHINA. **Yunnan** (Pingbian).

*Note.* There was no material of *Michelia flaviflora* available. In Law's description, no dimensions of the flowers were given, but we think it represents a distinct species.

21. **Michelia shiluensis** Chun & Y. Wu, Acta Phytotax. Sin. 8(4): 286. 1963. TYPE: *Hainan Exped. 90669* (IBSC not seen).

Tree to 18 m high and 30 cm diam.; bark gray; twigs, leaves, and petiole glabrous; young twigs slightly black, smooth; old ones dull gray to purple-brown, somewhat rough, longitudinally striped and lenticellate; terminal buds narrowly ellipsoid, orange or gray sericeous, glabrescent, 10–12 × 4–5 mm. Stipules pubescent, free from the petiole. Leaves coriaceous, ± rigid, dark green above, paler green beneath, obovate, obovate-oblong, 8–14(–20) × 4–7(–8) cm; apex acute, base attenuate to cuneate or broadly cuneate; midrib impressed above, nerves in 8–12 pairs, reticulation densely netted, both nerves and reticulation conspicuously visible on both sides when dry. Petiole wide sulcate above, 1–3 cm long, without scars. Brachyblast ca. 1.7 cm long. Flowers white, cup-shaped; tepals 9, fleshy, obovate, convex outside, 3–4.5 × 1.5–2.5 cm; stamens 2–2.5 cm long, anthers 12–17 mm long, filaments reddish; gynoecium pubescent, 1.4–2.1 cm long; carpels many (ca. 25 or more), ovoid, 2.5–4 mm long; styles ca. 1.5 mm long. Fruiting brachyblast with 2–3 bract scars. Fruits 4–5 cm long, peduncles ca. 2–3 cm long; carpels usually partly fertile; ripe carpels obovoid or obovoid-ellipsoid, 8–12 mm long, short-beaked at the apex. Seeds broadly ellipsoid, ca. 8 × 6 mm.

*Distribution.* CHINA. **Hainan** (Dingfang, Baoting).

*Ecology.* In evergreen broad-leaved forests. Altitude: 200–1,500 m. Flowering March April; fruiting June–August.

*Uses.* Wood straight-grained, even and fine-textured, slightly heavy, with a characteristic odor and durable; used for furniture, musical instruments, and building; the tree is grown as an ornamental.

*Note.* No collections could be consulted, but this is probably a good species. However, the original description does not give enough key characters.

31. **Michelia xanthantha** C. Y. Wu ex Law & Y. F. Wu, Acta Bot. Yunnanica 10(3): 338, t. 4. 1988. TYPE: *Sino-Ussr Exped. 7046* (KUN not seen).

Tree to 30 m high and 1 m diam.; buds cylindric, glabrous, ca. 1.5 cm long; young twigs dark brown to gray-yellow, ca. 4.5 cm diam., sparsely lenticellate. Stipules glabrous, free from the petiole. Leaves thinly coriaceous, oblong to obovate-oblong, 15–17 × 6.2–7.5 cm; apex short-acuminate, base cuneate to rounded; glabrous on both sides; midrib slightly impressed above, prominent beneath; nerves in 11–18 pairs, reticulation prominent on both sides. Petiole without stipular scars, 2–2.5 cm long. Brachyblast glabrous, ca. 1.5 cm long. Tepals 6, yellow, fragrant, subsimilar, narrowly oblong or narrowly obovate, 4–5.5 × 1–1.5 cm; stamens 2.3–2.5 cm, anthers 1.8–2 cm long, filaments ca. 3 mm long, connective appendage short-triangular, 1–2 mm long; gynoecium cylindric, 1.8–2 cm long; gynophore 2–3 cm long; carpels many, ovate, densely gray pubescent, 3–4 mm long; styles ca. 1 mm long. Fruit pendent, ca. 21 cm long; ripe carpels dark gray-brown, sparsely lenticellate.

*Distribution.* CHINA. **Yunnan** (Xishuangbanna).

*Ecology.* In forests. Altitude: 1,350 m.

*Note.* We were not able to study the type specimen of *Michelia xanthantha*. However, based on the description this seems to be a good species.

**MAGNOLIACEAE** subfamily **LIRIODENDROIDEAE** (Barkley) Law Yuh-wu, Acta Phytotax. Sinica 22: 105. 1984. Liriodendraceae Barkley, Phytologia 32: 304. 1975.

Leaves 2–10(usually 4–6)-lobed, the apex truncate or widely emarginate; stipules always free from the petiole. Anthers extrorse. Fruiting carpels woody, indehiscent, samaroid, produced at the apex into a long winglike beak, indehiscent, caducous. Testa adherent to the endocarp.

One genus:

V. **Liriodendron** L., Sp. Pl.: 535. 1753. TYPE SPECIES: *Liriodendron tulipifera* L.

*Tree.* Leaves deciduous. Flowers terminal, solitary, bisexual. Tepals 9–17, 3-merous, subequal. The connective produced into a short appendage. Gynoecium sessile. Carpels numerous, free, the lowermost sterile. Ovules 2. Seeds 1–2 in each carpel.

*Distribution.* Two species, southeastern Asia and southeastern North America.

1. **Liriodendron chinense** (Hemsley) Sarg., Trees & Shrubs 1: 103 t. 52. 1903. *Liriodendron tulipifera* L. var.? *chinense* Hemsley, J. Linn. Soc. Bot. 23: 25. 1886. SYNTYPES: *Shearer s.n.* (1875), *Maries s.n.* (1877) not seen.

Tree to 40 m high, 1 m or more diam.; young twigs 2–4 mm diam., gray, gray-brown, dull brown to purple-brown, glaucescent, old ones dull purple or gray-black, lenticellate. Stipules yellow to brownish, glabrous, free from the petiole. Leaves mem-

branaceous to chartaceous, (3–)5.5–12(–18) × 3–9.5(–23) cm; apex 2-lobed, with a pair of lateral lobes near the base; glabrous on both sides, bright green above, glaucescent to glaucous beneath; midrib elevated beneath, nerves rather prominent below, in 5–7 pairs. Petiole slender, glabrous, 2.5–8 cm long. Peduncle glabrous, 8–9 × 3–4 mm; bract single. Flower bud ovoid, 4.5–7 cm long; flower cup-shaped; tepals 9, subsimilar, greenish to yellowish, the outer 3 calycoid, glabrous, obovate to obovate-elliptic, abruptly constricted near the base and becoming short-clawed, 2.5–4.5 × 1.5–2 cm, the inner tepals 6, erect, obovate, 3–4 cm long, lengthwise yellow-striate outside; stamens 20–22 mm long, connective appendage triangular, short, filaments 6–8 mm long; gynoecium ovoid-cylindric, ca. 7 × 6 mm, carpels yellow-green; scars of perianth and stamens on torus ca. 3 × 5 mm. Fruiting peduncle 1–1.6 × 0.3–0.5 cm. Fruit ovoid, 4.5–9 × 2 cm, ripe carpels samaroid nutlets, 2–3 × 0.4–0.6 mm.

*Distribution.* CHINA. **Anhui**: Huangshan, Bai Zhang Tan, *Deng & Yao 79147*. **Zhejiang**: Hangchow, *Chiao C.Y. herb. no. 18844*. **Guangxi**: Guanyang, *Chen Z.Z. 52523*; Xingan Xian, *Yu S.L. 900086*. **Guizhou**: Libo, *Huang D.F. 1623*; Fanchingshan, *Chen J.C. 745*. **Hunan**: Dao Xian, *Yu S.L. 61528*. **Hubei**: Chienshih Hsien, *Chow H.C. 1094*. **Jiangsu, Nanjing**: *Chang H.T. 5396*. **Jiangxi**: Lushan, *Chang H.T. 5309*; Kuling, *Chiao C.Y. herb. no. 18560*. **Sichuan**: Hsiu-shan-hsien, *Tu & Sun 4070*. **Yunnan**: Sichour Hsien, Shiangpyng-shan, *Feng K.M. 11447*; Kunming, *Chang H.T. 5094*. Also in southern Shaanxi and cultivated in Taiwan and North Vietnam.

*Ecology.* In mixed forests, growing particularly well on sandstone, granite, and sandshale formations. Altitude: 500–1,700 m. Flowering May; fruiting September–October.

*Uses.* Wood reddish brown, fine-textured and straight-grained, used for furniture; bark for medicinal purposes; because of the shape of leaves, this is an especially ornamental tree.

*Collector's notes.* Tree, growing along sandy or rocky slopes, sometimes by roadsides and streams; bark pale gray; stipules tinged red at apex; flowers yellowish; fruits green when young, brown later.

*Note.* Finet & Gagnepain (1905) treated this species as *Liriodendron tulipifera* L.

2. **Liriodendron tulipifera** L., Sp. Pl. 1: 535. 1753 [*Tulipifera virginiana* Hermann, Hort. Ludg.-Bat. Cat.: 612, t. 613. 1687]. *Liriodendron procerum* Salisb., Prodr. Stirp. Chap. Allerton: 379. 1796. *Liriodendron truncatifolium* Stokes, Bot. Mat. Med. 3: 233. 1812. TYPE: t. 613 (P. Hermann, 1687).

Tree to 60 m high, 3.5 m diam.; bark deep longitudinally fissured; brown to purple, often pruinose. Leaves ca. 7–12 cm long; apex 2-lobed, with 2–3 lateral lobes, minutely white hairy when young, soon glabrous beneath. Petiole ca. 5–10 cm long. Flowers cup-shaped, tepals 9, outer tepals 3, green, calycoid, patent, inner tepals 6, green-yellow, erect, ovate, ca. 4–6 cm long, inside with orange nectaries below the middle; anthers ca. 1.5–2.5 cm long, filaments ca. 1–1.5 cm long; gynoecium yellow-green. Fruits ca. 7 cm long, nutlet samaroid, pale brown, ca. 5 mm long, apex pointed, the nutlets of the lower parts usually persistent.

*Distribution.* Native of northern America (in southern Ontario and the eastern and southeastern United States); cultivated in Kunming, Lushan, Nanjiang, and Qingdao.

*Ecology.* Flowering May; fruiting September–October.

LIST 1. List of taxa and keys in the order in which they appear in the text. Numbering system corresponds to that in the text.

Magnoliaceae
KEY TO THE GENERA OF MAGNOLIACEAE
MAGNOLIACEAE Subfamily MAGNOLIOIDEAE
Tribe Magnolieae
Tribe Michelieae
Tribe Magnolieae
**I.** Magnolia
KEY TO THE SUBGENERA AND SECTIONS OF MAGNOLIA
KEY TO THE SPECIES OF MAGNOLIA primarily based on floral characters
KEY TO THE SPECIES OF MAGNOLIA primarily based on fruit characters
**a.** Magnolia subg. Magnolia
**1.** Magnolia sect. Gwillimia
KEY TO THE SPECIES OF MAGNOLIA SECTION GWILLIMIA
1. Magnolia albosericea Chun & C. H. Tsoong.
2. Magnolia championii Benth.
3. Magnolia coco (Lour.) DC.
4. Magnolia delavayi Franch.
5. Magnolia henryi Dunn.
6. Magnolia phanerophlebia B. L. Chen

**2.** Magnolia sect. Rytidospermum
KEY TO THE SPECIES OF MAGNOLIA SECTION RYTIDOSPERMUM
7. Magnolia hypoleuca Siebold & Zucc.
8. Magnolia officinalis Rehder & E. H. Wilson.
9. Magnolia rostrata W. W. Smith.

**3.** Magnolia sect. Oyama
KEY TO THE SPECIES OF MAGNOLIA SECTION OYAMA
10. Magnolia globosa Hook, f. & Thomson.
11. Magnolia sieboldii K. Koch.
12. Magnolia sinensis (Rehder & E. H. Wilson) Stapf.
13. Magnolia wilsonii (Finet. & Gagnep.) Rehder.

**4.** Magnolia sect. Gynopodium
KEY TO THE SPECIES OF MAGNOLIA SECTION GYNOPODIUM
14. Magnolia kachirachirai (Kanehira & Yamamoto) Dandy.
15. Magnolia nitida W. W. Smith.

a. Magnolia nitida var. nitida
b. Magnolia nitida var. lotungensis (Chun & C. T. Tsoong) B. L. Chen & Noot., stat. nov.
c. Magnolia nitida var. robusta B. L. Chen & Noot. var. nov.

16. Magnolia omeiensis (Cheng) Dandy.

**5.** Magnolia sect. Alcimandra

17. Magnolia cathcartii (Hook. f. & Thomson) Noot.

**b.** Magnolia subg. Yulania

**1.** Magnolia sect. Yulania

KEY TO THE SPECIES OF MAGNOLIA SECTION YULANIA

18. Magnolia amoena Cheng.
19. Magnolia campbellii Hook. f. & Thomson.
20. Magnolia dawsoniana Rehder & E. H. Wilson.
21. Magnolia heptapeta (Buc'hoz) Dandy.
22. Magnolia sargentiana Rehder & E. H. Wilson.
23. Magnolia sprengeri Pamp.
24. Magnolia zenii Cheng.

**2.** Magnolia sect. Buergeria

KEY TO THE SPECIES OF MAGNOLIA SECTION BUERGERIA

25. Magnolia biondii Pamp.
26. Magnolia cylindrica E. H. Wilson.
27. Magnolia kobus DC.
28. Magnolia stellata (Siebold & Zucc.) Maxim.

**3.** Magnolia sect. Tulipastrum

29. Magnolia quinquepeta (Buc'hoz) Dandy.

**c.** Magnolia subg. Talauma

**1.** sect. Blumiana

30. Magnolia candollii (Blume) H. Keng var. obovata (Korth.)

HYBRIDS AND CULTIVATED SPECIES NOT NATIVE TO CHINA

31. Magnolia xsoulangiana Soulange ex Thieb. sect. Theorodon Spach (of subg. Magnolia)
32. Magnolia grandiflora L.

DUBIOUS SPECIES

**II.** Manglietia

KEY TO THE SPECIES OF MANGLIETIA primarily based on floral characters

KEY TO THE SPECIES OF MANGLIETIA primarily based on fruit characters

**1.** Manglietia Section Manglietia

1. Manglietia aromatica Dandy.
2. Manglietia conifera Dandy.
3. Manglietia dandyi (Gagnep.) Dandy.
4. Manglietia duclouxii Finet & Gagnep.
5. Manglietia fordiana Oliver.
   5a. Manglietia fordiana Oliver var. fordiana
   5b. Manglietia fordiana Oliver var. calcarea (X. H. Song) B. L. Chen & Noot. stat. nov.
   5c. Manglietia fordiana Oliver var. forrestii (W. W. Smith ex Dandy) B. L. Chen & Noot. stat. nov.
   5d. Manglietia fordiana Oliver var. kwangtungensis (Merr.) B. L. Chen & Noot. stat. nov.
6. Manglietia garrettii Craib.
7. Manglietia glauca Blume var. sumatrana (Miq.) Dandy.
8. Manglietia grandis Hu & Cheng.
9. Manglietia hookeri Cubitt & W. W. Smith.
10. Manglietia insignis (Wall.) Blume
11. Manglietia lucida B. L. Chen & S. C. Yang.
12. Manglietia megaphylla Hu & Cheng.
13. Manglietia microtricha Law.
14. Manglietia moto Dandy.
15. Manglietia pachyphylla Chang.
16. Manglietia szechuanica Hu.
17. Manglietia ventii Tiep.

**2.** Section Manglietiastrum

18. Manglietia sinica (Law) B. L. Chen & Noot. comb. nov.

**III.** Kmeria

1. Kmeria septentrionalis Dandy.

Tribe Michelieae

**IV.** Michelia

KEY TO THE SECTIONS OF MICHELIA

KEY TO THE SPECIES OF MICHELIA primarily based on floral characters

KEY TO THE SPECIES OF MICHELIA primarily based on fruit characters

**1.** Michelia Section Michelia

KEY TO THE SPECIES OF SECTION MICHELIA

1. Michelia aenea Dandy.
2. Michelia cavaleriei Finet & Gagnep.
3. Michelia champaca L.
4. Michelia compressa (Maxim.) Sarg.
5. Michelia coriacea Chang & B. L. Chen.
6. Michelia doltsopa Buch.-Ham. ex DC.
7. Michelia elliptilimba B. L. Chen & Noot. sp. nov.
8. Michelia flaviflora Law. & Y. F. Wu.
9. Michelia floribunda Finet & Gagnep.
10. Michelia foveolata Merr. ex Dandy.
11. Michelia fujianensis Q. F. Zheng.
12. Michelia fulva Chang & B. L. Chen.
13. Michelia ingrata B. L. Chen & S. C. Yang.
14. Michelia kisopa Buch.-Ham. ex DC.
15. Michelia lacei W. W. Smith.
16. Michelia macclurei Dandy.
17. Michelia masticata Dandy.
18. Michelia maudiae Dunn.
19. Michelia mediocris Dandy.
20. Michelia microtricha Hand.-Mazz.
21. Michelia shiluensis Chun & Y. Wu.
22. Michelia velutina DC.
23. Michelia wilsonii Finet & Gagnep.
24. Michelia ×alba DC.

**2.** Michelia Section Anisochlamys

25. Michelia hypolampra Dandy.

**3.** Michelia Section Dichlamys

KEY TO THE SPECIES OF SECTION DICHLAMYS

26. Michelia angustioblonga Law.
27. Michelia balansae (A. DC) Dandy.
28. Michelia chapensis Dandy.
29. Michelia leveilleana Dandy.
30. Michelia martinii (H. Lév.) Finet & Gagnep. ex H. Lév.
31. Michelia xanthantha C. Y. Wu ex Law & Y. F. Wu.

**4.** Michelia Section Micheliopsis

32. Michelia figo (Lour.) Sprengel.
    - 32a. Michelia figo var. figo
    - 32b. Michelia figo var. crassipes (Law) B. L. Chen & Noot., stat. nov.
33. Michelia yunnanensis Franchet.

**5.** Michelia Section Tsoongiodendron

34. Michelia odora (Chun) Noot. & B. L. Chen., stat. nov.

**6.** Section Paramichelia

35. Michelia baillonii (Pierre) Finet & Gagnep.

DUBIOUS SPECIES

MAGNOLIACEAE Subfamily LIRIODENDROIDEAE

**V.** Liriodendron

1. Liriodendron chinense (Hemsley) Sarg.
2. Liriodendron tulipifera L.

LIST 2. List of species showing numbering system used in the Collections Examined list that follows.

KMERIA

*1.* K. septentrionalis Dandy
*2.* K. duperreana (Pierre) Dandy

LIRIODENDRON

*3.* L. chinense (Hemsley) Sarg.
*4.* L. tulipifera L.

MANGLIETIA

*5.* M. aromatica Dandy
*6.* M. conifera Dandy
*7.* M. dandyi (Gagnep.) Dandy
*8.* M. duclouxii Finet & Gagnep.
*9.* M. fordiana Oliver var. fordiana
  - *9a.* M. fordiana var. calcarea (X. H. Song) B. L. Chen & Noot.
  - *9b.* M. fordiana var. forrestii (W. W. Smith ex Dandy) B. L. Chen & Noot.
  - *9c.* M. fordiana var. kwangtungensis (Dandy) B. L. Chen & Noot.

*10.* M. garrettii Craib
*11.* M. glauca var. sumatrana (Miq.) Dandy
*12.* M. grandis Hu & Cheng
*13.* M. hookeri Cubitt & W. W. Smith
*14.* M. insignis (Wall.) Blume

*15.* M. lucida B. L. Chen & S. C. Yang
*16.* M. megaphylla Hu & Cheng
*17.* M. microtricha Law
*18.* M. moto Dandy
*19.* M. pachyphylla Chang
*20.* M. sinica (Law) B. L. Chen & Noot.
*21.* M. szechuanica Hu
*22.* M. ventii Tiep

MAGNOLIA

SUBGENUS MAGNOLIA

*Section Gwillimia*

*23.* M. albosericea Chun & C. H. Tsoong
*24.* M. championii Benth.
*25.* M. coco (Lour.) DC.
*26.* M. delavayi Franchet
*27.* M. henryi Dunn
*28.* M. phanerophlebia B. L. Chen

*Section Rytidospermum*

*29.* M. hypoleuca Siebold & Zucc.
*30.* M. officinalis Rehder & E. H. Wilson
*31.* M. rostrata W. W. Smith

*Section Oyama*

*32.* M. globosa Hook. f. & Thomson
*33.* M. sieboldii K. Koch
*34.* M. sinensis (Rehder & E. H. Wilson) Stapf
*35.* M. wilsonii (Finet & Gagnep.) Rehder

*Section Theorhodon*

*36.* M. grandiflora L.

*Section Gynopodium*

*37.* M. kachirachirai (Kanehira & Yamamoto) Dandy
*38.* M. nitida W. W. Smith var. nitida
*38a.* M. nitida var. lotungensis (Chun & C. T. Tsoong) B. L. Chen & Noot.
*38b.* M. nitida var. robusta B. L. Chen & Noot.
*39.* M. omeiensis (Cheng) Dandy

*Section Alcimandra*

*40.* M. cathcartii (Hook. f. & Thomson) Noot.

SUBGENUS YULANIA

*Section Yulania*

*41.* M. amoena Cheng
*42.* M. campbellii Hook. f. & Thomson
*43.* M. dawsoniana Rehder & E. H. Wilson
*44.* M. heptapeta (Buc'hoz) Dandy
*45.* M. sargentiana Rehder & E. H. Wilson
*46.* M. sprengeri Pamp.
*47.* M. zenii Cheng

*Section Buergeria*

*48.* M. biondii Pamp.
*49.* M. cylindrica E. H. Wilson
*50.* M. praecocissima Koidz.
*51.* M. tomentosa Thunb.

*Section Tulipastrum*

*52.* M. quinquepeta (Buc'hoz) Dandy
*53.* M. ×soulangiana Soulange ex Thieb.

SUBGENUS TALAUMA

*Section Blumiana*

*54.* M. candollii var. obovata (Korth.) Noot.

MICHELIA

*Section Michelia*

*55.* M. ×alba DC.
*56.* M. champaca L.
*57.* M. doltsopa Buch.-Ham. ex DC.
*58.* M. elliptilimba B. L. Chen & Noot.
*59.* M. flaviflora Law & Y. F. Wu
*60.* M. floribunda Finet & Gagnep.
*61.* M. fulva Chang & B. L. Chen
*62.* M. kisopa Buch.-Ham. ex DC.
*63.* M. microtricha Hand.-Mazz.
*64.* M. velutina DC.
*65.* M. wilsonii Finet & Gagnep.
*66.* M. aenea Dandy
*67.* M. cavaleriei Finet & Gagnep.
*68.* M. compressa (Maxim.) Sarg.
*69.* M. coriacea Chang & B. L. Chen
*70.* M. foveolata Merr. ex Dandy
*71.* M. fujianensis Q. F. Zheng
*72.* M. ingrata B. L. Chen & S. C. Yang
*73.* M. lacei W. W. Smith
*74.* M. macclurei Dandy
*75.* M. masticata Dandy
*76.* M. maudiae Dunn
*77.* M. mediocris Dandy
*78.* M. shiluensis Chun & Y. Wu

*Section Anisochlamys*

*79.* M. hypolampra Dandy

*Section Dichlamys*

*80.* M. angustioblonga Law & Y. F. Wu
*81.* M. balansae (A. DC) Dandy
*82.* M. chapensis Dandy
*83.* M. leveilleana Dandy
*84.* M. martinii (H. Lév.) Finet & Gagnep. ex H. Lév.
*85.* M. xanthantha C. Y. Wu ex Law & Y. F. Wu

*Section Micheliopsis*

*86.* M. figo (Lour.) Sprengel var. figo
*86a.* M. figo var. crassipes (Law) B. L. Chen & Noot.
*87.* M. yunnanensis Franchet ex Finet & Gagnep.

*Section Tsoongiodendron*

*88.* M. odora (Chun) Noot. & B. L. Chen

*Section Paramichelia*

*89.* M. baillonii (Pierre) Finet & Gagnep.

LIST 3. List of exsiccatae. Numbers in italics following the colon after the collection number refer to species numbered as in List 2. [Please note: herbarium designations are not given because this part of the first author's

notes remains in China and has not yet been made available. The history of the project is outlined in the introductory section to the article.]

Volume 80, Number 4, pp. 787–1108 of the Annals of the Missouri Botanical Garden
was published on November 17, 1993.

# ANNALS OF THE MISSOURI BOTANICAL GARDEN: CHECKLIST FOR AUTHORS

## 1. General Instructions

- ☐ Text is in English or Spanish on numbered pages.
- ☐ Manuscript is typed on one side of nonglossy 8½ × 11 in. paper.
- ☐ At least 1 in. is left as margin all around, except on the first page, which has 3 in. left blank at the top.
- ☐ Text is double- or triple-spaced throughout, including abstract, notes, legends, tables, specimen lists, Literature Cited, and footnotes.
- ☐ Right-hand margin is not justified, and words are not broken there.
- ☐ Words to be set in italics are underlined instead of italicized. Boldface or other special typefaces are not used. [Editor will add printer's marks for these.] Common Latin words or phrases are not italicized (e.g., et al., i.e., sensu, etc.).
- ☐ Only names at the rank of genus and below are italicized.
- ☐ Correct accents, umlauts, and other diacritical marks have been included.
- ☐ All figures and tables are cited in the text.

## 2. Style

- ☐ Recent issue of *Annals* is used as model.
- ☐ *Chicago Manual of Style*, latest edition, is used as reference.

## 3. First Page

- ☐ Footnotes are typed as double-spaced paragraphs on the first page. The first footnote contains acknowledgments, including information on granting agencies, herbaria that loaned specimens, and the name of the artist. The second footnote is the author's address. Addresses for additional authors are each separate footnotes. No other footnotes occur, except in tables, where unavoidable.

## 4. Abstract

- ☐ A one-paragraph abstract precedes text. Papers in Spanish have an English abstract in addition to a Spanish resumen.
- ☐ The abstract is concise (1 paragraph) and includes brief statements about the paper's intent, materials and methods, results, and significance of findings.

## 5. Tables

- ☐ Tables are neat, double-spaced, and easily understood rather than long and complex.
- ☐ Tables do not contain vertical or horizontal lines. [Editor and/or printer will add them as needed.]
- ☐ Captions are typed double-spaced as paragraphs at the tops of the tables.
- ☐ Each table starts on a separate sheet, double-spaced.

## 6. Abbreviations

- ☐ Periods are used after all abbreviations (which are minimized) except metric measures, compass directions, and herbarium designations.
- ☐ When dates are given as part of collection information, three-letter month abbreviations are used, except for months with four letters, which are spelled out in full.
- ☐ States are not abbreviated, and cities are spelled out. [St. is acceptable.]
- ☐ Periodicals are abbreviated according to *B-P-H* (*Botanico-Periodicum-Huntianum*) and to *B-P-H/S* (*Botanico-Periodicum-Huntianum/Supplementum*).
- ☐ Authors' names are abbreviated according to *Authors of Plant Names* or spelled out in full.
- ☐ Book titles are abbreviated according to *Taxonomic Literature*, edition 2, but with initial letters capitalized. Book titles are spelled out in the Literature Cited.
- ☐ Authors' names in major taxonomic citations, such as the formal citation at the head of a taxonomic treatment, are spelled out.
- ☐ Herbaria are abbreviated according to *Index Herbariorum*, edition 8.

## 7. Taxonomic Treatment

- ☐ One paragraph per basionym is used as follows: *Taxon* author, literature citation, type citation, e.g., *Pleurothyrium amplifolium* (Mez) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 43. 1986. *Nectandra amplifolia* Mez, Arbeiten Königl. Bot. Gart. Breslau 1: 131. 1892. TYPE: Brazil. Rio de Janeiro Alto Macahé, *Glaziou 17731* (holotype, B; isotypes, B, G, K, NY, P). Figure 11.
- ☐ Lectotype designations are included together with an indication of where they were designated.
- ☐ Exclamation points are not used for specimens examined. Types not seen are indicated as such (e.g., MO, US not seen).
- ☐ A brief Latin diagnosis for each new taxon is provided rather than a complete Latin description.
- ☐ When relevant, nomina nuda, misapplied names and superfluous names are included in the discussion following the description, but are not part of the formal synonymy.

## 8. Specimens examined

- ☐ If many specimens were examined, those cited in the text are limited to one collection per geographical area.
- ☐ Long lists of specimens examined are placed at the end of the paper, following the Literature Cited. They are arranged alphabetically by collector, followed by collection number, followed by the number of the taxon in the text.
- ☐ Specimens are cited in the text as follows: *Additional specimens examined* (or *Selected specimens examined* or *Paratypes*). MEXICO. Oaxaca: Sierra San Pedro Nolesco, Talea, 3 Feb. 1987 (fl), *Jergensen 865* (BM, G, K, US). [Dates and reproductive status are optional.] Countries are run together in the same

paragraph, e.g., COUNTRY A. Major political division: . . . COUNTRY B. Major political division: . . .

### 9. Vouchers and Genetic Sequences

- ☐ If paper presents original data, it includes citation of vouchers. [Depending on the type of paper, reference to the original wild source may also be required.]
- ☐ Herbarium vouchers state the collector and number, herbarium in which the voucher is located, and a clear annotation that the material represents the voucher for the study in question.
- ☐ Genetic sequences have been banked, and accession numbers are provided.
- ☐ Author accepts responsibility for establishing the accuracy of information provided.

### 10. Keys

- ☐ Keys are clear and have been checked carefully for consistency with the descriptions.

### 11. Literature Cited

- ☐ The Literature Cited contains all references cited in the text.
- ☐ All entries in the Literature Cited are cited in the text.
- ☐ Spelling of author(s) name(s) and years of publication have been double-checked.
- ☐ All entries have been verified against original sources, especially journal titles, accents, diacritical marks, and spelling in languages other than English.
- ☐ Periodicals are listed as follows: author's last name, initial(s). Year. Full title of article. Journal abbreviated as in *B-P-H/S*. Volume: pages. No parenthetical part numbers after volume numbers is given unless each part is paginated separately.
- ☐ For more than one author, this style is followed: author's last name, initial(s), second author's initial(s), last name & third author's initial(s), last name.
- ☐ Books appear as follows: author's last name, initial(s). Year. Full Unabbreviated Title (edited by Editor), 3rd ed., Vol. 2. Publisher, City of Publication.
- ☐ Citations of work "in prep.," unpublished theses and dissertations, and similar references to inaccessible sources have been eliminated or kept to a minimum. They are not included in the Literature Cited.

### 12. Illustrations

- ☐ Author(s) name(s) and figure number(s) are written in pencil on the back of each figure or plate, on both originals and review copies.
- ☐ Scale bars appear on illustrations, photographs, and maps.
- ☐ Magnifications/reductions are not indicated in captions.
- ☐ All illustrative materials are mounted on stiff cardboard no thicker than ¼ in.
- ☐ Illustrations are presized to fit either column width (2⅝ in. or ca. 68 mm) or full page width (5½ in. or ca. 140 mm), *or* illustrations no larger than 11 × 16 in. (= 29 × 40 cm). [Maximum size for printed illustrations is 5½ × 8¼ in.]
- ☐ Figures are numbered in Arabic numerals in the order of their citation in the text. Parts of figures are labeled with capital letters.
- ☐ Photographs are crisp black-and-white prints.
- ☐ Figures are grouped into composite plates when possible; edges of photographs are abutted.
- ☐ No stripping is inserted between plate or figure segments. [Printer will insert stripping.]
- ☐ Edges of figures are squared.
- ☐ Maps include reference to latitude and longitude and are bounded by a fine border.
- ☐ Scanning electron micrographs are free of conspicuous charging.
- ☐ Axes on graphs are all labeled.
- ☐ Captions provide all explanatory text. No text appears on the figures. Captions are separate from other text, one paragraph for each group of figures, and following the style in current issues of the *Annals*.
- ☐ Symbols on maps are legible and reduction has been taken into consideration.

### 13. What to submit

- ☐ Full mailing address, telephone, fax, and electronic mail numbers are submitted in cover letter.
- ☐ Three copies of manuscript are submitted.
- ☐ Copies/photocopies of original figures are enclosed with first submission. Copies of half-tone figures (photographs) and plates must be of sufficiently good quality to show all the detail of the originals. [Send originals when requested – usually when manuscript is accepted. Editor will return after publication.]
- ☐ If the article is long, an MS-DOS 3½- or 5¼ in. diskette, as WordStar [preferable] or WordPerfect file, is submitted in addition to the printed documents.
- ☐ Draft-quality dot-matrix printout is not submitted.

## SCOPE OF THE *ANNALS*

The *Annals* publishes original articles in systematic botany and related fields. Papers whose purpose is the establishment of new nomenclatural entities in vascular plants and bryophytes are not accepted. Rather, they should be submitted to *Novon* for consideration. (*Novon* instructions are available from the managing editor.)

## CONDITIONS FOR PUBLICATION

Authors are urged to contact the managing editor prior to submitting manuscripts. Manuscripts sent already reviewed and revised are generally subject to the full normal review process initiated here. Manuscripts not properly prepared may be returned for revision prior to review. It is the author's responsibility to supply missing bibliographic information; the editor does not perform library research except by prior arrangement with authors not having access to crucial reference materials. Communication with the editor at all points of the publication process is encouraged.

## PAGE CHARGES

Page costs are $80 per page, although charges may be reduced under certain circumstances. Corrections in proof

will be billed nonnegotiably to the author at $3 per line changed.

## CORRESPONDENCE

# ANNALS OF THE MISSOURI BOTANICAL GARDEN

VOLUME 80
1993

## *Colophon*

This volume of the ANNALS of the Missouri Botanical Garden has been set in APS Bodoni. The text is set in 9 point type while the figure legends and literature cited sections are set in 8 point type.

The volume has been printed on 70# Vintage Gloss. This is an acid-free paper designed to have a shelf-life of over 100 years. Vintage Gloss is manufactured by the Potlatch Paper Company.

Photographs used in the ANNALS are reproduced using 300 line screen halftones. The binding used in the production of the ANNALS is a proprietary method known as Permanent Binding.

The ANNALS is printed and distributed by Allen Press, Inc. of Lawrence, Kansas 66044, U.S.A.

## Statistical Summary of Some of the Activities in the Missouri Botanical Garden Herbarium, 1992

| | 1992 | | |
|---|---|---|---|
| | Vascular | Bryophyte | Total |
| Acquisition of specimens | | | |
| Staff Collections (includes bryophytes) | 62,547 | — | 62,547 |
| Purchase | 2,157 | 535 | 2,692 |
| Exchange | 50,141 | 2,380 | 52,521 |
| Gifts | 12,503 | 1,671 | 14,174 |
| Total acquisitions | 127,348 | 4,586 | 131,934 |
| Mountings | | | |
| Newly mounted | 169,289 | 16,100 | 185,389 |
| Mounted when received | 1,633 | 0 | 1,633 |
| Total specimens filed | 170,922 | 16,100 | 187,022 |
| Repairs | | | |
| Specimens repaired | 21,227 | | 21,227 |
| Specimens stamped | 2,728 | | 2,728 |
| Total repairs | 23,955 | | 23,955 |
| Specimens sent | | | |
| On exchange | 51,906 | 5,266 | 57,172 |
| As gifts | 13,277 | 799 | 14,076 |
| Total | 65,183 | 6,065 | 71,248 |
| Loans sent | | | |
| Total transactions | 427 | 39 | 466 |
| Total specimens | 27,943 | 4,251 | 32,194 |
| To U.S. institutions | | | |
| Transactions | 231 | 23 | 254 |
| Specimens | 14,612 | 378 | 14,990 |
| To foreign institutions | | | |
| Transactions | 196 | 16 | 212 |
| Specimens | 13,331 | 3,873 | 17,204 |
| To student investigators | | | |
| Transactions | 51 | 3 | 54 |
| Specimens | 6,823 | 37 | 6,860 |
| To professional investigators | | | |
| Transactions | 376 | 36 | 412 |
| Specimens | 22,734 | 2,600 | 25,334 |
| Loans received | | | |
| Transactions | 355 | 17 | 372 |
| Specimens | 20,485 | 2,119 | 22,604 |

| | 1992 | | |
|---|---|---|---|
| | From U.S. | From abroad | Total |
| Visitors | 409 | 126 | 535 |

On 31 December 1992 the total number of mounted, accessioned specimens in the herbarium was 4,112,057 (3,892,146 vascular plants and 219,911 bryophytes).

## Recent Issues of the *Annals of the Missouri Botanical Garden*

### Phylogeny of Asteridae

*Annals of the Missouri Botanical Garden* 79(2) (Spring 1992). The monophyly, sister group (or groups), and patterns of relationships of the Asteridae are discussed in the symposium "Phylogeny of Asteridae," organized by Larry Hufford of the University of Minnesota. The symposium was jointly sponsored by the American Society of Plant Taxonomists and the Botanical Society of America and was held at their annual meeting, 7 Aug. 1990, in Richmond, Virginia. 238 pages. $27.00, plus postage.

### Knowledge Brokering: The Mechanics of Synthesis

*Annals of the Missouri Botanical Garden* 80(2) (Spring 1993). This symposium, the 38th Annual Systematics Symposium of the Missouri Botanical Garden (held 4–5 Oct. 1991, in St. Louis, Missouri), discusses the value and future necessity of assimilating diverse biological information into new and broader syntheses, taking advantage of computer-based data-management systems. 41 pages (entire issue 230 pages). $35.00, plus postage.

### *rbc*L Sequence Data and Phylogenetic Reconstruction in Seed Plants

*Annals of the Missouri Botanical Garden* 80(3) (Summer 1993). Fourteen papers plus an appendix containing voucher and sequence data. This collection of papers, organized by Douglas E. Soltis and Mark W. Chase, presents the first in-depth molecular phylogenetic analysis of seed plants in general, and angiosperms in particular. Investigators throughout the world involved in *rbc*L sequencing studies contributed their unpublished sequences for a broad phylogenetic analysis. 235 pages. $40.00, plus postage.

---

To place an order, send check or money order in U.S. funds, payable through a U.S. bank; bankcard orders also accepted. U.S. shipments: add $2.00 for one book and $.75 for each additional book; non-U.S. shipments: add $3.00 for one book, and $.75 for each additional book. Orders should be prepaid; a $1.00 fee will be added to orders requiring invoices. No shipments are made until payment is received. Mail or fax (for bankcard orders) form with your check or money order, payable to Missouri Botanical Garden, to:

Department Eleven, Missouri Botanical Garden
P.O. Box 299
St. Louis, MO 63166-0299, U.S.A.
Fax: (314) 577-9594
Phone: (314) 577-9534

## CONTENTS

Systematics of *Ruellia* (Acanthaceae) in Southern South America *Cecilia Ezcurra* ..... 787

Endemic Herbaceous Bamboo Genera of Cuba (Poaceae: Bambusoideae: Olyreae) *Fernando O. Zuloaga, Osvaldo Morrone & Emmet J. Judziewicz* ..... 846

Fenología y Estructura Floral de *Trichilia havanensis* Jacq. (Meliaceae) *Delhy Albert Puentes, Jesús Hernandez de Armas & Antonio López Almirall* ..... 862

The Genus *Clerodendrum* (Verbenaceae) in Mesoamerica *Ricardo M. Rueda* ..... 870

Pollen Development and Fertilization in *Lacandonia schismatica* (Lacandoniaceae) *J. Márquez-Guzmán, S. Vázquez-Santana, E. M. Engleman, A. Martínez-Mena & E. Martínez* ..... 891

Lack of Genetic Variation in *Lacandonia schismatica* (Lacandoniaceae: Triuridales) in its Only Known Locality *Gerardo Coello, Ana Escalante & Jorge Soberón* ..... 898

Patterns of Species Distributions in the Dry Seasonal Forests of South America *Darién E. Prado & Peter E. Gibbs* ..... 902

Diversity Patterns and Biomass of Epiphytic Bryophytes and Lichens Along an Altitudinal Gradient in the Northern Andes *Jan H. D. Wolf* ..... 928

Chromosome Cytology of the African Genus *Lapeirousia* (Iridaceae–Ixioideae) *Peter Goldblatt & Masahiro Takei* ..... 961

Chromosome Numbers of Neotropical *Castilleja* (Scrophulariaceae: Tribe Pedicularieae) and their Taxonomic Implications *T. I. Chuang & L. R. Heckard* ..... 974

Phylogenetic Relationships of the Bromeliiflorae–Commeliniflorae–Zingiberiflorae Complex of Monocots Based on *rbc*L Sequence Comparisons *W. Dennis Clark, Brandon S. Gaut, Melvin R. Duvall & Michael T. Clegg* ..... 987

Notes on Magnoliaceae III: The Magnoliaceae of China *Chen Bao Liang & Hans P. Nooteboom* ..... 999

**Cover illustration.** *Pleurothyrium giganthum* van der Werff, by J. Myers.
